About the Cover

Harlequin ghost pipefish (*Solenostomus paradoxus*) live among feather stars (a type of echinoderm), where the fish's skin flaps provide excellent camouflage from potential predators. Pipefish (which are related to the seahorses) position themselves upside down and nearly motionless as they seek their prey—tiny crustaceans living near the seafloor. Such intricate interactions among different types of organisms exemplify some of life's overarching principles. Photograph © Fred Bavendam/Minden Pictures.

To the many educators who have worked for change
in biology education in recent years

The Authors

DAVID M. HILLIS is the Alfred W. Roark Centennial Professor in Integrative Biology and the Director of the Center for Computational Biology and Bioinformatics at the University of Texas at Austin, where he also has directed the School of Biological Sciences. Dr. Hillis has taught courses in introductory biology, genetics, evolution, systematics, and biodiversity. He has been elected to the National Academy of Sciences and the American Academy of Arts and Sciences, awarded a John D. and Catherine T. MacArthur Fellowship, and has served as President of the Society for the Study of Evolution and of the Society of Systematic Biologists. He served on the National Research Council committee that wrote the report *BIO 2010: Transforming Undergraduate Biology Education for Research Biologists*. His research interests span much of evolutionary biology, including experimental studies of evolving viruses, empirical studies of natural molecular evolution, applications of phylogenetics, analyses of biodiversity, and evolutionary modeling. He is particularly interested in teaching and research about the practical applications of evolutionary biology.

DAVID SADAVA is the Pritzker Family Foundation Professor of Biology, Emeritus, at the Keck Science Center of Claremont McKenna, Pitzer, and Scripps, three of The Claremont Colleges. In addition, he is Adjunct Professor of Cancer Cell Biology at the City of Hope Medical Center. Twice winner of the Huntoon Award for superior teaching, Dr. Sadava has taught courses on introductory biology, biotechnology, biochemistry, cell biology, molecular biology, plant biology, and cancer biology. In addition to *Life: The Science of Biology*, he is the author or coauthor of books on cell biology and on plants, genes, and crop biotechnology. His research has resulted in many papers coauthored with his students, on topics ranging from plant biochemistry to pharmacology of narcotic analgesics to human genetic diseases. For the past 15 years, he has investigated multi-drug resistance in human small-cell lung carcinoma cells with a view to understanding and overcoming this clinical challenge. At the City of Hope, his current work focuses on new anti-cancer agents from plants.

H. CRAIG HELLER is the Lorry I. Lokey/Business Wire Professor in Biological Sciences and Human Biology at Stanford University. He has taught in the core biology courses at Stanford since 1972 and served as Director of the Program in Human Biology, Chairman of the Biological Sciences Department, and Associate Dean of Research. Dr. Heller is a fellow of the American Association for the Advancement of Science and a recipient of the Walter J. Gores Award for excellence in teaching. His research is on the neurobiology of sleep and circadian rhythms, mammalian hibernation, the regulation of body temperature, the physiology of human performance, and the neurobiology of learning. He has done research on a huge variety of animals and physiological problems ranging from sleeping kangaroo rats, diving seals, hibernating bears, photoperiodic hamsters, and exercising athletes. Dr. Heller has extended his enthusiasm for promoting active learning through the development of a two-year curriculum in human biology for the middle grades, and at the college level he directed the production of Virtual labs—interactive computer-based modules to teach physiology.

MARY V. PRICE is Professor of Biology, Emerita, at the University of California Riverside and Adjunct Professor in the School of Natural Resources and the Environment at the University of Arizona. In “retirement,” she continues to teach and study, having learned the joy and art of scientific discovery as an undergraduate student

at Vassar College and doctoral student at the University of Arizona. Dr. Price has mentored and published with independent-research students and has developed and taught general biology and ecology courses from introductory (majors and nonmajors) to graduate levels. She has particularly enjoyed leading field classes in the arid regions of North America and Australia, and the tropical forests of Central America, Africa, and Madagascar. Dr. Price’s research focuses on understanding the ecology of North American deserts and mountains. She has asked why so many desert rodents can coexist, how best to conserve endangered kangaroo rat species, how pollinators and herbivores influence floral evolution and plant population dynamics, and how climate change affects ecological systems.

Brief Table of Contents

1 Principles of Life 1

PART 1 ■■ CELLS

- 2 Life Chemistry and Energy 16
- 3 Nucleic Acids, Proteins, and Enzymes 34
- 4 Cells: The Working Units of Life 56
- 5 Cell Membranes and Signaling 78
- 6 Pathways that Harvest and Store Chemical Energy 100

PART 2 ■■ GENETICS

- 7 The Cell Cycle and Cell Division 124
- 8 Inheritance, Genes, and Chromosomes 144
- 9 DNA and Its Role in Heredity 165
- 10 From DNA to Protein: Gene Expression 187
- 11 Regulation of Gene Expression 208
- 12 Genomes 226
- 13 Biotechnology 244
- 14 Genes, Development, and Evolution 263

PART 3 ■■ EVOLUTION

- 15 Mechanisms of Evolution 288
- 16 Reconstructing and Using Phylogenies 315
- 17 Speciation 332
- 18 The History of Life on Earth 347

PART 4 ■■ DIVERSITY

- 19 Bacteria, Archaea, and Viruses 366
- 20 The Origin and Diversification of Eukaryotes 388
- 21 The Evolution of Plants 407
- 22 The Evolution and Diversity of Fungi 437
- 23 Animal Origins and Diversity 456

PART 5 ■■ PLANT FORM AND FUNCTION

- 24 The Plant Body 506
- 25 Plant Nutrition and Transport 521
- 26 Plant Growth and Development 539
- 27 Reproduction of Flowering Plants 556
- 28 Plants in the Environment 572

PART 6 ■■ ANIMAL FORM AND FUNCTION

- 29 Physiology, Homeostasis, and Temperature Regulation 588
- 30 Animal Hormones 603
- 31 Immunology: Animal Defense Systems 620
- 32 Animal Reproduction 638
- 33 Animal Development 655
- 34 Neurons and Nervous Systems 672
- 35 Sensors 695
- 36 Musculoskeletal Systems 712
- 37 Gas Exchange in Animals 729
- 38 Circulatory Systems 746
- 39 Nutrition, Digestion, and Absorption 765
- 40 Salt and Water Balance and Nitrogen Excretion 784
- 41 Animal Behavior 799

PART 7 ■■ ECOLOGY

- 42 Organisms in Their Environment 822
- 43 Populations 842
- 44 Ecological and Evolutionary Consequences of Species Interactions 859
- 45 Ecological Communities 873
- 46 The Global Ecosystem 892

Investigations

- 1.9** Controlled Experiments Manipulate a Variable 12
- 1.10** Comparative Experiments Look for Differences among Groups 13
- 2.16** Synthesis of Prebiotic Molecules in an Experimental Atmosphere 32
- 3.10** Primary Structure Specifies Tertiary Structure 44
- 4.14** The Role of Microfilaments in Cell Movement: Showing Cause and Effect in Biology 72
- 5.2** Rapid Diffusion of Membrane Proteins 82
- 5.5** Aquaporins Increase Membrane Permeability to Water 86
- 5.15** The Discovery of a Second Messenger 95
- 6.6** An Experiment Demonstrates the Chemiosmotic Mechanism 105
- 7.9** Regulation of the Cell Cycle 133
- 8.1** Mendel's Monohybrid Experiments 146
- 8.4** Homozygous or Heterozygous? 149
- 8.13** Some Alleles Do Not Assort Independently 156
- 9.3** Transformation of Eukaryotic Cells 168
- 10.8** Demonstrating the Existence of Introns 194
- 10.10** Deciphering the Genetic Code 196
- 10.20** Testing the Signal 205
- 12.8** Using Transposon Mutagenesis to Determine the Minimal Genome 234
- 13.4** Recombinant DNA 248
- 14.3** Cloning a Plant 266
- 14.4** Cloning a Mammal 267
- 15.9** Sexual Selection in Action 296
- 15.19** A Heterozygote Mating Advantage 306
- 16.5** The Accuracy of Phylogenetic Analysis 323
- 17.12** Flower Color and Reproductive Isolation 343
- 18.8** Atmospheric Oxygen Concentrations and Body Size in Insects 355
- 19.14** What Is the Highest Temperature Compatible with Life? 376
- 20.19** Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching? 404
- 21.22** The Effect of Stigma Retraction in Monkeyflowers 429
- 25.2** Nickel Is an Essential Element for Plants 523
- 26.11** Photomorphogenesis and Red Light 552
- 27.9** The Flowering Signal Moves from Leaf to Bud 565
- 28.5** Nicotine Is a Defense against Herbivores 578
- 29.13** The Hypothalamus Regulates Body Temperature 600
- 30.2** A Diffusible Substance Triggers Molting 606
- 31.4** The Discovery of Specific Immunity 626
- 33.9** The Dorsal Lip Induces Embryonic Organization 663
- 33.10** Differentiation Can Be Due to Inhibition of Transcription Factors 664
- 35.13** A Rod Cell Responds to Light 706
- 36.7** Neurotransmitters and Stretch Alter the Membrane Potential of Smooth Muscle Cells 719
- 37.9** Sensitivity of the Respiratory Control System Changes with Exercise 740
- 38.4** The Autonomic Nervous System Controls Heart Rate 753
- 39.14** A Single-Gene Mutation Leads to Obesity in Mice 781
- 40.10** ADH Induces Insertion of Aquaporins into Plasma Membranes 797
- 41.4** The Mouse Vomeronasal Organ Identifies Gender 803

- 45.18** Species Richness Can Enhance Wetland Restoration 889
- 46.8** Where Does the Extra Nitrogen Come From? 899

Preface

We wrote *Principles of Life* to serve as a textbook for instructors who are changing the way they teach biology to college undergraduates. Many instructors see the value of emphasizing an understanding of major concepts over memorization of details. When students understand how biological concepts have been developed through observation and experimentation, and when they gain experience in applying those concepts to real biological problems, they are more likely to retain an understanding of the big picture. This emphasis on *understanding* rather than *memorizing* biology is especially effective when coupled with active learning approaches, including problem solving, analyzing real data, discussing and synthesizing ideas, and using interactive simulations—all based on a foundational understanding of a few overarching concepts. *Principles of Life* is intended for such an active learning approach to understanding the fundamental concepts of biology.

Existing introductory textbooks for biology majors are impressive encyclopedic summaries of biological knowledge, and many instructors like having a wealth of examples for their course. Such tomes can be effective for presenting an overview of biology; indeed, most of the authors of *Principles of Life* are also among the authors of one of these comprehensive texts—*Life: The Science of Biology*, now in its ninth edition. We are proud of that textbook and believe it has set a standard for the field for many years. We recognize, however, that comprehensive textbooks contain far more information than is needed for an introductory course in biology. Many students are overwhelmed by the detail, and may have a hard time focusing on the most important concepts.

In *Life: The Science of Biology*, we introduced active problem solving as an important component of learning the major concepts of biology. In *Principles of Life*, we have expanded these efforts at promoting active learning, and to do so we have greatly abbreviated the volume of detail found in all introductory texts. Our intention is not to leave out important concepts, but to give students more opportunities to learn those concepts through applying them. We believe that students who spend their time diligently committing to memory the myriad details and vast terminology of a broad array of biological topics actually learn and retain fewer of the concepts that are the foundation for further study in advanced biology courses.

Voices for Change in Undergraduate Biology Education

Our motivation to write this book comes from the numerous reports published by education agencies and national study groups over the past 10 years that have called for reforms in undergraduate biology education. For example, the National

Research Council published a report called *BIO2010: Transforming Undergraduate Education for Future Research Biologists*, sponsored by the National Institutes of Health and the Howard Hughes Medical Institute. Similar reports, containing many of the same recommendations, have been published by committees of the American Association for the Advancement of Science, the National Academy of Sciences, the National Evolutionary Synthesis Center, the College Board, and many other organizations that are invested in science education.

These recent reports note that even though science is constantly changing, undergraduate science education has changed relatively little over several decades. They emphasize a consensus that instructors should move away from teaching biology as a set of facts to be memorized and focus instead on major concepts. They also advise instructors to showcase the logical structure of scientific investigation, including lab, field, and computer modeling approaches. Students should be able to apply the concepts they learn by analyzing original data, and they need to understand the growing relevance of quantitative science in addressing life-science questions. There should be an integration of analyses of experimental and observational data into the course. And finally, biology courses should incorporate inquiry-based approaches that encourage active learning.

We have been participants in some of these study groups, and we agree with their conclusions and prescription for change in biology education. Our goal in this new book, *Principles of Life*, is to use our experience as authors and educators to incorporate recommendations from these reports into a new approach to introductory biology. To help us create this new breed of biology textbook, our publishers Sinauer Associates and W. H. Freeman enlisted the help of an Advisory Board made up of leading biology educators and instructors in introductory biology from throughout North America. This Advisory Board met with the authors and publishers to help develop new ideas and features for *Principles of Life*. Board members reviewed the potential contents of the book, identifying material that was less than essential for teaching introductory biology. They then reviewed the emerging chapters and have provided considerable feedback at every stage of the book's development.

How Is *Principles of Life* Different?

Each chapter of *Principles of Life* is organized into a series of *Concepts* that are important for mastering introductory biology. We have carefully chosen these concepts in light of feedback from our colleagues, from the Advisory Board, and from the numerous reports examining introductory biology. Concepts are elaborated upon, but not with the extensive detail found in

current introductory texts. *Principles of Life* is focused; it is not meant to be encyclopedic.

Students learn concepts best when they apply the concepts to practical problems. Each chapter of *Principles of Life* contains exercises, called *Apply the Concept*, that present data for students to analyze. Each of these exercises uses problem solving to reinforce a concept that is central to the respective chapter. Science students need to understand basic methods for data presentation and analysis, so many of these problems ask students about statistical significance of the results. To help students understand issues in data presentation and interpretation, we have provided a short introduction to biological statistics in Appendix B. Although this Appendix is not meant to replace a more formal introduction to statistics, we believe that statistical thinking is an important skill that should be developed in all introductory science courses. We have kept the problems and examples straightforward to emphasize the concepts of statistical analysis rather than the details of any particular statistical test. Some of the *Apply the Concept* exercises are simple enough that they can be presented, analyzed, and discussed in class; others are better suited for homework assignments.

Our *Investigation* figures let students see *how* we know *what* we know. These figures present a Hypothesis, Method, Results, and Conclusion. Most of these *Investigation* figures now include a section titled *Analyze the Data*, in which we have extracted a subset of data from the published experiment. Students are asked to analyze these data and to make connections between observations, analyses, hypotheses, and conclusions. As with *Apply the Concept* problems, students are asked to apply basic statistical approaches to understand the results and draw conclusions. We have also provided extensive online resources for each *Investigation* figure, available on the book's free web site (*thelifewire.com*) and integrated with the online version of the book on the BioPortal (*yourBioPortal.com*). These resources include expanded discussions of the original research, links to the original publications, and discussion and links for any follow-up investigations that have been published. For many *Investigations*, we have expanded *Working with Data* problems, which provide students with an opportunity to explore and analyze the original published data in greater depth.

Each chapter begins with an application of a major concept—a true story that illustrates and provides a motivation for understanding the chapter's content, and provides a social, medical, scientific, or historical context for the material. Each of these vignettes ends with an open-ended question that students can keep in mind as they read and study the rest of the chapter. We return to this opening question at the close of the chapter to show how information presented throughout the chapter illuminates the question and helps provide an answer. By pondering these questions as they read and study, students can begin to think like scientists.

At the end of each conceptual discussion we pose a series of questions (*Do You Understand Concept X?*) designed to help students self-evaluate their understanding of the material. These questions span the incremental levels of Bloom's Taxonomy of Cognitive Domains: factual knowledge, comprehension, application, analysis, synthesis, and evaluation.

Another important element for student success is reinforcement and application of concepts through online resources such as *Animated Tutorials*, *Activities*, and *Interactive Tutorials*. These are provided for each chapter, both in BioPortal and on the free Companion Website. For many concepts, students can conduct their own simulations, explore a concept in greater depth, and understand concepts through active discovery.

The interdisciplinary connections among the different subfields of biology are an emphasis of modern biology education. To help students build bridges between different portions of the course, and make connections between different areas of knowledge, we have provided *Links* throughout the book. Using these *Links*, students can see that information they learn about molecular or cell biology is connected and relates to topics in evolution, diversity, physiology, and ecology, for example.

Biologists make new discoveries and apply biological concepts to new applications every day. These applications are often in the news, and students are often excited to see the connections between current developments and the fundamental concepts they are learning. We highlight many such developments in *Frontiers* in each chapter. These *Frontiers* highlight exciting applications and provide a connection between introductory biology and current technological applications.

Students need to learn about some of the major *Research Tools* that are used in biology, including major laboratory, computational, and field methods. Our *Research Tools* figures explain these tools and provide a context for how they are used by biologists.

Our art program for *Principles of Life* builds on our success with *Life: The Science of Biology*. We pioneered the use of balloon captions to help students understand and interpret the biological processes illustrated in figures without repeatedly going back and forth between the figure, its legend, and the text. Without these guides, students often skip or miss the important points of figures.

Principles of Life Value Options

Loose-Leaf Version

This shrink-wrapped, unbound, 3-hole punched version is designed to fit into a 3-ring binder. Students take only what they need to class and can easily integrate any instructor hand-outs or other resources.

Alternative Electronic Choices

The *Principles of Life* eBook is a complete interactive version of the textbook. Available as a stand-alone and within BioPortal, the eBook—like the loose-leaf version—offers a substantial discount from the price of the printed textbook. This online version of *Principles of Life* gives students an efficient and rich learning experience by integrating all of the resources from the student website directly into the eBook platform. It also incorporates additional features that allow students and instructors to customize the text.

Media and Supplements

To support both students and instructors, we offer a wide range of media and supplements to accompany *Principles of Life*. All new copies of *Principles of Life* include access to BioPortal—the online platform that integrates all of the student and instructor resources with the interactive eBook, powerful assessment tools, and Prep-U adaptive quizzing. Throughout the textbook, references to *Animated Tutorials*, *Web Activities*, and *Working with Data* exercises refer students to the rich collection of resources available within BioPortal. BioPortal also includes a robust set of assessment and course management features for instructors, making it easy to quickly gauge class and individual progress, build assignments, customize the content of the eBook, and more.

The rich collection of visual resources in the *Principles of Life* Instructor's Media Library provides instructors with a wide range of options for enhancing lectures, course websites, and assignments. Highlights include multiple versions of all textbook figures, a wealth of PowerPoint® resources including layered art presentations, a large collection of videos, and in-class active learning exercises that help instructors bring the active learning approach of the textbook into the classroom.

For a complete list of all the media and supplements available for *Principles of Life*, please refer to “Media and Supplements to accompany *Principles of Life*” on page *xiv*. Also, refer to the inside of the back cover for a complete list of all the student media resources referenced in the text.

Many People to Thank

Our editor and publisher, Andy Sinauer, has been a source of inspiration and support at every stage of this book's development. He embraced the need for change in introductory biology textbooks and has helped make our vision into a reality. Bill Purves and Gordon Orians, our co-authors on earlier editions of *Life: The Science of Biology*, were instrumental in articulating the concepts developed in *Principles of Life*, and many aspects of this book can be traced back to their critical contributions. In the development of *Principles of Life*, Nickolas M. Waser, Frank E. Price, Kathleen Hunt, and the members of our Advisory Board

(see the next page) provided detailed suggestions for organizing our chapters around the fundamental concepts of biology.

For this new book, Sinauer Associates assembled a talented and dedicated team of professionals. Foremost were the contributions of editors Carol Wigg and Laura Green, who participated in the planning and shared the developmental editing. Their meticulous work included many refinements of the new pedagogical features. Norma Roche added her editorial expertise to the unit on biological diversity and provided organizational input for the brand-new ecology unit. Carol and Laura worked closely with two top-notch copyeditors, Jane Murfett and Liz Pierson. Elizabeth Morales, “our” artist, worked with each of us to develop effective and beautiful line art. David McIntyre cheerfully took on the challenge of finding superior images for the photographs in the book. Designer Joanne Delphia brought a fresh look to the book that we find both functional and handsome. Jeff Johnson did a masterful job of assembling all the book's elements into clear and attractive pages. Chris Small coordinated production and imposed his exacting standards on keeping the myriad components consistent. Susan McGlew and Johannah Walkowicz organized and commissioned the many expert academic reviews. Jason Dirks coordinated the ever-growing team that created the vast array of media and supplements that compose BioPortal. Dean Scudder, Director of Sales and Marketing, participated in every stage of the book's development.

At W. H. Freeman, we were fortunate to have the long-term input of Executive Editor Susan Winslow, whose advice on all sorts of issues has been invaluable. Associate Director of Marketing Debbie Clare, in collaboration with the Regional Specialists, Regional Sales Managers, and the Market Development team, did an impressive job coordinating all the stages of informing Freeman's skilled sales force of our book's story. We also wish to thank the Freeman media group for their expertise in producing the e-Book and BioPortal.

Media and Supplements to accompany *Principles of Life*

BIOPORTAL featuring Prep-U

yourBioPortal.com

BioPortal brings together the extensive teaching and learning resources for *Principles of Life*, including Prep-U Personal Adaptive Quizzing, a fully integrated eBook, dynamic features such as In-Class Active Exercises and BioNews, and additional assessment resources—all in a convenient, fully customizable online course environment that makes organizing and administering your course easy. BioPortal includes:

Principles of Life eBook

- Integration of all activities, animated tutorials, and other media resources
- Quick, intuitive navigation to any section or subsection, as well as any printed book page number
- In-text links to all glossary entries
- Easy text highlighting
- A bookmarking feature that allows for quick reference to any page
- A powerful notes feature that allows students to add notes to any page
- A full glossary and index
- Full-text search, including an additional option to search the glossary and index
- Automatic saving of all notes, highlighting, and bookmarks

Additional eBook features for instructors:

- *Content Customization*: Instructors can easily add pages of their own content and/or hide chapters or sections that they do not cover in their course.
- *Instructor Notes*: Instructors can choose to create an annotated version of the eBook with their own notes on any page. When students in the course log in, they see the instructor's personalized version of the eBook. Instructor notes can include text, Web links, images, links to all BioPortal content, and more.

Built by educators, Prep-U focuses student study time exactly where it should be, through the use of personalized, adaptive quizzes that move students toward a better grasp of the material—and better grades. Prep-U is fully integrated into BioPortal, making it easy for instructors to take advantage of this powerful quizzing engine in their course. Features include:

- Personalized adaptive quizzing
- Automatic results reporting into the BioPortal gradebook
- Instant “How’s My Class Doing?” reports that include strengths and weaknesses, common misconceptions, and comparisons to national data

Student Resources

DIAGNOSTIC QUIZZING. The diagnostic quiz for each chapter of *Principles of Life* assesses student understanding of that chapter, and generates a Personalized Study Plan to effectively focus student study time. The plan includes links to specific textbook sections, animated tutorials, and activities.

INTERACTIVE SUMMARIES. For each chapter, these dynamic summaries combine a review of important concepts with links to all of the key figures from the chapter as well as all of the relevant animated tutorials, activities, and key terms.

ANIMATED TUTORIALS. A comprehensive set of in-depth animated tutorials present complex topics in a clear, easy-to-follow format that combines a detailed animation with an introduction, conclusion, and quiz.

ACTIVITIES. A variety of activities help students learn important facts and concepts through a wide range of exercises, such as labeling steps in processes or parts of structures, building diagrams, and identifying different types of organisms.

INTERACTIVE TUTORIALS. These tutorial modules help students understand key concepts through the use of problem scenarios, experimental techniques, and interactive models.

INTERACTIVE QUIZZES. Each question includes an image from the textbook, thorough feedback on both correct and incorrect answer choices, references to textbook pages, and links to eBook pages, for quick review.

LECTURE NOTEBOOK. This invaluable resource provides all the artwork and tables from the textbook, with ample space for note-taking. Students can download chapters of the Lecture Notebook as PDF files and then either enter notes electronically into the PDFs, or print out the chapters/sections they need.

BIONEWS FROM SCIENTIFIC AMERICAN. BioNews makes it easy for instructors to bring the dynamic nature of the biological sciences and up-to-the minute currency into their course. Accessible from within BioPortal, BioNews is a continuously updated feed of current news, podcasts, magazine articles, science blog entries, “strange but true” stories, and more.

BIONAVIGATOR. This unique visual resource is an innovative way to access the wide variety of *Principles of Life* animations and activities. A visual interface begins with a whole-Earth view and allows the user to zoom to any level of biological inquiry, encountering links to a wealth of animations, activities, and tutorials on the full range of topics along the way.

WORKING WITH DATA. A companion to the in-text Analyze the Data problems, these exercises are built around some of the original experiments depicted in the Investigation figures. They help students build their quantitative skills and encourage student interest in how scientists do research, by looking at real experimental data and answering questions based on those data.

FLASHCARDS & KEY TERMS. For each chapter of the book, there is a set of flashcards that allows the student to review all the key terminology from the chapter. Students can review the terms in study mode and then quiz themselves on a list of terms.

INVESTIGATION LINKS. For each Investigation figure in the textbook, BioPortal includes an overview of the experiment featured in the figure and related research or applications that followed, a link to the original paper, and links to additional information related to the experiment.

GLOSSARY. The language of biology is often difficult for students taking introductory biology to master, so BioPortal includes a full glossary that features audio pronunciations of all terms.

TREE OF LIFE. An interactive version of the Tree of Life in Appendix A. Includes links to the extensive Discover Life online biodiversity database.

MATH FOR LIFE. A collection of mathematical shortcuts and references to help students with the quantitative skills they need in the laboratory.

SURVIVAL SKILLS. A guide to more effective study habits. Topics include time management, note-taking, effective highlighting, and exam preparation.

Instructor Resources

Assessment

- Diagnostic Quizzing provides instant class comprehension feedback to instructors, along with targeted lecture resources for those areas requiring the most attention.

- Multiple question banks (test bank, diagnostic quiz, interactive quiz, and study guide) include thousands of questions, all referenced to specific textbook sections and ranked according to Bloom’s taxonomy.
- Question filtering allows instructors to select questions based on Bloom’s category and/or textbook section.
- Easy-to-use customized assessment tools allow instructors to quickly create quizzes and many other types of assignments using any combination of the questions and resources provided in BioPortal, along with their own materials.
- In-class active learning exercises help instructors engage students in the classroom.

Media Resources

(see Instructor’s Media Library below for details)

- Videos
- PowerPoint Presentations (Textbook Figures, Lectures, Layered Art, Editable Labels)
- Supplemental Photos
- Active Learning Exercises
- Instructor’s Manual
- Answers to the Apply the Concept, Analyze the Data, and Working with Data questions

Course Management

- Complete course customization capabilities
- Custom resources/document posting
- Robust gradebook
- Communication Tools: Announcements, Calendar, Course Email, Discussion Boards

Note: The printed textbook, the eBook, BioPortal, and Prep-U can all be purchased individually as stand-alone items, in addition to being available in a package.

Student Supplements

Study Guide

For each chapter of the textbook, the *Principles of Life* Study Guide offers a variety of study and review tools. The Big Picture provides the student with a quick overview of the chapter’s main concepts and themes. The Study Strategies section offers suggestions for the most effective ways to study the specific material in the chapter, and points out areas students are most likely to find difficult. The Key Concept Review section incorporates a review of each numbered concept from the chapter, with review questions that help the student apply what they have learned (including diagram questions). Each Study Guide chapter also concludes with a Test Yourself section that allows the student to test their comprehension. All questions include answers.

Companion Website www.whfreeman.com/hillis1e

For those students who do not have access to BioPortal, the *Principles of Life* Companion Website is available free of charge (no access code required). The site features a variety of resources, including animations, flashcards, activities, study ideas, and more.

CatchUp Math & Stats

Michael Harris, Gordon Taylor, and Jacquelyn Taylor (ISBN 978-1-4292-0557-3)

This primer will help your students quickly brush up on the quantitative skills they need to succeed in biology. Presented in brief, accessible units, the book covers topics such as working with powers, logarithms, using and understanding graphs, calculating standard deviation, preparing a dilution series, choosing the right statistical test, analyzing enzyme kinetics, and many more.

Student Handbook for Writing in Biology, Third Edition

Karen Knisely (ISBN 978-1-4292-3491-7)

This book provides practical advice to students who are learning to write according to the conventions in biology. Using the standards of journal publication as a model, the author provides, in a user-friendly format, specific instructions on: using biology databases to locate references; paraphrasing for improved comprehension; preparing lab reports, scientific papers, posters; preparing oral presentations in PowerPoint, and more.

Bioethics and the New Embryology: Springboards for Debate

Scott F. Gilbert, Anna Tyler, and Emily Zackin (ISBN 978-0-7167-7345-0)

Our ability to alter the course of human development ranks among the most significant changes in modern science and has brought embryology into the public domain. The question that must be asked is: Even if we can do such things, should we?

BioStats Basics: A Student Handbook

James L. Gould and Grant F. Gould (ISBN 978-0-7167-3416-1)

BioStats Basics provides introductory-level biology students with a practical, accessible introduction to statistical research. Engaging and informal, the book avoids excessive theoretical and mathematical detail, and instead focuses on how core statistical methods are put to work in biology.

Instructor Media & Supplements

Instructor's Media Library

The *Principles of Life* Instructor's Media Library (available both online via BioPortal and on disc) includes a wide range of electronic resources to help instructors plan their course, present engaging lectures, and effectively assess student

comprehension. The Media Library includes the following resources:

TEXTBOOK FIGURES AND TABLES. Every image and table from the textbook is provided in both JPEG (high- and low-resolution) and PDF formats. Each figure is provided both with and without balloon captions, and large, complex figures are provided in both a whole and split version.

UNLABELED FIGURES. Every figure is provided in an unlabeled format, useful for quizzing and custom presentation development.

SUPPLEMENTAL PHOTOS. The supplemental photograph collection contains over 1,000 photographs (in addition to those in the textbook), giving instructors a wealth of additional imagery to draw upon.

ANIMATIONS. A wide range of detailed animations, all created from the textbook's art program, and viewable in either narrated or step-through mode.

VIDEOS. A collection of video segments that covers topics across the entire textbook and helps demonstrate the complexity and beauty of life.

POWERPOINT RESOURCES. For each chapter of the textbook, several different PowerPoint presentations are available. These give instructors the flexibility to build presentations in the manner that best suits their needs. Included are:

- Textbook Figures and Tables
- Lecture Presentation
- Figures with Editable Labels
- Layered Art Figures
- Supplemental Photos
- Videos
- Animations

ACTIVE LEARNING EXERCISES. These exercises help instructors engage students in the classroom through a variety of questions and problems that include discussion questions, data analysis exercises, and more, in a format designed to be used with clicker systems.

INSTRUCTOR'S MANUAL. Includes a wealth of information to help instructors in the planning and teaching of their course. The Instructor's Manual includes the following sections for each chapter of the textbook:

- Chapter Overview
- Key Concepts/Chapter Outline
- Lecture Outline
- Key Terms

MEDIA GUIDE. A visual guide to the extensive media resources available with *Principles of Life*. The guide includes thumbnails and descriptions of every video, animation, activity, and supplemental photo in the Media Library, all organized by chapter.

TEST BANK in Microsoft Word® format for easy use in lecture and exam preparation.

INTUITIVE BROWSER INTERFACE provides a quick and easy way to preview and access all of the content on the Instructor's Media Library.

Test Bank

The Test Bank offers thousands of questions, covering the full range of topics presented in the textbook. All questions are referenced to textbook sections and page numbers, and are ranked according to Bloom's taxonomy. Each chapter includes a wide range of multiple choice and fill-in-the-blank questions. In addition, each chapter features a set of diagram questions that involve the student in working with illustrations of structures, graphs, steps in processes, and more. The electronic versions of the Test Bank (within BioPortal, on the Instructor's Media Library, and on the Computerized Test Bank CD) also include all of the BioPortal Diagnostic Quiz questions, Interactive Quiz questions, and all of the Study Guide multiple choice questions.

Computerized Test Bank

The entire printed Test Bank, plus the BioPortal Diagnostic Quizzes, the Interactive Quizzes, and the Study Guide multiple choice questions are all included in Wimba's easy-to-use Diploma[®] software. Designed for both novice and advanced users, Diploma enables instructors to quickly and easily create or edit questions, create quizzes or exams with a "drag-and-drop" feature, publish to online courses, and print paper-based assignments.

Course Management System Support

As a service for *Principles of Life* adopters using WebCT, Blackboard, or ANGEL for their courses, full electronic course packs are available.

Faculty Lounge for Majors Biology is the first publisher-provided website for the majors biology community that lets instructors freely communicate and share peer-reviewed lecture and teaching resources. It is continually updated and vetted by majors biology instructors—there is always something new to see. The Faculty Lounge offers convenient access to peer-recommended and vetted resources, including the following categories: Images, News, Videos, Labs, Lecture Resources, and Educational Research. In addition, the site includes special areas for resources for lab coordinators, resources and updates from the Scientific Teaching series of books, and information on biology teaching workshops.

<http://majorsbio.facultylounge.whfreeman.com>

Figure Correlation Tool

An invaluable resource for instructors switching to *Principles of Life* from another textbook, this online tool provides easy correlations between the figures in *Principles of Life* and figures in other majors biology textbooks.

Developed for educators by educators, iclicker is a hassle-free radio-frequency classroom response system that makes it easy for instructors to ask questions, record responses, take attendance, and direct students through lectures as active participants. For more information, visit www.iclicker.com.

LabPartner is a site designed to facilitate the creation of customized lab manuals. Its database contains a wide selection of experiments published by W. H. Freeman and Hayden-McNeil Publishing. Instructors can preview, choose, and re-order labs, interleave their own original experiments, add carbonless graph paper and a pocket folder, and customize the cover both inside and out. LabPartner offers a variety of binding types: paperback, spiral, or loose-leaf. Manuals are printed on-demand once W. H. Freeman receives an order from a campus bookstore or school. www.whfreeman.com/labpartner

The Scientific Teaching Book Series is a collection of practical guides, intended for all science, technology, engineering and mathematics (STEM) faculty who teach undergraduate and graduate students in these disciplines. The purpose of these books is to help faculty become more successful in all aspects of teaching and learning science, including classroom instruction, mentoring students, and professional development. Authored by well-known science educators, the Series provides concise descriptions of best practices and how to implement them in the classroom, the laboratory, or the department. For readers interested in the research results on which these best practices are based, the books also provide a gateway to the key educational literature.

Scientific Teaching

Jo Handelsman, Sarah Miller, and Christine Pfund (ISBN 978-1-4292-0188-9)

Transformations: Approaches to College Science Teaching

Deborah Allen and Kimberly Tanner (ISBN 978-1-4292-5335-2)

Entering Research: A Facilitator's Manual

Workshops for Students Beginning Research in Science

Janet L. Branchaw, Christine Pfund, and Raelyn Rediske (ISBN 978-1-429-25857-9)

This page intentionally left blank

Table of Contents

1 Principles of Life 1

CONCEPT 1.1 Living Organisms Share Common Aspects of Structure, Function, and Energy Flow 2

- Life as we know it had a single origin 2
- Life arose from non-life via chemical evolution 2
- Cellular structure evolved in the common ancestor of life 3
- Photosynthesis allowed living organisms to capture energy from the sun 3
- Eukaryotic cells evolved from prokaryotes 4
- Multicellularity allowed specialization of tissues and functions 4
- Biologists can trace the evolutionary tree of life 4

CONCEPT 1.2 Genetic Systems Control the Flow, Exchange, Storage, and Use of Information 6

- Discoveries in biology can be generalized 5
- Genomes encode the proteins that govern an organism's structure 6

CONCEPT 1.3 Organisms Interact with and Affect Their Environments 7

- Genomes provide insights into all aspects of an organism's biology 7
- Organisms use nutrients to supply energy and to build new structures 7
- Organisms regulate their internal environment 8
- Organisms interact with one another 8

CONCEPT 1.4 Evolution Explains Both the Unity and Diversity of Life 9

- Natural selection is an important mechanism of evolution 9
- Evolution is a fact, as well as the basis for broader theory 10

CONCEPT 1.5 Science Is Based on Quantifiable Observations and Experiments 10

- Observing and quantifying are important skills 10
- Scientific methods combine observation, experimentation, and logic 11
- Getting from questions to answers 11
- Good experiments have the potential to falsify hypotheses 12
- Statistical methods are essential scientific tools 13
- Not all forms of inquiry into nature are scientific 13

Cells

2 Life Chemistry and Energy 16

CONCEPT 2.1 Atomic Structure Is the Basis for Life's Chemistry 17

- An element consists of only one kind of atom 17
- Electrons determine how an atom will react 17

CONCEPT 2.2 Atoms Interact and Form Molecules 18

- Ionic bonds form by electrical attraction 19
- Covalent bonds consist of shared pairs of electrons 19
- Hydrogen bonds may form within or between molecules with polar covalent bonds 21
- Polar and nonpolar substances: Each interacts best with its own kind 22
- Functional groups confer specific properties to biological molecules 23

CONCEPT 2.3 Carbohydrates Consist of Sugar Molecules 24

- Monosaccharides are simple sugars 24
- Glycosidic linkages bond monosaccharides 25
- Polysaccharides store energy and provide structural materials 25
- Fats and oils are triglycerides 27

CONCEPT 2.4 Lipids Are Hydrophobic Molecules 26

- Phospholipids form biological membranes 27

CONCEPT 2.5 Biochemical Changes Involve Energy 29

There are two basic types of energy 29
 There are two basic types of metabolism 29
 Biochemical changes obey physical laws 29

3 **Nucleic Acids, Proteins, and Enzymes 34****CONCEPT 3.1** Nucleic Acids Are Informational Macromolecules 35

Nucleotides are the building blocks of nucleic acids 35
 Base pairing occurs in both DNA and RNA 35
 DNA carries information and is expressed through RNA 37
 The DNA base sequence reveals evolutionary relationships 38

CONCEPT 3.2 Proteins Are Polymers with Important Structural and Metabolic Roles 39

Amino acids are the building blocks of proteins 39
 Amino acids are bonded to one another by peptide linkages 41
 Higher-level protein structure is determined by primary structure 42
 Environmental conditions affect protein structure 45

CONCEPT 3.3 Some Proteins Act as Enzymes to Speed up Biochemical Reactions 46

To speed up a reaction, an energy barrier must be overcome 46
 Enzymes bind specific reactants at their active sites 47

CONCEPT 3.4 Regulation of Metabolism Occurs by Regulation of Enzymes 49

Enzymes can be regulated by inhibitors 50
 An allosteric enzyme is regulated via changes in its shape 51
 Some metabolic pathways are usually controlled by feedback inhibition 51
 Enzymes are affected by their environments 52

4 **Cells: The Working Units of Life 56****CONCEPT 4.1** Cells Provide Compartments for Biochemical Reactions 57

Cell size is limited by the surface area-to-volume ratio 57
 Cells can be studied structurally and chemically 58
 The plasma membrane forms the outer surface of every cell 58
 Cells are classified as either prokaryotic or eukaryotic 59

CONCEPT 4.2 Prokaryotic Cells Do Not Have a Nucleus 59

Prokaryotic cells share certain features 59
 Specialized features are found in some prokaryotes 60

CONCEPT 4.3 Eukaryotic Cells Have a Nucleus and Other Membrane-Bound Compartments 61

Compartmentalization is the key to eukaryotic cell function 64
 Ribosomes are factories for protein synthesis 64
 The nucleus contains most of the DNA 64
 The endomembrane system is a group of interrelated organelles 64
 Some organelles transform energy 68
 Several other membrane-enclosed organelles perform specialized functions 68

CONCEPT 4.4 The Cytoskeleton Provides Strength and Movement 69

Microfilaments are made of actin 69
 Intermediate filaments are diverse and stable 70
 Microtubules are the thickest elements of the cytoskeleton 70
 Cilia and flagella provide mobility 70
 Biologists manipulate living systems to establish cause and effect 71

CONCEPT 4.5 Extracellular Structures Allow Cells to Communicate with the External Environment 73

The plant cell wall is an extracellular structure 73
 The extracellular matrix supports tissue functions in animals 73
 Cell junctions connect adjacent cells 74

5 **Cell Membranes and Signaling 78****CONCEPT 5.1** Biological Membranes Have a Common Structure and Are Fluid 79

Lipids form the hydrophobic core of the membrane 79
 Membrane proteins are asymmetrically distributed 81
 Plasma membrane carbohydrates are recognition sites 81
 Membranes are constantly changing 82

CONCEPT 5.2 Some Substances Can Cross the Membrane by Diffusion 83

Diffusion is the process of random movement toward a state of equilibrium 83
 Simple diffusion takes place through the phospholipid bilayer 83
 Osmosis is the diffusion of water across membranes 83
 Diffusion may be aided by channel proteins 84
 Carrier proteins aid diffusion by binding substances 85

CONCEPT 5.3 Some Substances Require Energy to Cross the Membrane 86

Active transport is directional 87
 Different energy sources distinguish different active transport systems 87

CONCEPT 5.4 Large Molecules Cross the Membrane via Vesicles 88

Macromolecules and particles enter the cell by endocytosis 88
 Receptor-mediated endocytosis is specific 89
 Exocytosis moves materials out of the cell 90

CONCEPT 5.5 The Membrane Plays a Key Role in a Cell's Response to Environmental Signals 91

Cells are exposed to many signals and may have different responses 91
 Membrane proteins act as receptors 92
 Receptors can be classified by location and function 93

CONCEPT 5.6 Signal Transduction Allows the Cell to Respond to Its Environment 94

Second messengers can stimulate signal transduction 94

A signaling cascade involves enzyme regulation and signal amplification 96
 Signal transduction is highly regulated 96
 Cell functions change in response to environmental signals 97

6 Pathways that Harvest and Store Chemical Energy 100

CONCEPT 6.1 ATP, Reduced Coenzymes, and Chemiosmosis Play Important Roles in Biological Energy Metabolism 101

ATP hydrolysis releases energy 101
 Redox reactions transfer electrons and energy 102
 Oxidative phosphorylation couples the oxidation of NADH to the production of ATP 103

ATP and reduced coenzymes link catabolism and anabolism: An overview 104

CONCEPT 6.2 Carbohydrate Catabolism in the Presence of Oxygen Releases a Large Amount of Energy 106

In glycolysis, glucose is partially oxidized and some energy is released 106
 Pyruvate oxidation links glycolysis and the citric acid cycle 108
 The citric acid cycle completes the oxidation of glucose to CO₂ 108
 NADH is oxidized by the respiratory chain, and ATP is formed by chemiosmosis 108

CONCEPT 6.3 Carbohydrate Catabolism in the Absence of Oxygen Releases a Small Amount of Energy 110

CONCEPT 6.4 Catabolic and Anabolic Pathways Are Integrated 111

Catabolism and anabolism are linked 111
 Catabolism and anabolism are integrated 112

CONCEPT 6.5 During Photosynthesis, Light Energy Is Converted to Chemical Energy 113

Light energy is absorbed by chlorophyll and other pigments 113
 Light absorption results in photochemical change 115
 Reduction leads to ATP and NADPH formation 116

CONCEPT 6.6 Photosynthetic Organisms Use Chemical Energy to Convert CO₂ to Carbohydrates 118

PART **2**

Genetics

7 The Cell Cycle and Cell Division 124

CONCEPT 7.1 Different Life Cycles Use Different Modes of Cell Reproduction 125

Asexual reproduction by binary fission or mitosis results in genetic constancy 125
 Sexual reproduction by meiosis results in genetic diversity 125

CONCEPT 7.2 Both Binary Fission and Mitosis Produce Genetically Identical Cells 127

Prokaryotes divide by binary fission 127
 Eukaryotic cells divide by mitosis followed by cytokinesis 128
 Prophase sets the stage for DNA segregation 128
 Chromosome separation and movement are highly organized 130
 Cytokinesis is the division of the cytoplasm 131

CONCEPT 7.3 Cell Reproduction Is Under Precise Control 132

The eukaryotic cell division cycle is regulated internally 132
 The cell cycle is controlled by cyclin-dependent kinases 133

CONCEPT 7.4 Meiosis Halves the Nuclear Chromosome Content and Generates Diversity 134

Meiotic division reduces the chromosome number 136
 Crossing over and independent assortment generate diversity 138
 Meiotic errors lead to abnormal chromosome structures and numbers 139

CONCEPT 7.5 Programmed Cell Death Is a Necessary Process in Living Organisms 140

8 Inheritance, Genes, and Chromosomes 144

CONCEPT 8.1 Genes Are Particulate and Are Inherited According to Mendel's Laws 145

Mendel used the scientific method to test his hypotheses 145
 Mendel's first experiments involved monohybrid crosses 145

Mendel's first law states that the two copies of a gene segregate 147
 Mendel verified his hypotheses by performing test crosses 148
 Mendel's second law states that copies of different genes assort independently 148
 Probability is used to predict inheritance 150
 Mendel's laws can be observed in human pedigrees 151

CONCEPT 8.2 Alleles and Genes Interact to Produce Phenotypes 152

New alleles arise by mutation 152
 Dominance is not always complete 153
 Genes interact when they are expressed 154
 The environment affects gene action 154

CONCEPT 8.3 Genes Are Carried on Chromosomes 155

Genes on the same chromosome are linked, but can be separated by crossing over in meiosis 156
 Linkage is also revealed by studies of the X and Y chromosomes 157
 Some genes are carried on chromosomes in organelles 159

CONCEPT 8.4 Prokaryotes Can Exchange Genetic Material 161

Bacteria exchange genes by conjugation 161
 Plasmids transfer genes between bacteria 162

9 DNA and Its Role in Heredity 165

CONCEPT 9.1 DNA Structure Reflects Its Role as the Genetic Material 166

Circumstantial evidence suggested that DNA was the genetic material 166
 Experimental evidence confirmed that DNA is the genetic material 167
 The discovery of the three-dimensional structure of DNA was a milestone in biology 168
 The nucleotide composition of DNA was known 169
 Watson and Crick described the double helix 169
 Four key features define DNA structure 169
 The double-helical structure of DNA is essential to its function 170

CONCEPT 9.2 DNA Replicates Semiconservatively 172

DNA polymerases add nucleotides to the growing chain 173
 The two DNA strands grow differently at the replication fork 175
 Telomeres are not fully replicated in most eukaryotic cells 176

Errors in DNA replication can be repaired 177
 The basic mechanisms of DNA replication can be used to amplify DNA in a test tube 178

CONCEPT 9.3 Mutations Are Heritable Changes in DNA 179

Mutations can have various phenotypic effects 179
 Point mutations change single nucleotides 180
 Chromosomal mutations are extensive changes in the genetic material 181
 Mutations can be spontaneous or induced 182
 Some base pairs are more vulnerable than others to mutation 183
 Mutagens can be natural or artificial 183
 Mutations have both benefits and costs 183

10 From DNA to Protein: Gene Expression 187

CONCEPT 10.1 Genetics Shows That Genes Code for Proteins 188

Observations in humans led to the proposal that genes determine enzymes 188
 The concept of the gene has changed over time 188
 Genes are expressed via transcription and translation 189

CONCEPT 10.2 DNA Expression Begins with Its Transcription to RNA 190

RNA polymerases share common features 190
 Transcription occurs in three steps 191
 Eukaryotic coding regions are often interrupted by introns 192
 Eukaryotic gene transcripts are processed before translation 194

CONCEPT 10.3 The Genetic Code in RNA Is Translated into the Amino Acid Sequences of Proteins 196

The information for protein synthesis lies in the genetic code 196
 Point mutations confirm the genetic code 197

CONCEPT 10.4 Translation of the Genetic Code Is Mediated by tRNA and Ribosomes 199

Transfer RNAs carry specific amino acids and bind to specific codons 199
 Each tRNA is specifically attached to an amino acid 200
 Translation occurs at the ribosome 200
 Translation takes place in three steps 201
 Polysome formation increases the rate of protein synthesis 202

CONCEPT 10.5 Proteins Are Modified after Translation 204

Signal sequences in proteins direct them to their cellular destinations 204
 Many proteins are modified after translation 205

11 Regulation of Gene Expression 208

CONCEPT 11.1 Several Strategies Are Used to Regulate Gene Expression 209

Genes are subject to positive and negative regulation 209
 Viruses use gene regulation strategies to subvert host cells 210

CONCEPT 11.2 Many Prokaryotic Genes Are Regulated in Operons 212

Regulating gene transcription conserves energy 212
 Operons are units of transcriptional regulation in prokaryotes 213

Operator–repressor interactions regulate transcription in the *lac* and *trp* operons 213

RNA polymerase can be directed to a class of promoters 215

CONCEPT 11.3 Eukaryotic Genes Are Regulated by Transcription Factors and DNA Changes 216

Transcription factors act at eukaryotic promoters 216

The expression of sets of genes can be coordinately regulated by transcription factors 217

Epigenetic changes to DNA and chromatin can regulate transcription 218

Epigenetic changes can be induced by the environment 220

CONCEPT 11.4 Eukaryotic Gene Expression Can Be Regulated after Transcription 221

Different mRNAs can be made from the same gene by alternative splicing 221

MicroRNAs are important regulators of gene expression 222

Translation of mRNA can be regulated 222

Protein stability can be regulated 223

12 Genomes 226

CONCEPT 12.1 There Are Powerful Methods for Sequencing Genomes and Analyzing Gene Products 227

New methods have been developed to rapidly sequence DNA 227

Genome sequences yield several kinds of information 228

Phenotypes can be analyzed using proteomics and metabolomics 230

CONCEPT 12.3 Prokaryotic Genomes Are Relatively Small and Compact 235

Prokaryotic genomes are compact 231

Some sequences of DNA can move about the genome 232

Metagenomics allows us to describe new organisms and ecosystems 232

Will defining the genes required for cellular life lead to artificial life? 234

CONCEPT 12.3 Eukaryotic Genomes Are Large and Complex 235

Model organisms reveal many characteristics of eukaryotic genomes 235

Gene families exist within individual eukaryotic organisms 236

Eukaryotic genomes contain many repetitive sequences 237

CONCEPT 12.4 The Human Genome Sequence Has Many Applications 239

The human genome sequence held some surprises 239

Human genomics has potential benefits in medicine 239

DNA fingerprinting uses short tandem repeats 241

13 Biotechnology 244

CONCEPT 13.1 Recombinant DNA Can Be Made in the Laboratory 245

Restriction enzymes cleave DNA at specific sequences 245

Gel electrophoresis separates DNA fragments 246

Recombinant DNA can be made from DNA fragments 247

CONCEPT 13.2 DNA Can Genetically Transform Cells and Organisms 248

Genes can be inserted into prokaryotic or eukaryotic cells 249

Recombinant DNA enters host cells in a variety of ways 249

Reporter genes are used to identify host cells containing recombinant DNA 250

CONCEPT 13.3 Genes and Gene Expression Can Be Manipulated 252

DNA fragments for cloning can come from several sources 252

DNA mutations can be made in the laboratory 253

Genes can be inactivated by homologous recombination 253

Complementary RNA can prevent the expression of specific genes 254

DNA microarrays reveal RNA expression patterns 254

CONCEPT 13.4 Biotechnology Has Wide Applications 255

Expression vectors can turn cells into protein factories 256

Medically useful proteins can be made by biotechnology 256

DNA manipulation is changing agriculture 258

There is public concern about biotechnology 260

14 Genes, Development, and Evolution 263

CONCEPT 14.1 Development Involves Distinct but Overlapping Processes 264

Four key processes underlie development 264

Cell fates become progressively more restricted during development 265

Cell differentiation is not irreversible 265

Stem cells differentiate in response to environmental signals 266

CONCEPT 14.2 Changes in Gene Expression Underlie Cell Differentiation in Development 269

Differential gene transcription is a hallmark of cell differentiation 269

Gene expression can be regulated by cytoplasmic polarity 270

Inducers passing from one cell to another can determine cell fates 271

CONCEPT 14.3 Spatial Differences in Gene Expression Lead to Morphogenesis 273

Multiple genes interact to determine developmental programmed cell death 273

Expression of transcription factor genes determines organ placement in plants 273

Morphogen gradients provide positional information during development 274

A cascade of transcription factors establishes body segmentation in the fruit fly 275

CONCEPT 14.4 Gene Expression Pathways Underlie the Evolution of Development 278

Developmental genes in distantly related organisms are similar 278

Genetic switches govern how the genetic toolkit is used 278

Modularity allows for differences in the pattern of gene expression among organisms 280

CONCEPT 14.5 Developmental Genes Contribute to Species Evolution but Also Pose Constraints 281

Mutations in developmental genes can cause major evolutionary changes 282

Evolution proceeds by changing what's already there 282

Conserved developmental genes can lead to parallel evolution 282

PART
3

Evolution

15 **Mechanisms of Evolution 288**

CONCEPT 15.1 Evolution Is Both Factual and the Basis of Broader Theory 289

Darwin and Wallace introduced the idea of evolution by natural selection 289

Evolutionary theory has continued to develop over the past century 291

CONCEPT 15.2 Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution 292

Mutation generates genetic variation 292

Selection on genetic variation leads to new phenotypes 293

Natural selection increases the frequency of beneficial mutations in populations 293

Gene flow may change allele frequencies 294

Genetic drift may cause large changes in small populations 294

Nonrandom mating can change genotype or allele frequencies 295

CONCEPT 15.3 DNA Evolution Can Be Measured by Changes in Allele Frequencies 297

Evolution will occur unless certain restrictive conditions exist 298

Deviations from Hardy–Weinberg equilibrium show that evolution is occurring 300

CONCEPT 15.4 Selection Can Be Stabilizing, Directional, or Disruptive 300

Stabilizing selection reduces variation in populations 301

Directional selection favors one extreme 301

Disruptive selection favors extremes over the mean 302

CONCEPT 15.5 Genomes Reveal Both Neutral and Selective Processes of Evolution 302

Much of molecular evolution is neutral 303

Positive and purifying selection can be detected in the genome 304

Heterozygote advantage maintains polymorphic loci 306

Genome size and organization also evolve 306

CONCEPT 15.6 Recombination, Lateral Gene Transfer, and Gene Duplication Can Result in New Features 308

Sexual recombination amplifies the number of possible genotypes 308

Lateral gene transfer can result in the gain of new functions 309

Many new functions arise following gene duplication 309

CONCEPT 15.7 Evolutionary Theory Has Practical Applications 310

Knowledge of gene evolution is used to study protein function 310

In vitro evolution produces new molecules 311

Evolutionary theory provides multiple benefits to agriculture 312

Knowledge of molecular evolution is used to combat diseases 312

16 **Reconstructing and Using Phylogenies 315**

CONCEPT 16.1 All of Life Is Connected through Its Evolutionary History 316

Phylogenetic trees are the basis of comparative biology 317

Derived traits provide evidence of evolutionary relationships 318

CONCEPT 16.2 Phylogeny Can Be Reconstructed from Traits of Organisms 318

Parsimony provides the simplest explanation for phylogenetic data 320

Phylogenies are reconstructed from many sources of data 321

Mathematical models expand the power of phylogenetic reconstruction 322

The accuracy of phylogenetic methods can be tested 322

CONCEPT 16.3 Phylogeny Makes Biology Comparative and Predictive 324

Reconstructing the past is important for understanding many biological processes 324

Phylogenies allow us to understand the evolution of complex traits 326

Ancestral states can be reconstructed 326

Molecular clocks help date evolutionary events 326

CONCEPT 16.4 Phylogeny Is the Basis of Biological Classification 328

Evolutionary history is the basis for modern biological classification 329

Several codes of biological nomenclature govern the use of scientific names 329

17 Speciation 332

CONCEPT 17.1 Species Are Reproductively Isolated Lineages on the Tree of Life 333

We can recognize many species by their appearance 333

Reproductive isolation is key 333

The lineage approach takes a long-term view 334

The different species concepts are not mutually exclusive 334

CONCEPT 17.2 Speciation Is a Natural Consequence of Population Subdivision 335

Incompatibilities between genes can produce reproductive isolation 335

Reproductive isolation develops with increasing genetic divergence 336

CONCEPT 17.3 Speciation May Occur through Geographic Isolation or in Sympatry 337

Physical barriers give rise to allopatric speciation 337

Sympatric speciation occurs without physical barriers 338

CONCEPT 17.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact 340

Prezygotic isolating mechanisms prevent hybridization between species 341

Postzygotic isolating mechanisms result in selection against hybridization 343

Hybrid zones may form if reproductive isolation is incomplete 344

18 The History of Life on Earth 347

CONCEPT 18.1 Events in Earth's History Can Be Dated 348

Radioisotopes provide a way to date rocks 349

Radiometric dating methods have been expanded and refined 349

Scientists have used several methods to construct a geological time scale 350

CONCEPT 18.2 Changes in Earth's Physical Environment Have Affected the Evolution of Life 350

The continents have not always been where they are today 351

Earth's climate has shifted between hot and cold conditions 351

Volcanoes have occasionally changed the history of life 352

Extraterrestrial events have triggered changes on Earth 353

Oxygen concentrations in Earth's atmosphere have changed over time 353

CONCEPT 18.3 Major Events in the Evolution of Life Can Be Read in the Fossil Record 356

Several processes contribute to the paucity of fossils 356

Precambrian life was small and aquatic 357

Life expanded rapidly during the Cambrian period 358

Many groups of organisms that arose during the Cambrian later diversified 358

Geographic differentiation increased during the Mesozoic era 362

Modern biotas evolved during the Cenozoic era 363

The tree of life is used to reconstruct evolutionary events 363

PART
4

Diversity

19 Bacteria, Archaea, and Viruses 366

CONCEPT 19.1 Life Consists of Three Domains That Share a Common Ancestor 367

The two prokaryotic domains differ in significant ways 367

The small size of prokaryotes has hindered our study of their evolutionary relationships 368

The nucleotide sequences of prokaryotes reveal their evolutionary relationships 370

Lateral gene transfer can lead to discordant gene trees 370

The great majority of prokaryote species have never been studied 371

CONCEPT 19.2 Prokaryote Diversity Reflects the Ancient Origins of Life 371

The low-GC Gram-positives include the smallest cellular organisms 372

Some high-GC Gram-positives are valuable sources of antibiotics 373

Hyperthermophilic bacteria live at very high temperatures 373

Hadobacteria live in extreme environments 373

Cyanobacteria were the first photosynthesizers 373

Spirochetes move by means of axial filaments 374

Chlamydias are extremely small parasites 375

The proteobacteria are a large and diverse group 375

Gene sequencing enabled biologists to differentiate the domain Archaea 376

Most crenarchaeotes live in hot or acidic places 377

Euryarchaeotes are found in surprising places 377

Korarchaeotes and nanoarchaeotes are less well known 378

CONCEPT 19.3 Ecological Communities Depend on Prokaryotes 378

Many prokaryotes form complex communities 379

Prokaryotes have amazingly diverse metabolic pathways 379

Prokaryotes play important roles in element cycling 380

Prokaryotes live on and in other organisms 381

A small minority of bacteria are pathogens 381

CONCEPT 19.4 Viruses Have Evolved Many Times 383

Many RNA viruses probably represent escaped genomic components 383

Some DNA viruses may have evolved from reduced cellular organisms 386

20 The Origin and Diversification of Eukaryotes 388

CONCEPT 20.1 Eukaryotes Acquired Features from Both Archaea and Bacteria 389

The modern eukaryotic cell arose in several steps 389

Chloroplasts have been transferred among eukaryotes several times 391

CONCEPT 20.2 Major Lineages of Eukaryotes Diversified in the Precambrian 392

Alveolates have sacs under their plasma membranes 392

Excavates began to diversify about 1.5 billion years ago 395

Stramenopiles typically have two unequal flagella, one with hairs 396

Rhizaria typically have long, thin pseudopods 398

Amoebozoans use lobe-shaped pseudopods for locomotion 398

CONCEPT 20.3 Protists Reproduce Sexually and Asexually 401

Some protists have reproduction without sex and sex without reproduction 401

Some protist life cycles feature alternation of generations 402

CONCEPT 20.4 Protists Are Critical Components of Many Ecosystems 402

Phytoplankton are primary producers 402

Some microbial eukaryotes are deadly 403

Some microbial eukaryotes are endosymbionts 403

We rely on the remains of ancient marine protists 405

21 The Evolution of Plants 407

CONCEPT 21.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes 409

Several distinct clades of algae were among the first photosynthetic eukaryotes 409

There are ten major groups of land plants 410

CONCEPT 21.2 Key Adaptations Permitted Plants to Colonize Land 411

Two groups of green algae share many features with land plants 411

Adaptations to life on land distinguish land plants from green algae 411

Life cycles of land plants feature alternation of generations 411

Nonvascular land plants live where water is readily available 412

The sporophytes of nonvascular land plants are dependent on the gametophytes 413

CONCEPT 21.3 Vascular Tissues Led to Rapid Diversification of Land Plants 415

Vascular tissues transport water and dissolved materials 415

Vascular plants have been evolving for almost half a billion years 415
 The earliest vascular plants lacked roots 415
 The lycophytes are sister to the other vascular plants 416
 Horsetails and ferns constitute a clade 416
 The vascular plants branched out 417
 Heterospory appeared among the vascular plants 418

CONCEPT 21.4 Seeds Protect Plant Embryos 420

Features of the seed plant life cycle protect gametes and embryos 420
 The seed is a complex, well-protected package 422
 A change in anatomy enabled seed plants to grow to great heights 422
 Gymnosperms have naked seeds 423
 Conifers have cones but no motile gametes 424

CONCEPT 21.5 Flowers and Fruits Increase the Reproductive Success of Angiosperms 426

Angiosperms have many shared derived traits 426
 The sexual structures of angiosperms are flowers 426
 Flower structure has evolved over time 427
 Angiosperms have coevolved with animals 428
 Fruits aid angiosperm seed dispersal 429

The angiosperm life cycle produces diploid zygotes nourished by triploid endosperms 431
 Recent analyses have revealed the phylogenetic relationships of angiosperms 432

22 The Evolution and Diversity of Fungi 437

CONCEPT 22.1 Fungi Live by Absorptive Heterotrophy 438

Unicellular yeasts absorb nutrients directly 438
 Multicellular fungi use hyphae to absorb nutrients 438
 Fungi are in intimate contact with their environment 439

CONCEPT 22.2 Fungi Can Be Saprobic, Parasitic, Predatory, or Mutualistic 439

Saprobic fungi are critical to the planetary carbon cycle 439
 Some fungi engage in parasitic or predatory interactions 440
 Mutualistic fungi engage in relationships beneficial to both partners 441
 Endophytic fungi protect some plants from pathogens, herbivores, and stress 444

CONCEPT 22.3 Major Groups of Fungi Differ in Their Life Cycles 444

Fungi reproduce both sexually and asexually 445

Microsporidia are highly reduced, parasitic fungi 446
 Most chytrids have an aquatic life cycle 446
 Some fungal life cycles feature separate fusion of cytoplasm and nuclei 446
 Arbuscular mycorrhizal fungi form symbioses with plants 448
 The dikaryotic condition is a synapomorphy of sac fungi and club fungi 448
 The sexual reproductive structure of sac fungi is the ascus 450
 The sexual reproductive structure of club fungi is the basidium 451

CONCEPT 22.4 Fungi Can Be Sensitive Indicators of Environmental Change 452

Lichen diversity and abundance indicate air quality 452
 Fungi contain historical records of pollutants 452
 Reforestation may depend on mycorrhizal fungi 452

23 Animal Origins and Diversity 456

CONCEPT 23.1 Distinct Body Plans Evolved among the Animals 457

Animal monophyly is supported by gene sequences and cellular morphology 457
 Basic developmental patterns and body plans differentiate major animal groups 458
 Most animals are symmetrical 459
 The structure of the body cavity influences movement 459
 Segmentation improves control of movement 460
 Appendages have many uses 460

CONCEPT 23.2 Some Animal Groups Fall Outside the Bilateria 461

Sponges and placozoans are weakly organized animals 461
 Ctenophores are radially symmetrical and diploblastic 463
 Cnidarians are specialized carnivores 463

CONCEPT 23.3 There are Two Major Groups of Protostomes 465

Cilia-bearing lophophores and trochophore larvae evolved among the lophotrochozoans 466
 Ecdysozoans must shed their cuticles 471

CONCEPT 23.4 Arthropods Are Diverse and Abundant Animals 476

Arthropod relatives have fleshy, unjointed appendages 476
 Chelicerates are characterized by pointed, nonchewing mouthparts 477
 Mandibles and antennae characterize the remaining arthropod groups 478
 Over half of all described species are insects 479

CONCEPT 23.5 Deuterostomes Include Echinoderms, Hemichordates, and Chordates 483

Echinoderms have unique structural features 483

Hemichordates are wormlike marine deuterostomes 485
 Chordate characteristics are most evident in larvae 485
 Adults of most cephalochordates and urochordates are sessile 486
 A dorsal supporting structure replaces the notochord in vertebrates 487
 The vertebrate body plan can support large, active animals 488
 Fins and swim bladders improved stability and control over locomotion 488

CONCEPT 23.6 Life on Land Contributed to Vertebrate Diversification 490

Jointed fins enhanced support for fishes 490
 Amphibians adapted to life on land 491

Amniotes colonized dry environments 492
 Reptiles adapted to life in many habitats 493
 Crocodylians and birds share their ancestry with the dinosaurs 494
 The evolution of feathers allowed birds to fly 495
 Mammals radiated as nonavian dinosaurs declined in diversity 496
 Most mammals are viviparous 498

CONCEPT 23.7 Humans Evolved among the Primates 499

Human ancestors evolved bipedal locomotion 499
 Human brains became larger as jaws became smaller 501

Plant Form and Function

24 The Plant Body 506

CONCEPT 24.1 The Plant Body Is Organized and Constructed in a Distinctive Way 507

Plants develop differently than animals 507
 Apical–basal polarity and radial symmetry are characteristic of the plant body 508
 The plant body is constructed from three tissue systems 509

CONCEPT 24.2 Meristems Build Roots, Stems, and Leaves 511

A hierarchy of meristems generates the plant body 511

The root apical meristem gives rise to the root cap and the root primary meristems 512
 The products of the root's primary meristems become root tissues 512
 The root system anchors the plant and takes up water and dissolved minerals 514
 The products of the stem's primary meristems become stem tissues 515
 The stem supports leaves and flowers 515
 Leaves are the primary site of photosynthesis 516
 Many eudicot stems and roots undergo secondary growth 517

CONCEPT 24.3 Domestication Has Altered Plant Form 518

25 Plant Nutrition and Transport 521

CONCEPT 25.1 Plants Acquire Mineral Nutrients from the Soil 522

Nutrients can be defined by their deficiency 522
 Experiments using hydroponics have identified essential elements 522
 Soil provides nutrients for plants 523
 Ion exchange makes nutrients available to plants 524
 Fertilizers can be used to add nutrients to soil 524

CONCEPT 25.2 Soil Organisms Contribute to Plant Nutrition 525

Plants send signals for colonization 525

Mycorrhizae expand the root system 527
 Rhizobia capture nitrogen from the air and make it available to plant cells 527
 Some plants obtain nutrients directly from other organisms 528

CONCEPT 25.3 Water and Solutes Are Transported in the Xylem by Transpiration–Cohesion–Tension 529

Differences in water potential govern the direction of water movement 529
 Water and ions move across the root cell plasma membrane 530
 Water and ions pass to the xylem by way of the apoplast and symplast 531
 Water moves through the xylem by the transpiration–cohesion–tension mechanism 532
 Stomata control water loss and gas exchange 533

CONCEPT 25.4 Solutes Are Transported in the Phloem by Pressure Flow 535

Sucrose and other solutes are carried in the phloem 535
 The pressure flow model describes the movement of fluid in the phloem 536

26 Plant Growth and Development 539

CONCEPT 26.1 Plants Develop in Response to the Environment 540

The seed germinates and forms a growing seedling 540
 Several hormones and photoreceptors help regulate plant growth 540

Genetic screens have increased our understanding of plant signal transduction 541

CONCEPT 26.2 Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action 542

Gibberellins have many effects on plant growth and development 543

The transport of auxin mediates some of its effects 544

Auxin plays many roles in plant growth and development 546

At the molecular level, auxin and gibberellins act similarly 547

CONCEPT 26.3 Other Plant Hormones Have Diverse Effects on Plant Development 548

Ethylene is a gaseous hormone that promotes senescence 549

Cytokinins are active from seed to senescence 549

Brassinosteroids are plant steroid hormones 550

Abscisic acid acts by inhibiting development 551

CONCEPT 26.4 Photoreceptors Initiate Developmental Responses to Light 551

Phototropin, cryptochromes, and zeaxanthin are blue-light receptors 551

Phytochrome mediates the effects of red and far-red light 552

Phytochrome stimulates gene transcription 553

Circadian rhythms are entrained by photoreceptors 554

27 Reproduction of Flowering Plants 556

CONCEPT 27.1 Most Angiosperms Reproduce Sexually 557

The flower is the reproductive organ of angiosperms 557

Angiosperms have microscopic gametophytes 558

Angiosperms have mechanisms to prevent inbreeding 559

A pollen tube delivers sperm cells to the embryo sac 559

Angiosperms perform double fertilization 560

Embryos develop within seeds contained in fruits 560

CONCEPT 27.2 Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State 562

Shoot apical meristems can become inflorescence meristems 562

A cascade of gene expression leads to flowering 563

Photoperiodic cues can initiate flowering 563

Plants vary in their responses to photoperiodic cues 563

Night length is the key photoperiodic cue that determines flowering 564

The flowering stimulus originates in the leaf 565

Florigen is a small protein 565

Flowering can be induced by temperature or gibberellins 566

Some plants do not require an environmental cue to flower 567

CONCEPT 27.3 Angiosperms Can Reproduce Asexually 568

Angiosperms use many forms of asexual reproduction 568

Vegetative reproduction is important in agriculture 570

28 Plants in the Environment 572

CONCEPT 28.1 Plants Have Constitutive and Induced Responses to Pathogens 573

Physical barriers form constitutive defenses 573

Induced responses to pathogens may be genetically determined 573

The hypersensitive response fights pathogens at the site of infection 574

Plants can develop systemic resistance to pathogens 575

CONCEPT 28.2 Plants Have Mechanical and Chemical Defenses against Herbivores 576

Constitutive defenses are physical and chemical 576

Plants respond to herbivory with induced defenses 577

Why don't plants poison themselves? 579

Plants don't always win the arms race 579

CONCEPT 28.3 Plants Adapt to Environmental Stresses 580

Some plants have special adaptations to live in very dry conditions 580

Some plants grow in saturated soils 581

Plants can respond to drought stress 582

Plants can cope with temperature extremes 583

Some plants can tolerate soils with high salt concentrations 584

Some plants can tolerate heavy metals 584

Animal Form and Function

29 Physiology, Homeostasis, and Temperature Regulation 588

CONCEPT 29.1 Multicellular Animals Require a Stable Internal Environment 589

Multicellular animals have an internal environment of extracellular fluid 589

Homeostasis is the process of maintaining stable conditions in the internal environment 589

Cells, tissues, and organs serve homeostatic needs 590

CONCEPT 29.2 Physiological Regulation Achieves Homeostasis of the Internal Environment 591

Regulating physiological systems requires feedback information 591

Feedback information can be negative or positive 592

CONCEPT 29.3 Living Systems Are Temperature-Sensitive 592

Q_{10} is a measure of temperature sensitivity 592

Animals can acclimatize to seasonal temperature changes 593

Animals can regulate body temperature 593

CONCEPT 29.4 Animals Control Body Temperature by Altering Rates of Heat Gain and Loss 594

Mammals and birds have high rates of metabolic heat production 595

Basal metabolic rates are correlated with body size 596

Insulation is the major adaptation of endotherms to cold climates 596

Some fish can conserve metabolic heat 597

Evaporation is an effective but expensive avenue of heat loss 598

Some ectotherms elevate their metabolic heat production 598

Behavior is a common thermoregulatory adaptation in ectotherms and endotherms 598

CONCEPT 29.5 A Thermostat in the Brain Regulates Mammalian Body Temperature 599

The mammalian thermostat uses feedback information 599

The thermostat can be adjusted up and down 600

30 Animal Hormones 603

CONCEPT 30.1 Hormones Are Chemical Messengers 604

Endocrine signals can act locally or at a distance 604

Hormones can be divided into three chemical groups 604

Hormonal communication has a long evolutionary history 604

Insect studies reveal hormonal control of development 605

CONCEPT 30.2 Hormones Act by Binding to Receptors 607

Hormone receptors can be membrane-bound or intracellular 607

Hormone action depends on the nature of the target cell and its receptors 607

Hormone receptors are regulated 608

CONCEPT 30.3 The Pituitary Gland Links the Nervous and Endocrine Systems 609

The pituitary gland has two parts 610

The neurohormones of the anterior pituitary are produced in minute amounts 611

Negative feedback loops also regulate the pituitary hormones 612

CONCEPT 30.4 Hormones Regulate Mammalian Physiological Systems 613

Thyroxine helps regulate metabolic rate and body temperature 614

Hormonal regulation of calcium concentration is vital 615

The two segments of the adrenal gland coordinate the stress response 616

Sex steroids from the gonads control reproduction 617

31 Immunology: Animal Defense Systems 620

CONCEPT 31.1 Animals Use Innate and Adaptive Mechanisms to Defend Themselves against Pathogens 621

White blood cells play many roles in immunity 621

Immune system proteins bind pathogens or signal other cells 621

CONCEPT 31.2 Innate Defenses Are Nonspecific 622

Barriers and local agents defend the body against invaders 622

Other innate defenses include specialized proteins and cellular processes 623

Inflammation is a coordinated response to infection or injury 623

Inflammation can cause medical problems 624

CONCEPT 31.3 The Adaptive Immune Response Is Specific 625

Adaptive immunity has four key features 625

Two types of adaptive immune responses interact 628

CONCEPT 31.4 The Adaptive Humoral Immune Response Involves Specific Antibodies 629

Plasma cells produce antibodies 629

Antibodies share a common overall structure 630

Antibody diversity results from DNA rearrangements and other mutations 630

Antibodies bind to pathogens on cells or in the bloodstream 633

CONCEPT 31.5 The Adaptive Cellular Immune Response Involves T Cells and Their Receptors 633

T cell receptors specifically bind to antigens on cell surfaces 633
 MHC proteins present antigen to T cells and result in recognition 634
 Activation of the cellular response results in death of the targeted cell 634
 Regulatory T cells suppress the humoral and cellular immune responses 635
 AIDS is an immune deficiency disorder 635

32 Animal Reproduction 638**CONCEPT 32.1 Reproduction Can Be Sexual or Asexual 639**

Budding and regeneration produce new individuals by mitosis 639
 Parthenogenesis is the development of unfertilized eggs 639
 Most animals reproduce sexually 639

CONCEPT 32.2 Gametogenesis Produces Haploid Gametes 640

Spermatogenesis produces four sperm from one parent cell 640
 Oogenesis produces one large ovum from one parent cell 640
 Hermaphrodites can produce both sperm and ova 641

CONCEPT 32.3 Fertilization Is the Union of Sperm and Ovum 642

Fertilization may be external or internal 642
 Recognition molecules enable sperm to penetrate protective layers around the ovum 642
 Only one sperm can fertilize an ovum 644
 Fertilized ova may be released into the environment or retained in the mother's body 645

CONCEPT 32.4 Human Reproduction Is Hormonally Controlled 645

Male sex organs produce and deliver semen 645
 Male sexual function is controlled by hormones 647
 Female sex organs produce ova, receive sperm, and nurture the embryo 648
 The female reproductive cycle is controlled by hormones 648

In pregnancy, tissues derived from the embryo produce hormones 651
 Hormonal and mechanical stimuli trigger childbirth 651

CONCEPT 32.5 Humans Use a Variety of Methods to Control Fertility 651

Many contraceptive methods are available 651
 Reproductive technologies help solve problems of infertility 653

33 Animal Development 655**CONCEPT 33.1 Fertilization Activates Development 656**

The sperm and ovum make different contributions to the zygote 656
 Rearrangements of egg cytoplasm set the stage for determination 656

CONCEPT 33.2 Cleavage Repackages the Cytoplasm of the Zygote 657

Cleavage increases cell number without cell growth 657
 Cleavage in mammals is unique 658
 Specific blastomeres generate specific tissues and organs 659

CONCEPT 33.3 Gastrulation Creates Three Tissue Layers 660

Invagination of the vegetal pole characterizes gastrulation in the sea urchin 660
 Gastrulation in the frog begins at the gray crescent 661

The dorsal lip of the blastopore organizes amphibian embryo formation 661
 Transcription factors underlie the organizer's actions 663
 Reptilian and avian gastrulation is an adaptation to yolky eggs 663
 Placental mammals retain the avian/reptilian gastrulation pattern but lack yolk 664

CONCEPT 33.4 Neurulation Creates the Nervous System 665

The notochord induces formation of the neural tube 665
 The central nervous system develops from the embryonic neural tube 666
 Body segmentation develops during neurulation 666

CONCEPT 33.5 Extraembryonic Membranes Nourish the Growing Embryo 668

Extraembryonic membranes form with contributions from all germ layers 668
 Extraembryonic membranes in mammals form the placenta 669

34 Neurons and Nervous Systems 672**CONCEPT 34.1 Nervous Systems Consist of Neurons and Glia 673**

Neurons transmit electrical and chemical signals 673
 Glia support, nourish, and insulate neurons 673

Neurons are linked into information-processing networks 674

CONCEPT 34.2 Neurons Generate and Transmit Electrical Signals 675

Simple electrical concepts underlie neural function 675

The sodium–potassium pump sets up concentration gradients of Na^+ and K^+ 676

The resting potential is mainly caused by K^+ leak channels 676

The Nernst equation can predict a neuron’s membrane potential 676

Gated ion channels can alter membrane potential 677

Graded changes in membrane potential spread to nearby parts of the neuron 677

Sudden changes in Na^+ and K^+ channels generate action potentials 678

Action potentials are conducted along axons without loss of signal 678

Action potentials travel faster in large axons and in myelinated axons 679

CONCEPT 34.3 Neurons Communicate with Other Cells at Synapses 681

The neuromuscular junction is a model chemical synapse 681

The postsynaptic cell sums excitatory and inhibitory input 682

To turn off responses, synapses must be cleared of neurotransmitter 682

There are many types of neurotransmitters 683

Synapses can be fast or slow depending on the nature of receptors 684

CONCEPT 34.4 The Vertebrate Nervous System Has Many Interacting Components 684

The autonomic nervous system controls involuntary physiological functions 685

The spinal cord transmits and processes information 685

Interneurons coordinate polysynaptic reflexes 686

The brainstem transfers information between the brain and spinal cord 687

Deeper parts of the forebrain control physiological drives, instincts, and emotions 687

Regions of the telencephalon interact to produce consciousness and control behavior 688

Each cerebral hemisphere has four lobes 689

CONCEPT 34.5 Specific Brain Areas Underlie the Complex Abilities of Humans 690

Language abilities are localized in the left cerebral hemisphere 690

Some learning and memory can be localized to specific brain areas 690

There are two different states of sleep 691

We still cannot answer the question “What is consciousness?” 692

35 Sensors 695

CONCEPT 35.1 Sensory Systems Convert Stimuli into Action Potentials 696

Sensory transduction involves changes in membrane potentials 696

Different sensory receptors detect different types of stimuli 696

Sensation depends on which neurons receive action potentials from sensory cells 696

Many receptors adapt to repeated stimulation 697

CONCEPT 35.2 Chemoreceptors Detect Specific Molecules or Ions 697

Olfaction is the sense of smell 698

Some chemoreceptors detect pheromones 698

Gustation is the sense of taste 699

CONCEPT 35.3 Mechanoreceptors Detect Physical Forces 700

Many different cells respond to touch and pressure 700

Mechanoreceptors are found in muscles, tendons, and ligaments 701

Hair cells are mechanoreceptors of the auditory and vestibular systems 701

Auditory systems use hair cells to sense sound waves 702

Flexion of the basilar membrane is perceived as pitch 703

Various types of damage can result in hearing loss 704

The vestibular system uses hair cells to detect forces of gravity and momentum 704

CONCEPT 35.4 Photoreceptors Detect Light 705

Rhodopsins are responsible for photosensitivity 705

Rod cells respond to light 707

Animals have a variety of visual systems 707

Visual information is processed by the retina and the brain 708

Color vision is due to cone cells 709

36 Musculoskeletal Systems 712

CONCEPT 36.1 Cycles of Protein–Protein Interactions Cause Muscles to Contract 713

Sliding filaments cause skeletal muscle to contract 714

Actin–myosin interactions cause filaments to slide 715

Actin–myosin interactions are controlled by calcium ions 715

Cardiac muscle is similar to and different from skeletal muscle 718

Smooth muscle causes slow contractions of many internal organs 718

CONCEPT 36.2 The Characteristics of Muscle Cells Determine Muscle Performance 720

Single skeletal muscle fibers can generate graded contractions 720

Muscle fiber types determine endurance and strength 721

Muscle ATP supply limits performance 722

CONCEPT 36.3 Muscles Pull on Skeletal Elements to Generate Force and Cause Movement 723

A hydrostatic skeleton consists of fluid in a muscular cavity 723

Exoskeletons are rigid outer structures 723

Vertebrate endoskeletons consist of cartilage and bone 723

Bones develop from connective tissues 724

Bones that have a common joint can work as a lever 725

37 Gas Exchange in Animals 729**CONCEPT 37.1 Fick's Law of Diffusion Governs Respiratory Gas Exchange 730**

Diffusion is driven by concentration differences 730

Fick's law applies to all systems of gas exchange 730

Air is a better respiratory medium than water 730

O₂ availability is limited in many environments 731

CO₂ is easily lost by diffusion 732

CONCEPT 37.2 Respiratory Systems Have Evolved to Maximize Partial Pressure Gradients 732

Respiratory organs have large surface areas 732

Partial pressure gradients can be optimized in several ways 732

Insects have airways throughout their bodies 733

Fish gills use countercurrent flow to maximize gas exchange 733

Most terrestrial vertebrates use tidal ventilation 734

Birds have air sacs that supply a continuous unidirectional flow of fresh air 735

CONCEPT 37.3 The Mammalian Lung Is Ventilated by Pressure Changes 737

At rest, only a small portion of the lung's volume is exchanged 737

Lungs are ventilated by pressure changes in the thoracic cavity 738

CONCEPT 37.4 Respiration Is under Negative Feedback Control by the Nervous System 739

Respiratory rate is primarily regulated by CO₂ 739

CO₂ affects the medulla indirectly via pH changes 739

O₂ is also monitored 739

CONCEPT 37.5 Respiratory Gases Are Transported in the Blood 741

Hemoglobin combines reversibly with O₂ 741

Myoglobin holds an O₂ reserve 742

Various factors influence hemoglobin's affinity for O₂ 742

CO₂ is transported primarily as bicarbonate ions in the blood 743

38 Circulatory Systems 746**CONCEPT 38.1 Circulatory Systems Can Be Open or Closed 747**

Open circulatory systems move extracellular fluid 747

Closed circulatory systems circulate blood through a system of blood vessels 747

CONCEPT 38.2 Circulatory Systems May Have Separate Pulmonary and Systemic Circuits 748

Most fishes have a two-chambered heart and a single circuit 748

Lungfishes evolved a partially separate circuit that serves the lung 748

Amphibians and most reptiles have partially separated circuits 749

Crocodylians, birds, and mammals have fully separated pulmonary and systemic circuits 749

CONCEPT 38.3 A Beating Heart Propels the Blood 750

Blood flows from right heart to lungs to left heart to body 750

The heartbeat originates in the cardiac muscle 751

A conduction system coordinates the contraction of heart muscle 753

Electrical properties of ventricular muscles sustain heart contraction 754

The ECG records the electrical activity of the heart 754

CONCEPT 38.4 Blood Consists of Cells Suspended in Plasma 755

Red blood cells transport respiratory gases 755

Platelets are essential for blood clotting 756

CONCEPT 38.5 Blood Circulates through Arteries, Capillaries, and Veins 757

Arteries have elastic, muscular walls that help propel and direct the blood 757

Capillaries have thin, permeable walls that facilitate exchange of materials with interstitial fluid 758

Blood flow through veins is assisted by skeletal muscles 760

Lymphatic vessels return interstitial fluid to the blood 760

CONCEPT 38.6 Circulation is Regulated by Autoregulation, Nerves, and Hormones 761

Blood pressure is determined by heart rate, stroke volume, and peripheral resistance 761

Autoregulation matches local blood pressure and flow to local need 761

Sympathetic and parasympathetic nerves affect blood pressure 762

Many hormones affect blood pressure 762

39 Nutrition, Digestion, and Absorption 765

CONCEPT 39.1 Food Provides Energy and Nutrients 766

Food provides energy 766
 Excess energy is stored as glycogen and fat 766
 Food provides essential molecular building blocks 767
 Food provides essential minerals 767
 Food provides essential vitamins 768
 Nutrient deficiencies result in diseases 769

CONCEPT 39.2 Digestive Systems Break Down Macromolecules 770

Simple digestive systems are cavities with one opening 770
 Tubular guts have an opening at each end 771
 Heterotrophs may specialize in different types of food 772

CONCEPT 39.3 The Vertebrate Digestive System Is a Tubular Gut with Accessory Glands 773

The vertebrate gut consists of concentric tissue layers 773
 Digestion begins in the mouth 773
 The stomach breaks up food and begins protein digestion 774
 Muscle contractions mix the stomach's contents and push them into the small intestine 775

Ruminants have a specialized four-chamber stomach 775

The small intestine continues digestion and does most absorption 775

Absorbed nutrients go to the liver 778

The large intestine absorbs water and ions 778

CONCEPT 39.4 Food Intake and Metabolism Are Regulated 778

Neuronal reflexes control many digestive functions 778

Hormones regulate many digestive functions 778

Insulin and glucagon regulate blood glucose 779

The liver directs the traffic of the molecules that fuel metabolism 780

Many hormones affect food intake 780

40 Salt and Water Balance and Nitrogen Excretion 784

CONCEPT 40.1 Excretory Systems Maintain Homeostasis of the Extracellular Fluid 785

Excretory systems maintain osmotic equilibrium 785

Animals can be osmoconformers or osmoregulators 785

Animals can be ionic conformers or ionic regulators 785

CONCEPT 40.2 Excretory Systems Eliminate Nitrogenous Wastes 787

Animals excrete nitrogen in a number of forms 787

Most species produce more than one nitrogenous waste 787

CONCEPT 40.3 Excretory Systems Produce Urine by Filtration, Reabsorption, and Secretion 788

The metanephridia of annelids process coelomic fluid 788

The Malpighian tubules of insects depend on active transport 788

The vertebrate kidney is adapted for excretion of excess water 789

Mechanisms to conserve water have evolved in several groups of vertebrates 790

CONCEPT 40.4 The Mammalian Kidney Produces Concentrated Urine 791

A mammalian kidney has a cortex and a medulla 791

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule 793

The loops of Henle create a concentration gradient in the renal medulla 793

The distal convoluted tubule fine-tunes the composition of the urine 794

Urine is concentrated in the collecting duct 794

Kidney failure is treated with dialysis 794

CONCEPT 40.5 The Kidney Is Regulated to Maintain Blood Pressure, Blood Volume, and Blood Composition 795

The renin-angiotensin-aldosterone system raises blood pressure 795

ADH decreases excretion of water 795

The heart produces a hormone that helps lower blood pressure 796

41 Animal Behavior 799

CONCEPT 41.1 Behavior Has Proximate and Ultimate Causes 800

Biologists ask four questions about a behavior 800

Questions about proximate causes lead to mechanistic approaches 800

Questions about ultimate causes lead to ecological/evolutionary approaches 801

CONCEPT 41.2 Behaviors Can Have Genetic Determinants 801

Breeding experiments can reveal genetic determinants of a behavior 801
 Studies of mutants can reveal the roles of specific genes 802
 Gene knockouts can reveal the roles of specific genes 802

CONCEPT 41.3 Developmental Processes Shape Behavior 804

Hormones can determine behavioral potential and timing 804

Some behaviors can be acquired only at certain times 805

Bird song learning involves genetics, imprinting, and hormonal timing 805
 The timing and expression of bird song are under hormonal control 806

CONCEPT 41.4 Physiological Mechanisms Underlie Behavior 806

Biological rhythms coordinate behavior with environmental cycles 806
 Animals must find their way around their environment 808
 Animals use multiple modalities to communicate 810

CONCEPT 41.5 Individual Behavior Is Shaped by Natural Selection 812

Animals must make choices 812
 Behaviors have costs and benefits 812

CONCEPT 41.6 Social Behavior and Social Systems Are Shaped by Natural Selection 814

Mating systems maximize the fitness of both partners 814
 Fitness can be enhanced through the reproductive success of related individuals 815
 Eusociality is the extreme result of kin selection 816
 Group living has benefits and costs 817

PART

Ecology

42 **Organisms in Their Environment 822**

CONCEPT 42.1 Ecological Systems Vary in Space and over Time 823

Ecological systems comprise organisms plus their external environment 823
 Ecological systems can be small or large 823
 Each ecological system at each time is potentially unique 825

CONCEPT 42.2 Climate and Topography Shape Earth's Physical Environments 825

Latitudinal gradients in solar energy input drive climate patterns 825
 Solar energy drives global air circulation patterns 827
 The spatial arrangement of continents and oceans influences climate 828
 Walter climate diagrams summarize climate in an ecologically relevant way 829

Topography produces additional environmental heterogeneity 830

CONCEPT 42.3 Physical Geography Provides the Template for Biogeography 830

Similarities in terrestrial vegetation led to the biome concept 830
 The biome concept can be extended to aquatic environments 832

CONCEPT 42.4 Geological History Has Shaped the Distributions of Organisms 834

Barriers to dispersal affect the distributions of species 834
 The movement of continents accounts for biogeographic regions 834
 Phylogenetic methods contribute to our understanding of biogeography 837

CONCEPT 42.5 Human Activities Affect Ecological Systems on a Global Scale 838

Human-dominated ecosystems are more uniform than the natural ones they replace 838
 Human activities are simplifying remaining natural ecosystems 838
 Human-assisted dispersal of species blurs biogeographic boundaries 839

CONCEPT 42.6 Ecological Investigation Depends on Natural History Knowledge and Modeling 839

Models are often needed to deduce testable predictions with complex systems 839

43 **Populations 842**

CONCEPT 43.1 Populations Are Patchy in Space and Dynamic over Time 843

Population density and population size are two measures of abundance 843
 Abundance varies in space and over time 843

CONCEPT 43.2 Births Increase and Deaths Decrease Population Size 844

CONCEPT 43.3 Life Histories Determine Population Growth Rates 845

Life histories are quantitative descriptions of life cycles 846
 Life histories are diverse 846
 Resources and physical conditions shape life histories 847
 Species' distributions reflect the effects of environment on per capita growth rates 848

CONCEPT 43.4 Populations Grow Multiplicatively, but Not for Long 850

Multiplicative growth generates large numbers very quickly 850
 Multiplicatively growing populations have a constant doubling time 851
 Density dependence prevents populations from growing indefinitely 851
 Variable environmental conditions cause the carrying capacity to change 852
 Technology has increased Earth's carrying capacity for humans 853

CONCEPT 43.5 Extinction and Recolonization Affect Population Dynamics 854**CONCEPT 43.6 Ecology Provides Tools for Managing Populations 855**

Knowledge of life histories helps us to manage populations 855
 Knowledge of metapopulation dynamics helps us conserve species 856

44 Ecological and Evolutionary Consequences of Species Interactions 859

CONCEPT 44.1 Interactions between Species May Be Positive, Negative, or Neutral 860

Interspecific interactions are classified by their effect on per capita growth rates 860
 Many interactions have both positive and negative aspects 861

CONCEPT 44.2 Interspecific Interactions Affect Population Dynamics and Species Distributions 862

Interspecific interactions can modify per capita growth rates 863

Interspecific interactions can lead to extinction 863

Interspecific interactions can affect the distributions of species 864

Rarity advantage promotes species coexistence 864

CONCEPT 44.3 Interactions Affect Individual Fitness and Can Result in Evolution 865

Intraspecific competition can increase carrying capacity 865

Interspecific competition can lead to resource partitioning and coexistence 866

Consumer–resource interactions can lead to an evolutionary arms race 866

Mutualisms can involve exploitation and cheating 868

CONCEPT 44.4 Introduced Species Alter Interspecific Interactions 869

Introduced species can become invasive 869

Introduced species alter ecological relationships of native species 870

45 Ecological Communities 873

CONCEPT 45.1 Communities Contain Species That Colonize and Persist 874**CONCEPT 45.2 Communities Change over Space and Time 875**

Species composition varies along environmental gradients 875

Several processes cause communities to change over time 875

CONCEPT 45.3 Trophic Interactions Determine How Energy and Materials Move through Communities 877

Consumer–resource interactions determine an important property of communities 877

Energy is lost as it moves through a food web 878

Trophic interactions can change the species composition of communities 879

CONCEPT 45.4 Species Diversity Affects Community Function 881

The number of species and their relative abundances contribute to species diversity 881

Species diversity affects community processes and outputs 881

CONCEPT 45.5 Diversity Patterns Provide Clues to Determinants of Diversity 882

Species richness varies with latitude 882

Diversity represents a balance between colonization and extinction 883

CONCEPT 45.6 Community Ecology Suggests Strategies for Conserving Community Function 885

Ecological communities provide humans with goods and services 885

Ecosystem services have economic value 887

Island biogeography suggests strategies for maintaining community diversity 887

Trophic cascades suggest the importance of conserving critical components of food webs 888

The relationship of diversity to community function suggests strategies for restoring degraded habitats 888

46 The Global Ecosystem 892

CONCEPT 46.1 Climate and Nutrients Affect Ecosystem Function 893

NPP is a measure of ecosystem function 893

NPP varies predictably with climate and nutrients 893

CONCEPT 46.2 Biological, Geological, and Chemical Processes Move Materials through Ecosystems 896

The form and location of elements determine their accessibility to organisms 896

Fluxes of matter are driven by biogeochemical processes 896

CONCEPT 46.3 Certain Biogeochemical Cycles Are Especially Critical for Ecosystems 897

Water transports materials among compartments 897

Nitrogen is often a limiting nutrient 898

Carbon flux is linked to energy flow through ecosystems 900

Biogeochemical cycles interact 901

**CONCEPT 46.4 Biogeochemical Cycles
Affect Global Climate 902**

Earth's surface is warm because of the atmosphere 902

Recent increases in greenhouse gases are warming Earth's surface 903

Human activities are contributing to changes in Earth's radiation balance 903

**CONCEPT 46.5 Rapid Climate Change
Affects Species and Communities 904**

Rapid climate change can leave species behind 905

Changes in seasonal timing can disrupt interspecific interactions 906

Climate change can alter community composition by several mechanisms 906

Extreme climate events also have an impact 907

**CONCEPT 46.6 Ecological Challenges
Can Be Addressed through Science and
International Cooperation 907**

Principles of Life

1

When you take a walk through the woods and fields or a park near your home, what do you see? If you are like most people, you probably notice the trees, colorful flowers, and some animals. You probably spend little time, however, thinking about how these living things function, reproduce, interact with one another, or affect their environment. An introduction to biology should inspire you to ask questions about what life is, how living systems work, and how the living world came to be as we observe it today.

Biologists have amassed a huge amount of information about the living world, and some introductory biology classes focus on memorizing these details. This book takes a different approach, focusing on the major principles of life that underlie everything in biology.

What do we mean by *principles of life*? Consider the photograph. Why is the view so overwhelmingly green? The color is explained by a fundamental principle of life, namely that all living organisms require energy in order to grow, move, reproduce, and maintain their bodies. Ultimately, most of that energy comes from the sun. The green leaves of plants contain chlorophyll, a pigment that captures energy from the sun and uses it to transform water and carbon dioxide into sugar and oxygen (a process called photosynthesis). That sugar can then be broken down again by the plant, or by other organisms that eat the plant, to provide energy. The frog in the photograph is using energy to grasp the trunk of the tree. That energy came from molecules in the bodies of insects eaten by the frog. The insects, in turn, built up their bodies by ingesting tissues of plant leaves, which grew by capturing the sun's energy through photosynthesis. The frog, like the plants, is ultimately solar-powered.

The photograph illustrates other principles of biology. You probably noticed

the frog and the trees in the photograph above, but did you notice the patches of growth on the trunk of the tree? Most of those are lichens, a complex interaction between a fungus and a photosynthetic organism (in this case, a species of algae). Living organisms often survive and thrive by interacting with one another in complex ways. In lichen, the fungus and the alga live in an obligate symbiosis, meaning that they depend on each other for survival. Many other organisms in this scene are too small to be seen, but they are critical components for keeping this living system functioning over time.

After reading this book, you should understand the main principles of life. You'll be able to describe how organisms capture and transform energy; pass genetic information to their offspring in reproduction; grow, develop, and behave; and interact with other organisms and with their physical environment. You'll also learn how this system of life on Earth evolved, and how it continues to change. May a walk in the park never be the same for you again!

What principles of life are illustrated in this scene?

KEY CONCEPTS

- 1.1 Living Organisms Share Common Aspects of Structure, Function, and Energy Flow
- 1.2 Genetic Systems Control the Flow, Exchange, Storage, and Use of Information
- 1.3 Organisms Interact with and Affect Their Environments
- 1.4 Evolution Explains Both the Unity and Diversity of Life
- 1.5 Science Is Based on Quantifiable Observations and Experiments

concept
1.1

Living Organisms Share Common Aspects of Structure, Function, and Energy Flow

Biology is the scientific study of living things. Most biologists define “living things” as all the diverse organisms descended from a single-celled ancestor that evolved on Earth almost 4 billion years ago. We can imagine other origins, perhaps on other planets, of self-replicating systems that have properties similar to life as we know it. But the evidence suggests that all of life on Earth today has a single origin—a single *common ancestor*—and we consider all the organisms that descended from that common ancestor to be a part of life.

Life as we know it had a single origin

The overwhelming evidence for the common ancestry of life lies in the many distinctive characteristics that are shared by all living organisms. All organisms:

- are composed of a common set of chemical components such as nucleic acids and amino acids, and similar structures such as cells enclosed within plasma membranes
- contain genetic information that uses a nearly universal code to specify the assembly of proteins
- convert molecules obtained from their environment into new biological molecules
- extract energy from the environment and use it to do biological work
- regulate their internal environment
- replicate their genetic information in the same manner when reproducing themselves
- share sequence similarities among a fundamental set of genes
- evolve through gradual changes in their genetic information

If life had multiple origins, there would be little reason to expect similarities across gene sequences, or a nearly universal genetic code, or a common set of amino acids. If we were to discover an independent origin of a similar self-replicating system (i.e., life) on another planet, we would expect it to be fundamentally different in these aspects. Organisms from another origin of life might be similar in some ways to life on Earth, such as using genetic information to reproduce. But we would not expect the details of their genetic code or the fundamental sequences of their genomes to be like ours.

The simple list of characteristics above, however, is an inadequate description of the incredible complexity and diversity of life. Some forms of life may not even display all of these characteristics all of the time. For example, the seed of a desert plant may go for many years without extracting energy from the environment, converting molecules, regulating its internal environment, or reproducing; yet the seed is alive.

And what about viruses? Viruses do not consist of cells, and they cannot carry out the functions of life enumerated in the list above on their own; they must parasitize host cells to do those jobs for them. Yet viruses contain genetic information and use the same basic genetic code and amino acids as do other living things, and they certainly mutate and evolve. The existence of viruses depends on cells, and there is strong evidence that viruses evolved from cellular life forms. So, although viruses are not independent cellular organisms, they are a part of life and are studied by biologists.

This book explores the characteristics of life, how these characteristics evolved and how they vary among organisms, and how they work together to enable organisms to survive and reproduce.

Life arose from non-life via chemical evolution

Geologists estimate that Earth formed between 4.6 and 4.5 billion years ago. At first, the planet was not a very hospitable place. It was some 600 million years or more before the earliest life evolved. If we picture the history of Earth as a 30-day month, life first appeared somewhere toward the end of the first week (FIGURE 1.1).

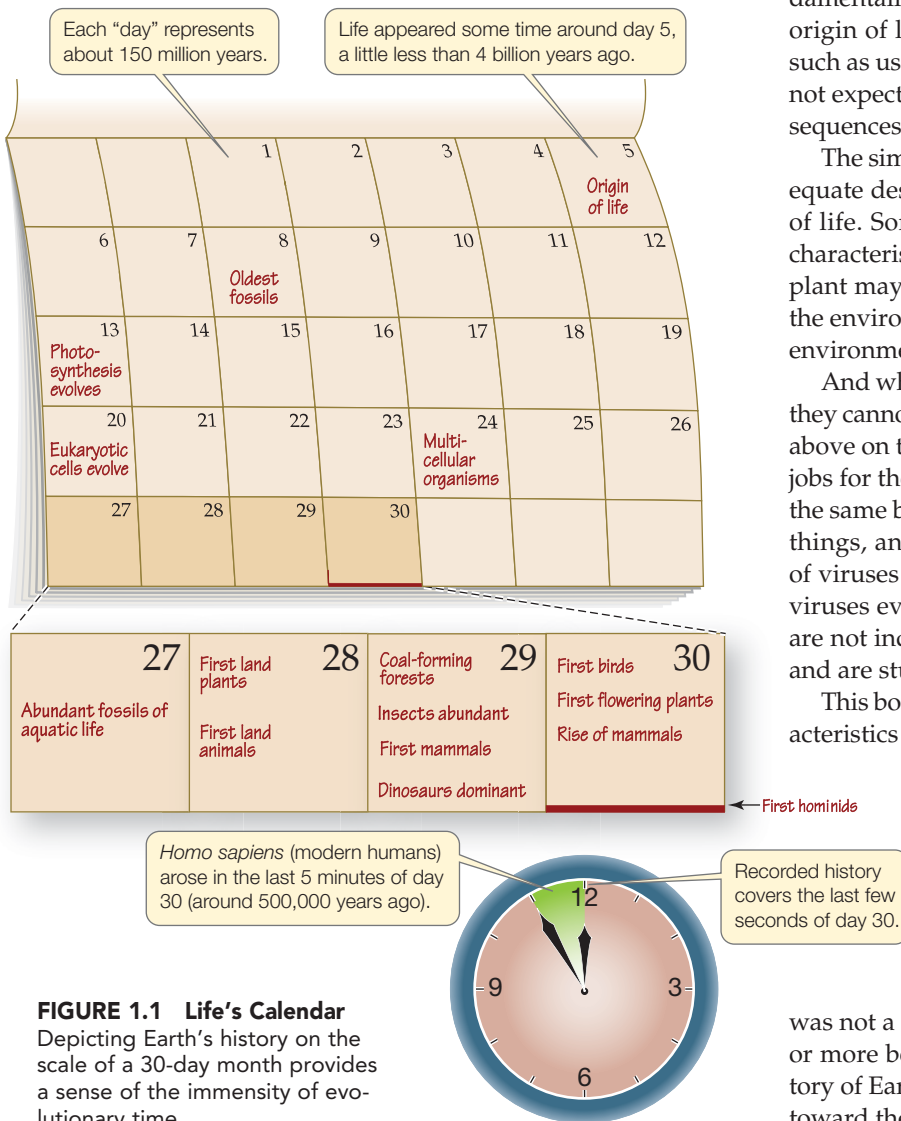

FIGURE 1.1 Life’s Calendar
 Depicting Earth’s history on the scale of a 30-day month provides a sense of the immensity of evolutionary time.

When we consider how life might have arisen from nonliving matter, we must take into account the properties of the young Earth's atmosphere, oceans, and climate, all of which were very different than they are today. Biologists postulate that complex biological molecules first arose through the random physical association of chemicals in that environment. Experiments simulating the conditions on early Earth have confirmed that the generation of complex molecules under such conditions is possible, even probable. The critical step for the evolution of life, however, was the appearance of *nucleic acids*—molecules that could reproduce themselves and also serve as templates for the synthesis of large molecules with complex but stable shapes. The variation in the shapes of these large, stable molecules—*proteins*—enabled them to participate in increasing numbers and kinds of chemical reactions with other molecules.

Cellular structure evolved in the common ancestor of life

The next step in the origin of life was the enclosure of complex proteins and other biological molecules by *membranes* that contained them in a compact internal environment separate from the surrounding external environment. Molecules called *fatty acids* played a critical role because these molecules do not dissolve in water; rather, they form membranous films. When agitated, these films can form spherical *vesicles*, which could have enveloped assemblages of biological molecules. The creation of an internal environment that concentrated the reactants and products of chemical reactions opened up the possibility that those reactions could be integrated and controlled within a tiny *cell*. Scientists postulate that this natural process of membrane formation resulted in the first cells with the ability to reproduce—the evolution of the first cellular organisms.

For more than 2 billion years after cells originated, every organism consisted of only one cell. These first unicellular organisms were (and are, as multitudes of their descendants exist in similar form today) **prokaryotes**. Prokaryotic cells consist of

genetic material and other biochemicals enclosed in a membrane (**FIGURE 1.2**). Early prokaryotes were confined to the oceans, where there was an abundance of complex molecules they could use as raw materials and sources of energy. The ocean shielded them from the damaging effects of ultraviolet (UV) light, which was intense at that time because there was little or no oxygen (O_2) in the atmosphere, and hence no protective ozone (O_3) layer in the upper atmosphere.

Photosynthesis allowed living organisms to capture energy from the sun

To fuel their cellular metabolism, the earliest prokaryotes took in molecules directly from their environment and broke these small molecules down to release and use the energy contained in their chemical bonds. Many modern species of prokaryotes still function this way, and very successfully.

About 2.7 billion years ago, the emergence of **photosynthesis** changed the nature of life on Earth. The chemical reactions of photosynthesis transform the energy of sunlight into a form of biological energy that can power the synthesis of large molecules. These large molecules are the building blocks of cells, and they can be broken down to provide metabolic energy. Photosynthesis is the basis of much of life on Earth today because its energy-capturing processes provide food for other organisms. Early photosynthetic cells were probably similar to present-day prokaryotes called *cyanobacteria* (**FIGURE 1.3**). Over time, photosynthetic prokaryotes became so abundant that vast quantities of O_2 , which is a by-product of photosynthesis, slowly began to accumulate in the atmosphere.

During the early eons of life on Earth, there was no O_2 in the atmosphere. In fact, O_2 was poisonous to many of the prokaryotes that lived at that time. Those organisms that did tolerate O_2 , however, were able to proliferate, and the presence of O_2 opened up vast new avenues of evolution. *Aerobic metabolism* (energy production using O_2) is more efficient than *anaerobic* (non- O_2 -using) *metabolism*, and it allowed organisms to grow larger. Aerobic metabolism is used by the majority of living organisms today.

Oxygen in the atmosphere also made it possible for life to move onto land. For most of life's history, UV radiation falling on Earth's surface was so intense that it destroyed any living cell that was not well shielded by water. But the accumulation of photosynthetically generated O_2 in the atmosphere for more than 2 billion years gradually produced a layer of ozone in the upper atmosphere. By about 500 million years ago, the ozone layer was sufficiently dense and absorbed enough of the sun's UV radiation to make it possible for organisms to leave the protection of the water and live on land.

FIGURE 1.2 The Basic Unit of Life is the Cell The concentration of reactions within the enclosing membrane of a cell allowed the evolution of integrated organisms. Today all organisms, even the largest and most complex, are made up of cells. Unicellular organisms such as this one, however, remain the most abundant living organisms (in absolute numbers) on Earth.

FIGURE 1.3 Photosynthetic Organisms Changed Earth's Atmosphere Cyanobacteria were the first photosynthetic organisms on Earth. (A) Colonies of cyanobacteria called stromatolites are known from the ancient fossil record. (B) Living stromatolites are still found in appropriate environments on Earth today.

Eukaryotic cells evolved from prokaryotes

Another important step in the history of life was the evolution of cells with membrane-enclosed compartments called **organelles**, within which specialized cellular functions could be performed away from the rest of the cell. The first organelles probably appeared about 2.5 billion years after the appearance of life on Earth (about day 20 on Figure 1.1). One of these organelles, the *nucleus*, came to contain the cell's genetic information. The nucleus (Latin *nux*, “nut” or “core”) gives these cells their name: **eukaryotes** (Greek *eu*, “true”; *karyon*, “kernel” or “core”). The eukaryotic cell is completely distinct from the cells of prokaryotes (*pro*, “before”), which lack nuclei and other internal compartments.

Some organelles are hypothesized to have originated by **endosymbiosis** (“living inside another”) when larger cells ingested smaller ones. The *mitochondria* that generate a cell's energy probably evolved from engulfed prokaryotic organisms. And *chloroplasts*—the organelles specialized to conduct

photosynthesis—could have originated when photosynthetic prokaryotes were ingested by larger eukaryotes. If the larger cell failed to break down this intended food object, a partnership could have evolved in which the ingested prokaryote provided the products of photosynthesis and the host cell provided a good environment for its smaller partner.

Multicellularity allowed specialization of tissues and functions

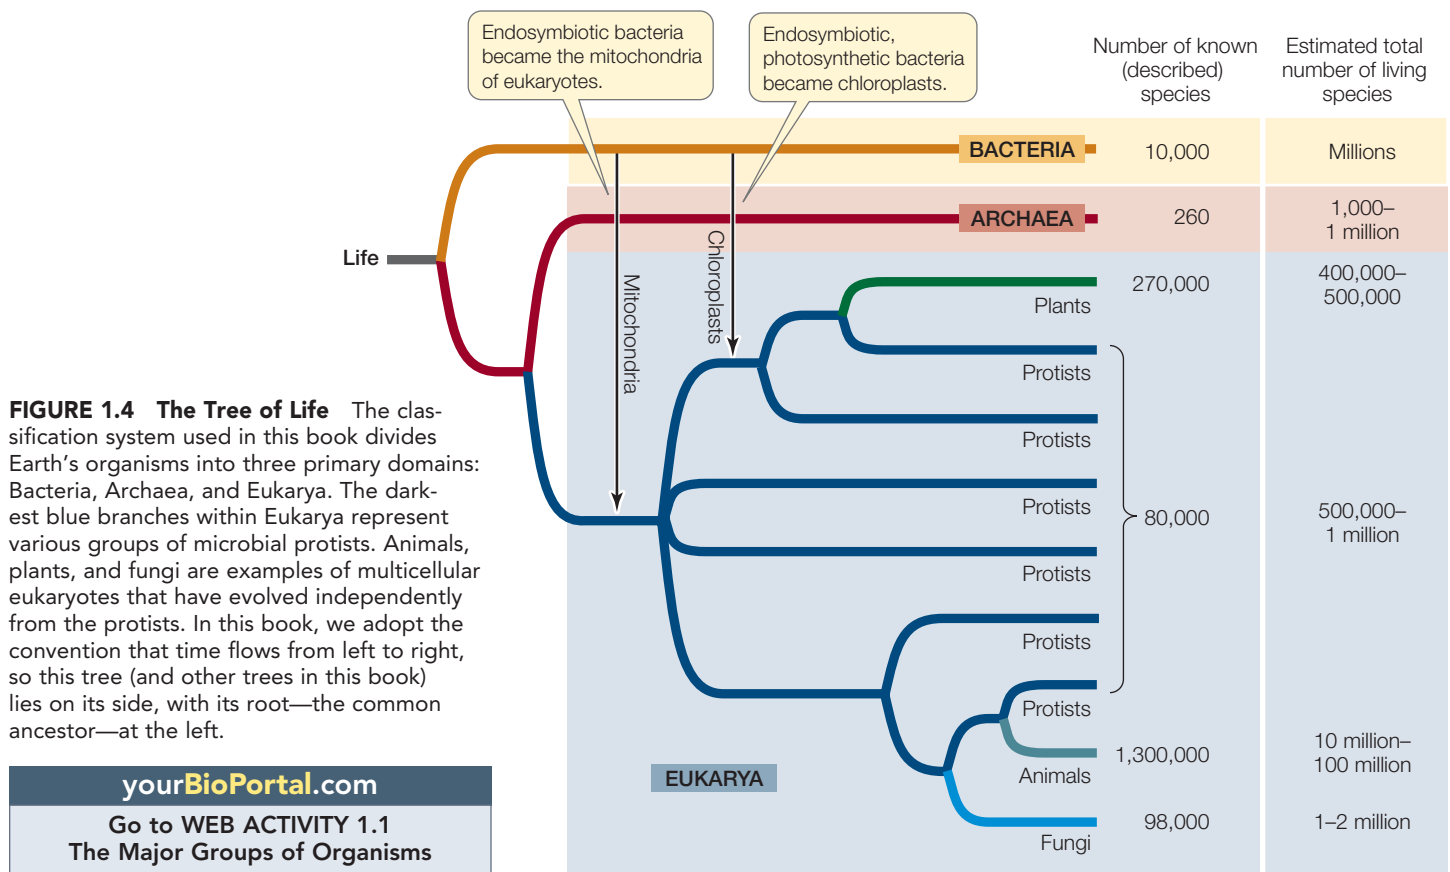

For the first few billion years of life, all the organisms that existed—whether prokaryotic or eukaryotic—were unicellular. At some point, the cells of some eukaryotes failed to separate after cell division, remaining attached to each other. Such permanent colonial aggregations of cells made it possible for some of the associated cells to specialize in certain functions, such as reproduction, while other cells specialized in other functions, such as absorbing nutrients. **Cellular specialization** enabled multicellular eukaryotes to increase in size and become more efficient at gathering resources and adapting to specific environments.

Biologists can trace the evolutionary tree of life

If all the organisms on Earth today are the descendants of a single kind of unicellular organism that lived almost 4 billion years ago, how have they become so different? Organisms reproduce by replicating their genomes, as we will discuss shortly. This replication process is not perfect, however, and changes, called **mutations**, are introduced almost every time a genome is replicated. Some mutations give rise to structural and functional changes in organisms. As individuals mate with one another, these changes can spread within a population, but the population will remain one species. However, if something happens to isolate some members of a population from the others, structural and functional differences between the two groups will accumulate over time. The two groups may diverge to the point where their members can no longer reproduce with each other; thus the two populations become distinct species.

Tens of millions of species exist on Earth today. Many times that number lived in the past but are now extinct. Biologists give each of these species a distinctive scientific name formed from two Latinized words—a **binomial**. The first name identifies the species' *genus*—a group of species that share a recent common ancestor. The second is the name of the species. For example, the scientific name for the human species is *Homo sapiens*: *Homo* is our genus and *sapiens* our species. *Homo* is Latin for “man”; *sapiens* is from the Latin word for “wise” or “rational.” Our closest relatives in the genus *Homo* (the Neanderthals) are now extinct and are known only from fossil remains.

Much of biology is based on comparisons among species, and these comparisons are useful precisely because we can place species in an evolutionary context relative to one another. Our ability to do this has been greatly enhanced in recent decades by our ability to sequence and compare the genomes

of different species. Genome sequencing and other molecular techniques have allowed biologists to augment evolutionary knowledge based on the fossil record with a vast array of molecular evidence. The result is the ongoing compilation of *phylogenetic trees* that document and diagram evolutionary relationships as part of an overarching tree of life, the broadest categories of which are shown in **FIGURE 1.4**. (The tree is expanded in Appendix A; you can also explore the tree interactively at <http://tolweb.org/tree>.)

Although many details remain to be clarified, the broad outlines of the tree of life have been determined. Its branching patterns are based on a rich array of evidence from fossils, structures, metabolic processes, behavior, and molecular analyses of genomes. Molecular data in particular have been used to separate the tree into three major **domains**: Archaea, Bacteria, and Eukarya. The organisms of each domain have been evolving separately from those in the other domains for more than a billion years.

Organisms in the domains **Archaea** and **Bacteria** are single-celled prokaryotes. However, members of these two groups differ so fundamentally in their metabolic processes that they are believed to have separated into distinct evolutionary lineages very early. Species belonging to the third domain—**Eukarya**—have eukaryotic cells whose mitochondria and chloroplasts originated from endosymbioses of bacteria.

Plants, fungi, and animals are examples of familiar multicellular eukaryotes that evolved from different groups of

unicellular eukaryotes, informally known as *protists*. We know that these three groups (as well as others) had independent origins of multicellularity because they are each most closely related to different groups of unicellular protists, as can be seen from the branching pattern of Figure 1.4.

Discoveries in biology can be generalized

Because all life is related by descent from a common ancestor, shares a genetic code, and consists of similar molecular building blocks, knowledge gained from investigations of one type of organism can, with care, be generalized to other organisms. Biologists use **model systems** for research, knowing they can extend their findings to other organisms, including humans. Our basic understanding of the chemical reactions in cells came from research on bacteria but is applicable to all cells, including those of humans. Similarly, the biochemistry of photosynthesis—the process by which plants use sunlight to produce sugars—was largely worked out from experiments on *Chlorella*, a unicellular green alga. Much of what we know about the genes that control plant development is the result of work on *Arabidopsis thaliana*, a relative of the mustard plant. Knowledge about how animals develop has come from work on sea urchins, frogs, chickens, roundworms, and fruit flies. And recently, the discovery of a major gene controlling human skin color came from work on zebrafish. Being able to generalize from model systems is a powerful tool in biology.

1.2

Genetic Systems Control the Flow, Exchange, Storage, and Use of Information

The information required for an organism to function and interact with other organisms—the “blueprint” for existence—is contained in the organism’s **genome**, the sum total of all the information encoded by its genes. The study of genetic information and how organisms are able to “decode” and use it to build the proteins that underlie a body’s structure and function is another fundamental principle that we discuss and expand upon throughout the book.

Genomes encode the proteins that govern an organism’s structure

Early in the chapter we mentioned the importance of self-replicating nucleic acids in the origin of life. Nucleic acid molecules contain long sequences of four subunits called **nucleotides**. The sequence of these nucleotides in **deoxyribonucleic acid**, or **DNA**, allows the organism to make proteins. Each gene is a specific segment of DNA whose sequence carries the information for building or controlling the expression of one or more **proteins** (FIGURE 1.5). Protein molecules govern the chemical reactions within cells and form much of an organism’s structure.

By analogy with a book, the nucleotides of DNA are like the letters of an alphabet. The sentences of the book are genes that describe proteins, or provide instructions for making the proteins at a particular time or place. If you were to write out your own genome using four letters to represent the four DNA nucleotides, you would write more than 3 billion letters. Using the size type you are reading now, your genome would fill more than a thousand books the size of this one.

All the cells of a given multicellular organism contain the same genome, yet the different cells have different functions and form different proteins—hemoglobin forms in red blood cells, gut cells produce digestive proteins, and so on. Therefore, different types of cells in an organism must express different parts of the genome. How any given cell controls which genes it expresses (and which genes it suppresses) is a major focus of current biological research.

FIGURE 1.5 DNA Is Life’s Blueprint The instructions for life are contained in the sequences of nucleotides in DNA molecules. Specific DNA nucleotide sequences comprise genes. The average length of a single human gene is 27,000 nucleotides. The information in each gene provides the cell with the information it needs to manufacture molecules of a specific protein.

The genome of an organism contains thousands of genes. If mutations alter the nucleotide sequence of a gene, the protein that the gene encodes is often altered as well. Mutations may occur spontaneously, as happens when mistakes occur during replication of DNA. Mutations can also be caused by certain chemicals (such as those in cigarette smoke) and radiation

(including UV radiation from the sun). Most mutations are either harmful or have no effect, but occasionally a mutation improves the functioning of the organism under the environmental conditions the individual encounters. Mutations are the raw material of evolution.

Genomes provide insights into all aspects of an organism's biology

The first complete DNA sequence of an organism's genome was determined in 1976. This first sequence was that of a virus, and viral genomes are very small compared with those of most cellular organisms. It was another two decades before the first bacterial genome was sequenced, in 1995. The first animal genome (a relatively small one, that of a roundworm) was determined in late 1998. A massive effort to sequence the complete human genome began in 1990 and culminated 13 years later. Since then, the methods developed in these pioneering projects (as well as new DNA sequencing technologies that appear each year) have resulted in the sequencing of genomes from hundreds of species. As methods have improved, the cost and time for sequencing a complete genome have dropped dramatically. Many biologists expect the routine sequencing of genomes from individual organisms to be commonplace in biological applications of the near future.

What are we learning from genome sequencing? One surprise came when some genomes turned out to contain many fewer genes than expected—for example, there are only about 24,000 different genes that encode proteins in a human genome, whereas most biologists had expected many times more. Gene sequence information is a boon for many areas of biology, making it possible to study the genetic basis of everything from physical structure to the basis of inherited diseases. Biologists can also compare genomes from many species to learn how and why one species differs from another. Such studies allow biologists to trace the evolution of genes through time and to document how particular changes in gene sequence result in changes in structure and function.

The vast amount of information being collected from genome studies has led to rapid development of the field of *bioinformatics*, or the study of biological information. In this emerging field, biologists and computer scientists work in close association to develop new computational tools to organize, process, and study comparative genomic databases.

concept 1.3 Organisms Interact with and Affect Their Environments

Another pervasive theme of biology relates to the concepts of *hierarchy* and *integration* of biological systems. Biological systems are organized in a hierarchy from basic building blocks to complete functioning ecosystems of living and nonliving components (FIGURE 1.6). Traditionally, each biologist concentrated on understanding a particular level of this hierarchy. Today, however, much of biology involves integrating investigations across many of the hierarchical levels.

yourBioPortal.com

Go to WEB ACTIVITY 1.2
The Hierarchy of Life

Organisms use nutrients to supply energy and to build new structures

Living organisms acquire *nutrients* from their environments. Life depends on thousands of biochemical reactions that occur inside cells, and nutrients supply the organism with the energy and

FIGURE 1.6 Biology Is Studied at Many Levels of Organization

(A) Life's properties emerge when DNA and other molecules are organized in cells, which form building blocks for organisms. (B) Organisms exist in populations and interact with other populations to form communities, which interact with the physical environment to make up ecosystems.

(B) Organisms to ecosystems

raw materials to carry out these chemical transformations. Some of the reactions break down nutrient molecules into smaller chemical units, and in the process some of the energy contained in the chemical bonds of the nutrients is captured by molecules that can be used to do different kinds of cellular work.

The most basic cellular work is the building, or *synthesis*, of new complex molecules and structures from smaller chemical units. For example, we are all familiar with the fact that carbohydrates eaten today may be deposited in the body as fat tomorrow. Another kind of work that cells do is mechanical—moving molecules from one cellular location to another, moving whole cells or tissues, or even moving the organism itself, as the proteins in muscle cells do. Still another kind of work is the electrical work that is the essence of information processing in nervous systems, such as vision (recall that you are using captured solar energy to read this book).

The sum total of all the chemical transformations and other work done in all the cells of an organism is called **metabolism**. The many biochemical reactions constantly taking place in cells are integrally linked in that the products of one are the raw materials of the next. Let's consider how these networks of reactions are integrated and controlled.

Organisms regulate their internal environment

The cells of multicellular organisms are specialized, or *differentiated*, to contribute in some way to maintaining the internal environment. With the evolution of specialization, differentiated cells lost many of the functions carried out by single-celled organisms. To accomplish their specialized tasks, assemblages of differentiated cells are organized into *tissues*. For example, a single muscle cell cannot generate much force, but when many cells combine to form the tissue of a working muscle, considerable force and movement can be generated. Different tissue types are organized to form *organs* that accomplish specific functions. The heart, brain, and stomach are each constructed of several types of tissues, as are the roots, stems, and leaves of plants. Organs whose functions are interrelated can be grouped into *organ systems*; the stomach, intestine, and esophagus are parts of the digestive system. The functions of cells, tissues, organs, and organ systems are all integral to the multicellular organism.

The specialized organ systems of multicellular organisms exist in an *internal environment* that is *acellular* (i.e., not made up of cells). The individual cells of a body are surrounded by an extracellular environment of fluids, from which the cells receive nutrients and into which they excrete waste products of metabolism. The maintenance of a narrow range of conditions in this internal environment is known as **homeostasis**. A relatively stable internal (but extracellular) environment means that cells can function efficiently even when conditions outside the organism's body become unfavorable for cellular processes. The organism's *regulatory systems* obtain information from *sensors*, process and integrate this information, and issue instructions to components of physiological systems that produce changes in the organism's internal environment.

Physiological regulatory systems are especially well developed in animals, but they exist in other organisms as well. For

example, when conditions are hot and dry, plants can close the small pores (called *stomata*) on the surfaces of their leaves, thereby reducing moisture loss. When external conditions become favorable again, the plants open their stomata, allowing carbon dioxide—which is necessary for photosynthesis—to enter the leaf. This regulatory system is a simple example of a *feedback loop*: cells in the root of the plant (the sensors) release a chemical when they become dehydrated, and this chemical causes the cells around the stomata to shrink, thereby closing the pores. If external conditions improve and the cells in the root become hydrated again, the sensor cells stop releasing the chemical and the stomata open.

The concept of homeostasis extends beyond the regulation of the internal, acellular environment of multicellular organisms. Individual cells (in both unicellular and multicellular organisms) also regulate their internal environment through the actions of a *plasma membrane*, which forms the outer surface of the cell. Thus self-regulation of a more or less constant internal environment is a general attribute of living organisms.

Organisms interact with one another

Organisms do not live in isolation, and the internal hierarchy of the individual organism is matched by the external hierarchy of the biological world (see Figure 1.6). A group of individuals of the same species that interact with one another is a *population*, and populations of all the species that live and interact in the same area are called a *community*. Communities together with their abiotic (nonliving) environment constitute an *ecosystem*.

Individuals in a population interact in many different ways. Animals eat plants and other animals (usually members of another species) and compete with other species for food and other resources. Some animals will prevent other individuals of their own species from exploiting a resource, be it food, nesting sites, or mates. Animals may also *cooperate* with members of their species, forming social units such as a termite colony or a flock of birds. Such interactions have resulted in the evolution of social behaviors such as communication and courtship displays.

Plants also interact with their external environment, which includes other plants, fungi, animals, and microorganisms. All terrestrial plants depend on partnerships with fungi, bacteria, and animals. Some of these partnerships are necessary to obtain nutrients, some to produce fertile seeds, and still others to disperse seeds. Plants compete with each other for light and water, and they have ongoing evolutionary interactions with the animals that eat them. Through time, many adaptations have evolved in plants that protect them from predation (such as thorns) or that help then attract the animals that assist in their reproduction (such as sweet nectar or colorful flowers). The interactions of populations of plant and animal species in a community are major evolutionary forces that produce specialized adaptations.

Communities interacting over a broad geographic area with distinguishing physical features form ecosystems; examples might include the Arctic tundra, a coral reef, or a tropical rainforest. The ways in which species interact with one another and with their environment in communities and in ecosystems is the subject of *ecology*.

concept 1.4 Evolution Explains Both the Unity and Diversity of Life

Evolution—change in the genetic makeup of biological populations through time—is a major unifying principle of biology. A common set of evolutionary mechanisms applies to populations of all organisms. The constant change that occurs among these populations gives rise to all the diversity we see in life. These two themes—unity and diversity—provide a framework for organizing and thinking about biological systems. The similarities of life allow us to make comparisons and predictions from one species to another, and the differences are what make biology such a rich and exciting field for investigation and discovery.

Natural selection is an important mechanism of evolution

Charles Darwin compiled factual evidence for evolution in his 1859 book *On the Origin of Species*. Since then, biologists have gathered massive amounts of data supporting Darwin's idea that all living organisms are descended from a common ancestor. Darwin also proposed one of the most important processes that produce evolutionary change. He argued that differential survival and reproduction among individuals in a population, which he termed **natural selection**, could account for much of the evolution of life.

Although Darwin proposed that living organisms are descended from common ancestors and are therefore related to

one another, he did not have the advantage of understanding the mechanisms of genetic inheritance. But he knew that offspring differed from their parents, even though they showed strong similarities. Any population of a plant or animal species displays variation, and if you select breeding pairs on the basis of some particular trait, that trait is more likely to be present in their offspring than in the general population. Darwin himself bred pigeons, and was well aware of how pigeon fanciers selected breeding pairs to produce offspring with unusual feather patterns, beak shapes, or body sizes. He realized that if humans could select for specific traits, the same process could operate in nature; hence the term *natural selection* as opposed to the artificial (human-imposed) selection that has been practiced on crop plants and domesticated animals since the dawn of human civilization.

How does natural selection function? Darwin postulated that different probabilities of survival and reproductive success could account for evolutionary change. He reasoned that the reproductive capacity of plants and animals, if unchecked, would result in unlimited growth of populations, but we do not observe such growth in nature; in most species, only a small percentage of offspring survive to reproduce. Thus any trait that confers even a small increase in the probability that its possessor will survive and reproduce will spread in the population.

Because organisms with certain traits survive and reproduce best under specific sets of conditions, natural selection leads to **adaptations**: structural, physiological, or behavioral traits that enhance an organism's chances of survival and reproduction in its environment (**FIGURE 1.7**). Consider the feet of the frog

shown in the opening photograph of this chapter. The toes of the frog's foot are greatly expanded compared with those of frog species that do not live in trees. Expanded toes increase the ability of tree frogs to climb trees, which allows them to seek insects for food in the forest canopy and to escape terrestrial predators. Thus the expanded toe pads of tree frogs are an adaptation to arboreal life.

(A) *Dyscophus guineti*

(B) *Xenopus laevis*

(C) *Agalychnis callidryas*

(D) *Rhacophorus nigropalmatus*

FIGURE 1.7 Adaptations to the Environment The limbs of frogs show adaptations to the different environments of each species. (A) This terrestrial frog walks across the ground using its short legs and peglike digits (toes). (B) Webbed rear feet are evident in this highly aquatic species of frog. (C) This arboreal species has toe pads, which are adaptations for climbing. (D) A different arboreal species has extended webbing between the toes, which increases surface area and allows the frog to glide from tree to tree.

In addition to natural selection, evolutionary processes such as sexual selection (selection due to mate choice) and genetic drift (the random fluctuation of gene frequencies in a population due to chance events) contribute to the rise of biological diversity. These processes operating over evolutionary history have led to the remarkable array of life on Earth.

Evolution is a fact, as well as the basis for broader theory

The famous biologist Theodosius Dobzhansky once wrote that “Nothing in biology makes sense except in the light of evolution.” Dobzhansky was emphasizing the need to integrate an evolutionary perspective and approach into all aspects of biological study. Everything in biology is a product of evolution, and biologists need to incorporate a perspective of change and adaptation to fully understand biological systems.

You may have heard it said that evolution is “just a theory,” thereby implying that there is some question about whether or not biological populations evolve. This is a common misunderstanding that originates in part from the different meanings of the word “theory” in everyday language and in science. In everyday speech, some people use the word “theory” to mean “hypothesis” or even—disparagingly—“a guess.” In science, however, a **theory** is a *body of scientific work in which rigorously tested and well-established facts and principles are used to make predictions about the natural world*. In short, evolutionary theory is (1) a body of knowledge supported by facts and (2) the resulting understanding of the various mechanisms by which biological populations have changed and diversified over time, and by which Earth’s populations continue to evolve.

Evolution can be observed and measured directly, and many biologists conduct experiments on evolving populations. We constantly observe changes in the genetic composition of populations over relatively short-term time frames. In addition, we can directly observe a record of the history of evolution in the fossil record over the almost unimaginably long periods of geological time. Exactly *how* biological populations change through time is something that is subject to testing and experimentation. The fact that biological populations evolve, however, is not disputed among biologists.

You will see evolution and the other major principles of life described in this chapter at work in each part of this book. In Part I you will learn about the molecular structure of life. We will discuss the origin of life, the energy inherent in atoms and molecules, and how proteins and nucleic acids became the self-replicating cellular systems of life. Part II will describe how these self-replicating systems work and the genetic principles that explain heredity and mutation, which are the building blocks of evolution. In Part III we will describe the mechanisms of evolution and go into greater detail about how evolution works. Part IV will examine the products of evolution: the vast diversity of life and the many different ways organisms solve some common problems such as reproducing, defending themselves, and obtaining nutrients. Parts V and VI will explore the physiological adaptations that allow plants and animals to survive and function in a wide range of physical environments.

Finally, in Part VII we will discuss these environments and the integration of individual organisms, populations, and communities into the interrelated ecosystems of the biosphere.

You may enjoy returning to this chapter occasionally as the course progresses; the necessarily terse explanations given here should begin to cohere and make more sense as you read about the facts and phenomena that underlie the principles. Our knowledge of the “facts” of biology, however, is not based just on reading, contemplation, or discussion—although all of these activities are useful, even necessary. Scientific knowledge is based on active and always-ongoing research.

concept 1.5 Science Is Based on Quantifiable Observations and Experiments

Regardless of the many different tools and methods used in research, all scientific investigations are based on *observation* and *experimentation*. In both, scientists are guided by established principles of a set of scientific methods that allow us to discover new aspects about the structure, function, and history of the natural world.

Observing and quantifying are important skills

Many biologists are motivated by their observations of the living world. Learning *what to observe* in nature is a skill that develops with experience in biology. An intimate understanding of the **natural history** of a group of organisms—how the organisms get their food, reproduce, behave, regulate their internal environments (their cells, tissues, and organs), and interact with other organisms—facilitates observations and leads biologists to ask questions about those observations. The more a biologist knows about general principles, the more he or she is likely to gain new insights from observing nature.

Biologists have always observed the world around them, but today our ability to observe is greatly enhanced by technologies such as electron microscopes, rapid genome sequencing, magnetic resonance imaging, and global positioning satellites. These technologies allow us to observe everything from the distribution of molecules in the body to the daily movement of animals across continents and oceans.

Observation is a basic tool of biology, but as scientists we must also be able to **quantify** our observations. Whether we are testing a new drug or mapping the migrations of the great whales, mathematical and statistical calculations are essential. For example, biologists once classified organisms based entirely on qualitative descriptions of the physical differences among them. There was no way of objectively determining evolutionary relationships of organisms, and biologists had to depend on the fossil record for insight. Today our ability to quantify the molecular and physical differences among species, combined with explicit mathematical models of the evolutionary process, enables quantitative analyses of evolutionary history. These mathematical calculations, in turn, facilitate comparative investigations of all other aspects of an organism’s biology.

Scientific methods combine observation, experimentation, and logic

Often, science textbooks describe “the scientific method,” as if there is a single, simple flow chart that all scientists follow. This is an oversimplification. Although such flow charts incorporate much of what scientists do, you should not conclude that scientists necessarily progress through the steps of the process in one prescribed, linear order.

Observations lead to questions, and scientists make additional observations and often do experiments to answer those questions. This approach, called the *hypothesis–prediction method*, has five steps: (1) making *observations*; (2) asking *questions*; (3) forming *hypotheses*, or tentative answers to the questions; (4) making *predictions* based on the hypotheses; and (5) *testing* the predictions by making additional observations or conducting experiments. These are the steps seen in traditional flow charts such as the one shown in **FIGURE 1.8**.

After posing a question, a scientist often uses *inductive logic* to propose a tentative answer. Inductive logic involves taking observations or facts and creating a new proposition that is compatible with those observations or facts. Such a tentative proposition is called a **hypothesis**. In formulating a hypothesis,

scientists put together the facts they already know to formulate one or more possible answers to the question.

The next step in the scientific method is to apply a different form of logic—*deductive logic*—to make predictions based on the hypothesis. Deductive logic starts with a statement believed to be true and goes on to predict what facts would also have to be true to be compatible with that statement.

Getting from questions to answers

Let’s consider an example of how scientists can start with a general question and work to find answers. Amphibians—such as the frog in the opening photograph of this chapter—have been around for a long time. They watched the dinosaurs come and go. But today amphibian populations around the world are in dramatic decline, with more than a third of the world’s amphibian species threatened with extinction. Why?

Biologists work to answer general questions like this by making observations and doing experiments. There are probably multiple reasons that amphibian populations are declining, but scientists often break up a large problem into many smaller problems and investigate them one at a time. One hypothesis is that frog populations have been adversely affected by agricultural insecticides and herbicides (weed-killers). Several studies have shown that many of these chemicals tested at realistic concentrations do not kill amphibians. But Tyrone Hayes, a biologist at the University of California at Berkeley, probed deeper.

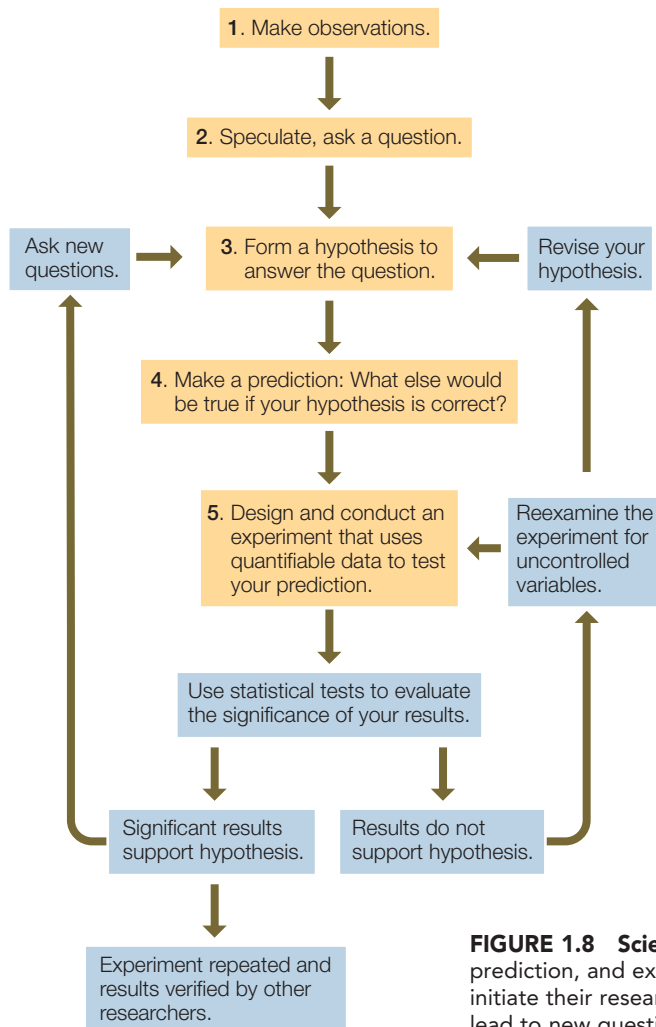

FIGURE 1.8 Scientific Methodology The process of observation, speculation, hypothesis, prediction, and experimentation is a cornerstone of modern science, although scientists may initiate their research at several different points. Answers gleaned through experimentation lead to new questions, more hypotheses, further experiments, and expanding knowledge.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 1.1**
Using Scientific Methodology

Hayes focused on atrazine, the most widely used herbicide in the world and a common contaminant in fresh water. More than 70 million pounds of atrazine are applied to farmland in the United States every year, and it is used in at least 20 countries. Atrazine kills several types of weeds that can choke fields of important crops such as corn. The chemical is usually applied before weeds emerge in the spring—at the same time many amphibians are breeding and thousands of tadpoles swim in the ditches, ponds, and streams that receive runoff from farms.

In his laboratory, Hayes and his associates raised frog tadpoles in water containing no atrazine and in water with concentrations ranging from 0.01 parts per billion (ppb) up to 25 ppb. The U.S. Environmental Protection Agency considers environmental levels of atrazine of 10–20 ppb of no concern; it considers 3 ppb a safe level in drinking water. Rainwater in Iowa has been measured to contain 40 ppb. In Switzerland, where the use of atrazine is illegal, the chemical has been measured at approximately 1 ppb in rainwater.

In the Hayes laboratory, an atrazine concentration as low as 0.1 ppb had a dramatic effect on tadpole development: it feminized the males. In some of the adult males that developed from these larvae, the vocal structures used in mating calls were smaller than normal, female sex organs developed, and eggs were found growing in the testes. In other studies, normal adult male frogs exposed to 25 ppb had a tenfold reduction in testosterone levels and did not produce sperm. You can imagine the disastrous effects these developmental and hormonal changes could have on the capacity of frogs to breed and reproduce.

But Hayes's experiments were performed in the laboratory, with a species of frog bred for laboratory use. Would his results be the same in nature? To find out, he and his students traveled across the middle of North America, sampling water and collecting frogs. They analyzed the water for atrazine and examined the frogs. In the only site where atrazine was undetectable in the water, the frogs were normal; in all the other sites, male frogs had abnormalities of the sex organs.

Like other biologists, Hayes made observations. He then made predictions based on those observations, and designed and carried out experiments to test his predictions. Some of the conclusions from his experiments, described below, could have profound implications not only for amphibians but also for other animals, including humans.

Good experiments have the potential to falsify hypotheses

Once predictions are made from a hypothesis, experiments can be designed to test those predictions. The most informative experiments are those that have the ability to show that the prediction is wrong. If the prediction is wrong, the hypothesis must be questioned, modified, or rejected.

There are two general types of experiments, both of which compare data from different groups or samples. A *controlled* experiment manipulates one or more of the factors being tested; *comparative* experiments compare unmanipulated data gathered from different sources.

In a **controlled experiment**, we start with groups or samples that are as similar as possible. We predict on the basis of our hypothesis that some critical factor, or **variable**, has an effect on the phenomenon we are investigating. We devise some method to manipulate *only that variable* in an "experimental" group and compare the resulting data with data from an unmanipulated "control" group. If the predicted difference occurs, we then apply statistical tests to ascertain the probability that the manipulation created the difference (as opposed to the difference being the result of random chance). **FIGURE 1.9** describes one of the many controlled experiments performed by the Hayes laboratory to quantify the effects of atrazine on male frogs.

The basis of controlled experiments is that one variable is manipulated while all others are held constant. The variable that is manipulated is called the *independent variable*, and the response that is measured is the *dependent variable*. A good

INVESTIGATION

FIGURE 1.9 Controlled Experiments Manipulate a Variable
The Hayes laboratory created controlled environments that differed only in the concentrations of atrazine in the water. Eggs from leopard frogs (*Rana pipiens*) raised specifically for laboratory use were allowed to hatch and the tadpoles were separated into experimental tanks containing water with different concentrations of atrazine.

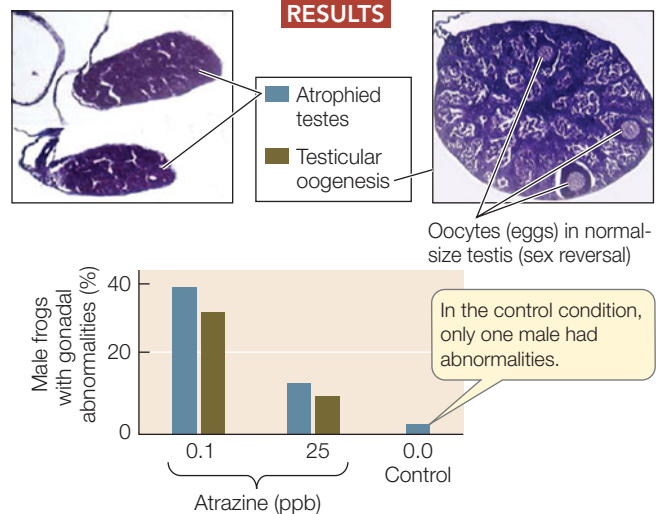

HYPOTHESIS

Exposure to atrazine during larval development causes abnormalities in the reproductive tissues of male frogs.

METHOD

1. Establish 9 tanks in which all attributes are held constant except the water's atrazine concentration. Establish 3 atrazine conditions (3 replicate tanks per condition): 0 ppb (control condition), 0.1 ppb, and 25 ppb.
2. Place *Rana pipiens* tadpoles from laboratory-reared eggs in the 9 tanks (30 tadpoles per replicate).
3. When tadpoles have transitioned into adults, sacrifice the animals and evaluate their reproductive tissues.
4. Test for correlation of degree of atrazine exposure with the presence of abnormalities in the gonads (testes) of male frogs.

RESULTS

CONCLUSION

Exposure to atrazine at concentrations as low as 0.1 ppb induces abnormalities in the gonads of male frogs. The effect is not proportional to the level of exposure.

controlled experiment is not easy to design because biological variables are so interrelated that it is difficult to alter just one.

A **comparative experiment** starts with the prediction that there will be a difference between samples or groups based on the hypothesis. In comparative experiments, however, we cannot control the variables; often we cannot even identify all the variables that are present. We are simply gathering and comparing data from different sample groups.

When his controlled experiments indicated that atrazine indeed affects reproductive development in frogs, Hayes and his colleagues performed a comparative experiment. They collected frogs and water samples from eight widely separated sites across the United States and compared the incidence of abnormal frogs from environments with very different levels of atrazine (FIGURE 1.10). Of course, the sample sites differed in many ways besides the level of atrazine present.

The results of experiments frequently reveal that the situation is more complex than the hypothesis anticipated, thus raising new questions. There are no “final answers” in science.

Investigations consistently reveal more complexity than we expect. As a result, biologists often develop new questions, hypotheses, and experiments as they collect more data.

Statistical methods are essential scientific tools

Whether we do comparative or controlled experiments, at the end we have to decide whether there is a difference between the samples, individuals, groups, or populations in the study. How do we decide whether a measured difference is enough to support or falsify a hypothesis? In other words, how do we decide in an unbiased, objective way that the measured difference is significant?

Significance can be measured with statistical methods. Scientists use statistics because they recognize that variation is always present in any set of measurements. Statistical tests calculate the probability that the differences observed in an experiment could be due to random variation. The results of statistical tests are therefore probabilities. A statistical test starts with a **null hypothesis**—the premise that any observed differences are simply the result of random differences that arise from drawing two finite samples from the same population. When quantified observations, or **data**, are collected, statistical methods are applied to those data to calculate the likelihood that the null hypothesis is correct.

More specifically, statistical methods tell us the probability of obtaining the same results by chance even if the null hypothesis were true. We need to eliminate, insofar as possible, the chance that any differences showing up in the data are merely the result of random variation in the samples tested. Scientists generally conclude that the differences they measure are significant if statistical tests show that the *probability of error* (that is, the probability that a difference as large as the one observed could be obtained by mere chance) is 5 percent or lower, although more stringent levels of significance may be set for some problems. Appendix B of this book is a short primer on statistical methods that you can refer to as you analyze data that will be presented throughout the text.

Not all forms of inquiry into nature are scientific

Science is a unique human endeavor that is bounded by certain standards of practice. Other areas of scholarship share with science the practice of making observations

INVESTIGATION

FIGURE 1.10 Comparative Experiments Look for Differences among Groups

To see whether the presence of atrazine correlates with testicular abnormalities in male frogs, the Hayes lab collected frogs and water samples from different locations around the U.S. The analysis that followed was “blind,” meaning that the frogs and water samples were coded so that experimenters working with each specimen did not know which site the specimen came from.

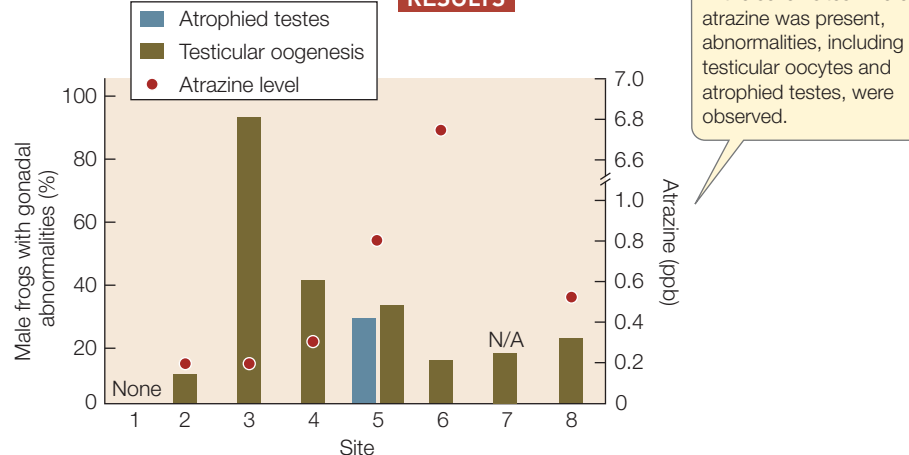

HYPOTHESIS

Presence of the herbicide atrazine in environmental water correlates with gonadal abnormalities in frog populations.

METHOD

1. Based on commercial sales of atrazine, select 4 sites (sites 1–4) less likely and 4 sites (sites 5–8) more likely to be contaminated with atrazine.
2. Visit all sites in the spring (i.e., when frogs have transitioned from tadpoles into adults); collect frogs and water samples.
3. In the laboratory, sacrifice frogs and examine their reproductive tissues, documenting abnormalities.
4. Analyze the water samples for atrazine concentration (the sample for site 7 was not tested).
5. Quantify and correlate the incidence of reproductive abnormalities with environmental atrazine concentrations.

RESULTS

CONCLUSION

Reproductive abnormalities exist in frogs from environments in which aqueous atrazine concentration is 0.2 ppb or above. The incidence of abnormalities does not appear to be proportional to atrazine concentration at the time of transition to adulthood.

and asking questions, but scientists are distinguished by what they do with their observations and how they answer their questions. Data, subjected to appropriate statistical analysis, are critical in the testing of hypotheses. Science is the most powerful approach humans have devised for learning about the world and how it works.

Scientific explanations for natural processes are objective and reliable because the hypotheses proposed *must be testable* and *must have the potential of being rejected* by direct observations and experiments. Scientists must clearly describe the methods they use to test hypotheses so that other scientists can repeat their results. Not all experiments are repeated, but surprising or controversial results are always subjected to independent verification. Scientists worldwide share this process of testing and rejecting hypotheses, contributing to a common body of scientific knowledge.

If you understand the methods of science, you can distinguish science from non-science. Art, music, and literature all contribute to the quality of human life, but they are not science. They do not use scientific methods to establish what is fact. Religion is not science, although religions have historically attempted to explain natural events ranging from unusual weather patterns to crop failures to human diseases. Most such phenomena that at one time were mysterious can now be explained in terms of scientific principles. Fundamental tenets of religious faith, such as the existence of a supreme deity or deities, cannot be confirmed

or refuted by experimentation and are thus outside the realm of science. The power of science derives from the uncompromising objectivity and absolute dependence on evidence that comes from *reproducible and quantifiable observations*. A religious or spiritual explanation of a natural phenomenon may be coherent and satisfying for the person holding that view, but it is not testable and therefore it is not science. To invoke a supernatural explanation (such as a “creator” or “intelligent designer” with no known bounds) is to depart from the world of science. Science does not say that religious beliefs are necessarily wrong; they are just not part of the world of science, and are untestable using scientific methods. In other words, science and religion are nonoverlapping approaches to inquiry.

Science describes how the world works; it is silent on the question of how the world “ought to be.” Many scientific advances that contribute to human welfare also raise major ethical issues. Recent developments in genetics and developmental biology may enable us to select the sex of our children, to use stem cells to repair our bodies, and to modify the human genome. Although scientific knowledge allows us to do these things, science cannot tell us whether or not we should do so, or if we choose to do them, how we should regulate them. Such issues are as crucial to human society as the science itself, and a responsible scientist does not lose sight of these questions or neglect the contributions of the humanities in attempting to come to grips with them.

PART

Cells

Life Chemistry and Energy

2

A major discovery of biology was that living things are composed of the same chemical elements as the vast nonliving portion of the universe. This mechanistic view—that life is chemically based and obeys the universal laws of chemistry and physics—is relatively new in human history. Until the nineteenth century, many scientists thought that a “vital force,” distinct from the forces governing the inanimate world, was responsible for life. Many people still assume that such a vital force exists, but the mechanistic view of life has led to great advances in biological science, and it underpins many applications of biology to medicine and agriculture. We assume a mechanistic view throughout this book.

Among the most abundant chemical elements in the universe are hydrogen and oxygen, and life as we know it requires the presence of these elements as water (H_2O). Water makes up about 70 percent of the bodies of most organisms, and those that live on land have evolved elaborate ways to retain the water in their bodies. Aquatic organisms do not need these water-retention mechanisms; thus biologists think that life originated in a watery environment.

Life has been found in some surprising places, often in extreme conditions. There are organisms living in hot springs at temperatures above the boiling point of water, beneath the Antarctic ice, 5 kilometers below Earth’s surface, at the bottom of the ocean, in extremely acid or salty conditions, and even inside nuclear reactors.

With trillions of galaxies in the universe, each with billions or trillions of stars, there are many planets out there, and if our

solar system is typical, some of them have the water needed for life. Indeed, space probes have detected water on the moons surrounding Saturn, at the poles and warmer mid-latitudes of Mars, and all over the surface of our own moon. The amount of water on these planetary bodies is not a lot by Earth standards—on the moon, there is about a liter of water per 1,000 kilograms of soil, which is less than the amount in the driest desert on Earth. But given that organisms are found on Earth in extreme environments, the existence of water outside of Earth makes extraterrestrial life seem possible.

Polar ice caps, as shown here, have been observed on Mars for a long time, but recent evidence also shows water at the milder mid-latitudes of Mars.

Why is the search for water important in the search for life?*

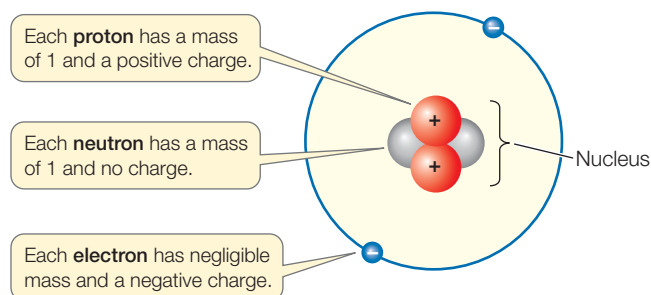

*You will find the answer to this question on page 31.

KEY CONCEPTS

- 2.1 Atomic Structure Is the Basis for Life’s Chemistry
- 2.2 Atoms Interact and Form Molecules
- 2.3 Carbohydrates Consist of Sugar Molecules
- 2.4 Lipids Are Hydrophobic Molecules
- 2.5 Biochemical Changes Involve Energy

concept 2.1 Atomic Structure Is the Basis for Life's Chemistry

Living and nonliving matter is composed of **atoms**. Each atom consists of a dense, positively charged **nucleus**, with one or more negatively charged **electrons** moving around it. The nucleus contains one or more positively charged **protons**, and may contain one or more **neutrons** with no electrical charge:

Charges that are different (+/−) attract each other, whereas charges that are alike (+/+, −/−) repel each other. Most atoms are electrically neutral because the number of electrons in an atom equals the number of protons.

The mass of a proton serves as a standard unit of measure called the *dalton* (named after the English chemist John Dalton). A single proton or neutron has a mass of about 1 dalton (Da), which is 1.7×10^{-24} grams, but an electron is even tinier, at 9×10^{-28} g (0.0005 Da). Because the mass of an electron is only about 1/2,000th of the mass of a proton or neutron, the contribution of electrons to the mass of an atom can usually be ignored when chemical measurements and calculations are made.

An element consists of only one kind of atom

An **element** is a pure substance that contains only one kind of atom. The element hydrogen consists only of hydrogen atoms, the element gold only of gold atoms. The atoms of each element have certain characteristics and properties that distinguish them from the atoms of other elements.

There are 94 elements in nature, and at least another 24 have been made in physics laboratories. Almost all of the 94 natural elements have been detected in living organisms, but just a few predominate. About 98 percent of the mass of every living organism (bacterium, turnip, or human) is composed of just six elements:

Carbon (symbol C)	Hydrogen (H)	Nitrogen (N)
Oxygen (O)	Phosphorus (P)	Sulfur (S)

The chemistry of these six elements will be our primary concern in this chapter, but other elements found in living organisms are important as well. Sodium and potassium, for example, are essential for nerve function; calcium can act as a biological signal; iodine is a component of a human hormone; and magnesium is bound to chlorophyll in green plants. The

physical and chemical (reactive) properties of atoms depend on the numbers of protons, neutrons, and electrons they contain.

The atoms of an element differ from those of other elements by the number of protons in their nuclei. The number of protons is called the **atomic number**, and it is unique to and characteristic of each element. The atomic number of carbon is 6, and a carbon atom always has six protons; the atomic number of oxygen is always 8. For electrical neutrality, each atom has the same number of electrons as protons, so a carbon atom has six electrons, and an oxygen atom has eight.

Along with a definitive number of protons, every element except hydrogen has one or more neutrons. The *mass number* of an atom is the total number of protons and neutrons in its nucleus. A carbon nucleus contains six protons and six neutrons and has a mass number of 12. Oxygen has eight protons and eight neutrons and has a mass number of 16.

Electrons determine how an atom will react

The **Bohr model** for atomic structure (see diagram at left) provides a concept of an atom that is largely empty space, with a central nucleus surrounded by electrons in orbits, or **electron shells**, at various distances from the nucleus. This model is much like our solar system, with planets orbiting around the sun. Although highly oversimplified (you will learn about the reality of atomic structure in physical chemistry courses), the Bohr model is useful for describing how atoms behave. Specifically, *the behaviors of electrons determine whether a chemical bond will form and what shape the bond will have*. These are two key properties for determining biological changes and structure.

In the Bohr model, each electron shell is a certain distance from the nucleus. Since electrons are negatively charged and protons are positive, an electron needs energy to escape from the attraction of the nucleus. The further away an electron shell is from the nucleus, the more energy the electron must have. We will return to this topic when we discuss biological energetics in Chapter 6. The electron shells, in order of their distance from the nucleus, can be filled with electrons as follows:

- First shell: two electrons
- Second and subsequent shells: eight electrons

FIGURE 2.1 illustrates the electron shell configurations for the six major elements found in living systems.

Atoms with unfilled outer shells (such as oxygen, which has six electrons in its outermost shell) tend to undergo chemical reactions to fill their outer shells. In the case of oxygen, adding two electrons to its outer shell will make a total of eight. These reactive atoms can attain stability either by sharing electrons with other atoms or by losing or gaining one or more electrons. In either case, the atoms involved are *bonded* together into stable associations called **molecules**. The tendency of atoms with at least two electron shells to form stable molecules so they have eight electrons in their outermost shells is known as the *octet rule*. Most atoms in biologically important molecules—for example, carbon (C) and nitrogen (N)—follow this rule.

FIGURE 2.1 Electron Shells Each shell can hold a specific maximum number of electrons and must be filled before electrons can occupy the next shell. The energy level of an electron is higher in a shell farther from the nucleus. An atom with less than the full complement (2 or 8) electrons in its outermost shell can react (bond) with other atoms.

Do You Understand Concept 2.1?

- What is the arrangement of protons, neutrons, and electrons in an atom?
- Sketch the electron shell configuration of a sodium atom (symbol Na), which has 11 protons. According to the octet rule, what would be the simplest way for a sodium atom to achieve electron stability?
- Many elements have isotopes, which are rare variants of the element with additional neutrons in the nucleus. Deuterium is an isotope of hydrogen that has one neutron (normal hydrogen has no neutrons). Does the neutron change the chemical reactivity of deuterium, compared with normal hydrogen? Explain why or why not.

We have introduced the individual elements that make up all living organisms—the atoms. We have shown how the energy levels of electrons drive an atomic quest for stability. Next we will describe the different types of chemical bonds that can lead to stability, joining atoms together into molecular structures with different properties.

concept 2.2

Atoms Interact and Form Molecules

A **chemical bond** is an attractive force that links two atoms together in a molecule. There are several kinds of chemical bonds (TABLE 2.1). In this section we will begin with *ionic bonds*, which form when atoms gain or lose one or more electrons

TABLE 2.1 Chemical Bonds and Interactions

NAME	BASIS OF INTERACTION	STRUCTURE	BOND ENERGY ^a
Ionic attraction	Attraction of opposite charges		3–7
Covalent bond	Sharing of electron pairs		50–110
Hydrogen bond	Sharing of H atom		3–7
Hydrophobic interaction	Interaction of nonpolar substances in the presence of polar substances (especially water)		1–2
van der Waals interaction	Interaction of electrons of nonpolar substances		1

^aBond energy is the amount of energy (Kcal/mol) needed to separate two bonded or interacting atoms under physiological conditions.

to achieve stability. Then we will turn to *covalent bonds*—the strong bonds that form when atoms share electrons. We will then consider weaker interactions, including *hydrogen bonds*, which are enormously important to biology. Finally, we will see how atoms are bonded to make *functional groups*—groups of atoms that give important properties to biological molecules.

Go to ANIMATED TUTORIAL 2.1
Chemical Bond Formation

Ionic bonds form by electrical attraction

In some cases, an atom can transfer or accept a few electrons to complete the octet in its outer shell. Consider sodium (11 protons) and chlorine (17 protons). A sodium atom has only one electron in its outermost shell; this condition is unstable. A chlorine atom has seven electrons in its outermost shell—another unstable condition. The most straightforward way for both atoms to achieve stability is to transfer an electron from sodium's outermost shell to that of chlorine (FIGURE 2.2). This reaction makes the two atoms more stable because they both have eight electrons in their outer shells. The result is two *ions*.

FIGURE 2.2 Ionic Bond between Sodium and Chlorine When a sodium atom reacts with a chlorine atom, the chlorine fills its outermost shell by “stealing” an electron from the sodium. In so doing, the chlorine atom becomes a negatively charged chloride ion (Cl^-). With one less electron, the sodium atom becomes a positively charged sodium ion (Na^+).

An **ion** is an electrically charged particle that forms when an atom gains or loses one or more electrons:

- The sodium ion (Na^+) in our example has a charge of +1 because it has one less electron than it has protons. The outermost electron shell of the sodium ion is full, with eight electrons, so the ion is stable. Positively charged ions are called **cations**.
- The chloride ion (Cl^-) has a charge of -1 because it has one more electron than it has protons. This additional electron gives Cl^- a stable outermost shell with eight electrons. Negatively charged ions are called **anions**.

Ionic bonds are formed as a result of the electrical attraction between ions bearing opposite charges. Ionic bonds result in stable molecules that are often referred to as *salts*. An example is sodium chloride (NaCl ; table salt), where cations and anions are held together by ionic bonds. While ionic bonds in salts may be stronger, attractions between ions in solution, as occur in living systems, are typically weak (see Table 2.1).

Given that most organisms consist of about 70 percent water, as we described in the opening of this chapter, most of biology (and biochemistry) occurs in the presence of water. Because ionic attractions are weak, salts dissolve in water; the ions separate from one another and become surrounded by water molecules. The water molecules are oriented with their negative poles nearest to the cations and their positive poles nearest to the anions:

Covalent bonds consist of shared pairs of electrons

A **covalent bond** forms when two atoms attain stable electron numbers in their outermost shells by *sharing* one or more pairs of electrons. In this case, each atom contributes one member of each electron pair. Consider two hydrogen atoms coming into close proximity, each with an unpaired electron in its single shell (FIGURE 2.3). When the electrons pair up, a stable association is formed, and this links the two hydrogen atoms in a covalent bond, forming the molecule H_2 .

Let's see how covalent bonds are formed in the somewhat more complicated methane molecule (CH_4). The carbon atom has six electrons: two electrons fill its inner shell, and four electrons are in its outer shell. Because its outer shell can hold up to eight electrons, carbon can share electrons with up to four other atoms—it can form four covalent bonds (FIGURE 2.4A). Methane forms when an atom of carbon reacts with four hydrogen atoms. As a result of electron sharing, the outer shell of the carbon atom is now filled with eight electrons—a stable configuration. The outer shell of each hydrogen atom is also

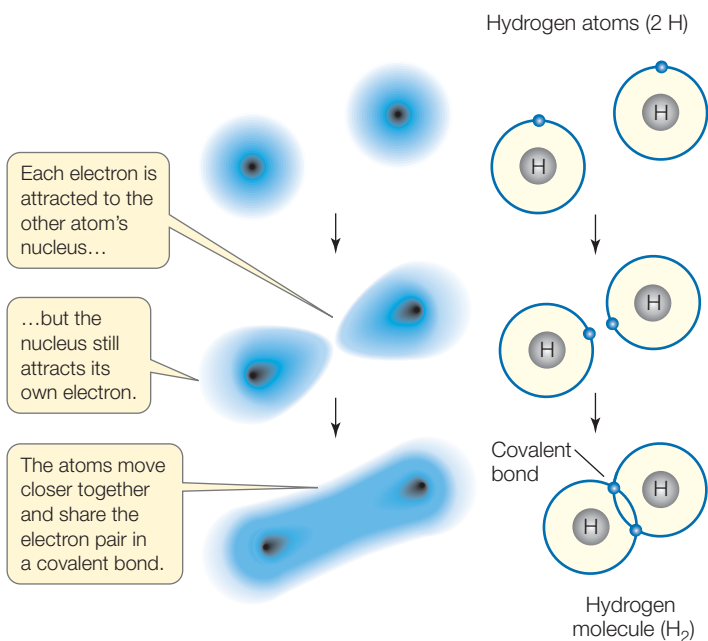

FIGURE 2.3 Electrons Are Shared in Covalent Bonds Two hydrogen atoms can combine to form a hydrogen molecule. A covalent bond forms when the electron shells of the two atoms overlap in an energetically stable manner.

filled. Four covalent bonds—four shared electron pairs—hold methane together. **FIGURE 2.4B** shows several different ways to represent the molecular structure of methane.

The properties of molecules are influenced by the characteristics of their covalent bonds. Four important aspects of covalent bonds are their orientation, their strength and stability, multiple covalent bonds, and the degree of sharing of electrons.

ORIENTATION For a given pair of elements, such as carbon bonded to hydrogen, the length of the covalent bond is always the same. And for a given atom within a molecule, the angle of each covalent bond with respect to the others is generally the same. This is true regardless of the type of larger molecule that contains the atom. For example, the four covalent bonds formed by the carbon atom in methane are always distributed in space so that the bonded hydrogens point to the corners of a regular tetrahedron, with the carbon in the center (see Figure 2.4B). Even when carbon is bonded to four atoms other than hydrogen, this three-dimensional orientation is more or less maintained. As you will see, the orientations of covalent bonds in space give molecules their three-dimensional geometry, and the shapes of molecules contribute to their biological functions.

FRONTIERS The activities of biological molecules depend largely on their shapes. As chemists learn more about the geometry of covalent bonds and the forces that affect them, it may be possible to predict the structures of molecules based on their atomic compositions. For a simple molecule like water with only two bonds, this is relatively straightforward. But for complex biological molecules with hundreds or thousands of atoms (like a protein or a new drug), this becomes a subject for modeling by sophisticated computer programs.

STRENGTH AND STABILITY Covalent bonds are very strong (see Table 2.1), meaning it takes a lot of energy to break them. At the temperatures at which life exists, the covalent bonds of biological molecules are quite stable, as are their three-dimensional structures. However, this stability does not preclude change, as we will discover.

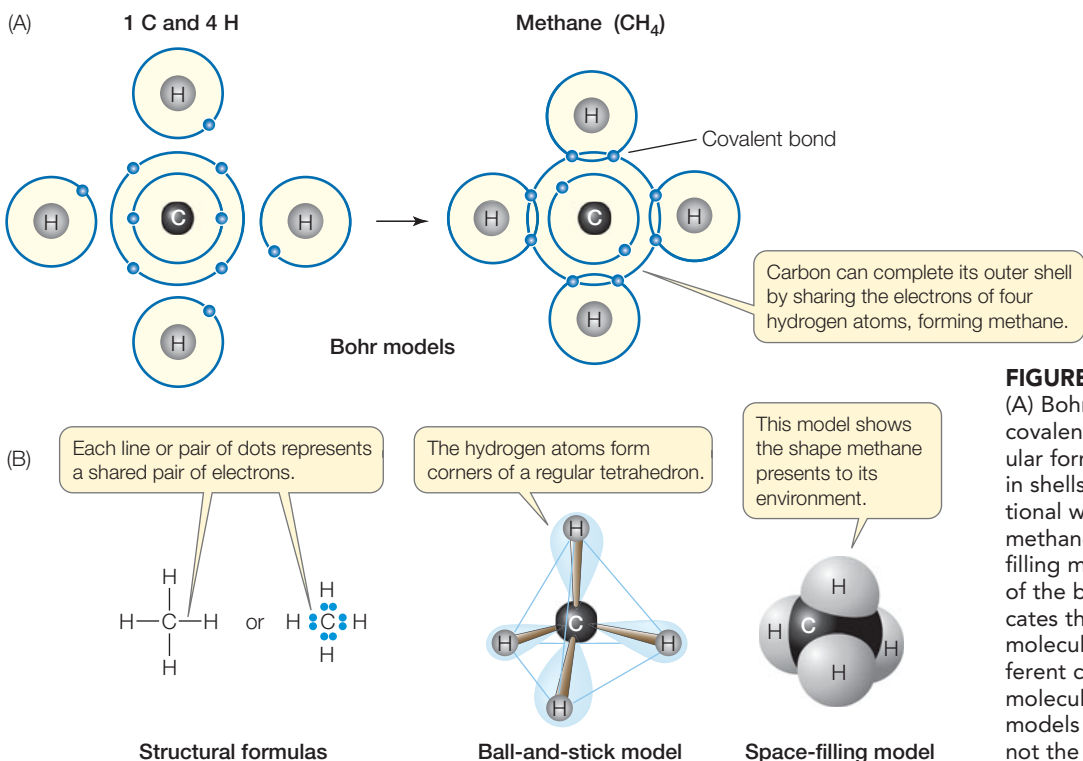

FIGURE 2.4 Covalent Bonding

(A) Bohr models showing the formation of covalent bonds in methane, whose molecular formula is CH_4 . Electrons are shown in shells around the nuclei. (B) Three additional ways of representing the structure of methane. The ball-and-stick and the space-filling models show the spatial orientations of the bonds. The space-filling model indicates the overall shape and surface of the molecule. In the chapters that follow, different conventions will be used to depict molecules. Bear in mind that these are models to illustrate certain properties, and not the most accurate portrayal of reality.

MULTIPLE COVALENT BONDS As shown in Figure 2.4B, covalent bonds can be represented by lines between the chemical symbols for the linked atoms:

- A *single bond* involves the sharing of a single pair of electrons (for example, H—H or C—H).
- A *double bond* involves the sharing of four electrons (two pairs; C=C).
- *Triple bonds*—six shared electrons—are rare, but there is one in nitrogen gas (N≡N), which is the major component of the air we breathe.

UNEQUAL SHARING OF ELECTRONS If two atoms of the same element are covalently bonded, there is an equal sharing of the pair(s) of electrons in their outermost shells. However, when the two atoms are different, the sharing is not necessarily equal. One nucleus may exert a greater attractive force on the electron pair than the other nucleus, so that the pair tends to be closer to that atom.

The attractive force that an atomic nucleus exerts on electrons in a covalent bond is called its **electronegativity**. The electronegativity of a nucleus depends on how many positive charges it has (nuclei with more protons are more positive and thus more attractive to electrons) and on the distance between the electrons in the bond and the nucleus (the closer the electrons, the greater the electronegative pull). **TABLE 2.2** shows the electronegativities (which are calculated to produce dimensionless quantities) of some elements important in biological systems.

If two atoms are close to each other in electronegativity, they will share electrons equally in what is called a *nonpolar covalent bond*. Two oxygen atoms, for example, each with an electronegativity of 3.4, will share electrons equally. So will two hydrogen atoms (each with an electronegativity of 2.2). But when hydrogen bonds with oxygen to form water, the electrons involved are *unequally shared*: they tend to be nearer to the oxygen nucleus because it is more electronegative than hydrogen. When electrons are drawn to one nucleus more than to the other, the result is a **polar covalent bond**:

Because of this unequal sharing of electrons, the oxygen end of the bond has a slightly negative charge (symbolized by δ^- and spoken of as “delta negative,” meaning a partial unit of charge), and the hydrogen end has a slightly positive charge (δ^+). The bond is *polar* because these opposite charges are separated at the two ends, or poles, of the bond. The partial charges that result from polar covalent bonds produce polar molecules or polar regions of large molecules. Polar bonds within molecules greatly influence the interactions they have with other polar

TABLE 2.2 Some Electronegativities

Hydrogen (H)	2.2
Sodium (Na)	0.9
Potassium (K)	0.8

molecules. The polarity of the water molecule has significant effects on its physical properties and chemical reactivity, as we will see in later chapters.

Hydrogen bonds may form within or between molecules with polar covalent bonds

In liquid water, the negatively charged oxygen (δ^-) atom of one water molecule is attracted to the positively charged hydrogen (δ^+) atoms of other water molecules (**FIGURE 2.5A**). The bond resulting from this attraction is called a **hydrogen bond**. These bonds are not restricted to water molecules. A hydrogen bond may also form between a strongly electronegative atom and a hydrogen atom that is covalently bonded to another electronegative atom (oxygen or nitrogen), as shown in **FIGURE 2.5B**.

A hydrogen bond is much weaker than a covalent bond (see Table 2.1). Although individual hydrogen bonds are weak, many of them can form within one molecule or between two molecules. In these cases, the hydrogen bonds together have considerable strength and can greatly influence the structure and properties of the substances. Hydrogen bonds play

FIGURE 2.5 Hydrogen Bonds Can Form between or within Molecules (A) A hydrogen bond forms between two molecules because of the attraction between a negatively charged atom on one molecule and a positively charged hydrogen atom on a second molecule. (B) Hydrogen bonds can form between different parts of the same large molecule.

important roles in determining and maintaining the three-dimensional shapes of giant molecules such as DNA and proteins (see Chapter 3). Hydrogen bonding between water molecules also contributes to two properties of water of great significance for living systems: heat capacity and cohesion.

HEAT CAPACITY In liquid water, at any given time, a water molecule forms an average of 3.4 hydrogen bonds (dotted red lines below) with other water molecules:

Liquid water

These multiple hydrogen bonds contribute to the high *heat capacity* of water. Raising the temperature of liquid water takes a lot of heat, because much of the heat energy is used to break the hydrogen bonds that hold the liquid together (indicated by the yellow energy bursts above). Think of what happens when you apply heat to a pan of water on the stove: it takes a while for the water to begin boiling. The same happens with an organism—the overwhelming presence of water in living tissues shields them from fluctuations in environmental temperature.

Hydrogen bonding also gives water a high **heat of vaporization**, which means that a lot of heat is required to change water from its liquid to its gaseous state (the process of *evaporation*). Once again, much of the heat energy is used to break the many hydrogen bonds between the water molecules. This heat must be absorbed from the environment in contact with the water. Evaporation thus has a cooling effect on the environment—whether a leaf, a forest, or an entire land mass. This effect explains why sweating cools the human body: as sweat evaporates from the skin, it transforms some of the adjacent body heat.

LINK Evaporation is important in the physiology of both plants and animals; see Concepts 25.3 and 29.4

COHESION The numerous hydrogen bonds that give water a high heat capacity and high heat of vaporization also explain the *cohesive strength* of liquid water. This cohesive strength, or **cohesion**, is defined as the capacity of water molecules to resist coming apart from one another when placed under tension. Water's cohesive strength permits narrow columns of liquid water to move from the roots to the leaves of tall trees. When water evaporates from the leaves, the entire column moves upward in response to the pull of the molecules at the top.

Polar and nonpolar substances: Each interacts best with its own kind

Just as water molecules can interact with one another through hydrogen bonds, any polar molecule can interact with any other

FIGURE 2.6 Hydrophilic and Hydrophobic (A) Molecules with polar covalent bonds are attracted to polar water (they are hydrophilic). (B) Molecules with nonpolar covalent bonds show greater attraction to one another than to water (they are hydrophobic). The color convention in the models shown here (gray, H; red, O; black, C) is often used.

polar molecule through the weak (δ^+ to δ^-) attractions of hydrogen bonds. Polar molecules interact with water in this way and are called **hydrophilic** (“water-loving”). In aqueous (watery) solutions, these molecules become separated and surrounded by water molecules (**FIGURE 2.6A**).

Nonpolar molecules tend to interact with other nonpolar molecules. For example, molecules containing only hydrogen and carbon atoms—called *hydrocarbon molecules*—are nonpolar. (Compare the electronegativities of hydrogen and carbon in Table 2.2 to see why.) In water these molecules tend to aggregate with one another rather than with the polar water molecules. Therefore, nonpolar molecules are known as **hydrophobic** (“water-hating”), and the interactions between them are called *hydrophobic interactions* (**FIGURE 2.6B**). Hydrophobic substances do not really “hate” water—they can form weak interactions with it, since the electronegativities of carbon and hydrogen are not exactly the same. But these interactions are far weaker than the hydrogen bonds between the water molecules, so the nonpolar substances tend to aggregate.

APPLY THE CONCEPT

Atoms interact and form molecules

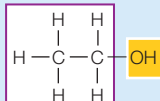

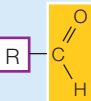

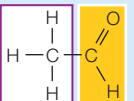

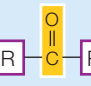

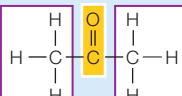

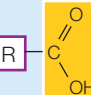

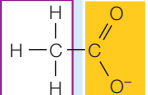

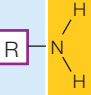

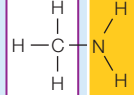

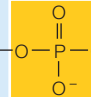

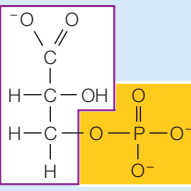

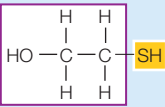

The concepts of chemical bonding and electronegativity (see Table 2.2) allow us to predict whether a molecule will be polar or nonpolar, and how it will interact with water. Typically, a difference in electronegativity greater than 0.5 will result in polarity. For each of the bonds below, indicate:

1. Whether the bond is polar or nonpolar
2. If polar, which is the δ^+ end
3. How a molecule with the bond will interact with water (hydrophilic or hydrophobic).

Functional groups confer specific properties to biological molecules

Certain small groups of atoms, called **functional groups**, are consistently found together in very different biological molecules. You will encounter several functional groups repeatedly in your study of biology (FIGURE 2.7). Each functional group has specific chemical properties, and when attached to a larger molecule, it confers those properties on the larger

Functional group	Class of compounds and an example	Properties
 Hydroxyl	Alcohols  Ethanol	Polar. Hydrogen bonds with water to help dissolve molecules. Enables linkage to other molecules by condensation.
 Aldehyde	Aldehydes  Acetaldehyde	C=O group is very reactive. Important in building molecules and in energy-releasing reactions.
 Keto	Ketones  Acetone	C=O group is important in carbohydrates and in energy reactions.
 Carboxyl	Carboxylic acids  Acetate	Acidic. Ionizes in living tissues to form COO^- and H^+ . Enters into condensation reactions by giving up OH . Some carboxylic acids important in energy-releasing reactions.
 Amino	Amines  Methylamine	Basic. Accepts H^+ in living tissues to form NH_3^+ . Enters into condensation reactions by giving up H^+ .
 Phosphate	Organic phosphates  3-Phosphoglycerate	Negatively charged. Enters into condensation reactions by giving up OH . When bonded to another phosphate, hydrolysis releases much energy.
 Sulfhydryl	Thiols  Mercaptoethanol	By giving up H, two SH groups can react to form a disulfide bridge (S-S), thus stabilizing protein structure.

molecule. One of these properties is polarity. Can you determine which functional groups in Figure 2.7 are the most polar? The consistent chemical behavior of functional groups helps us understand the properties of the molecules that contain them.

Biological molecules often contain many different functional groups. A single large protein may contain hydrophobic, polar, and charged functional groups. Each group gives a different specific property to its local site on the protein, and it may interact with another group on the same protein or with another molecule. Thus, the functional groups determine molecular shape and reactivity.

Large molecules called **macromolecules** are formed by covalent linkages of smaller molecules. Four kinds of macromolecules are characteristic of living things: proteins, carbohydrates, nucleic acids, and lipids.

With the exception of lipids, these *biological molecules* are **polymers** (*poly*, “many”; *mer*, “unit”) constructed by the covalent bonding of smaller molecules called **monomers**.

- *Proteins* are formed from different combinations of 20 *amino acids*, all of which share chemical similarities.
- *Carbohydrates* can be giant molecules, and are formed by linking together chemically similar sugar monomers (*monosaccharides*) to form *polysaccharides*.
- *Nucleic acids* are formed from four kinds of *nucleotide* monomers linked together in long chains.
- *Lipids* also form large structures from a limited set of smaller molecules, but in this case noncovalent forces maintain the interactions between the lipid monomers.

Polymers are both formed and broken down by a series of reactions involving water (FIGURE 2.8):

- In **condensation**, the removal of water links monomers together.
- In **hydrolysis**, the addition of water breaks a polymer into monomers.

Macromolecules: Carbohydrates and Lipids

Do You Understand Concept 2.2?

- Compare electron behavior in ionic, covalent, and hydrogen bonds. Which is strongest, and why?
- How do variations in electronegativity result in the unequal sharing of electrons in polar molecules?
- Consider the molecule carbon dioxide (CO_2). Are the bonds between the C and the O atoms ionic or covalent? Is this molecule hydrophobic or hydrophilic? Explain your answers.
- Here is the structure of the molecule glycine:

- Is this molecule hydrophilic or hydrophobic? Explain.
- Draw two glycine molecules and show how they can be linked by a condensation reaction.

We will begin our discussion of the molecules of life with carbohydrates, as they exemplify many of the chemical principles we have outlined so far.

concept 2.3**Carbohydrates Consist of Sugar Molecules**

Carbohydrates are a large group of molecules that all have similar atomic compositions but differ greatly in size, chemical properties, and biological functions. Carbohydrates have the general formula $\text{C}_n(\text{H}_2\text{O})_n$, which makes them appear to be hydrates of carbon—associations between water molecules and carbon; hence their name. However, when their molecular structures are examined, one sees that the carbon atoms are actually bonded with hydrogen atoms ($-\text{H}$) and hydroxyl groups ($-\text{OH}$), rather than with intact water molecules. Carbohydrates have four major biochemical roles:

- They are a source of stored energy that can be released in a form usable by organisms.
- They are used to transport stored energy within complex organisms.
- They function as structural molecules that give many organisms their shapes.
- They serve as recognition or signaling molecules that can trigger specific biological responses.

Some carbohydrates are relatively small, such as the simple sugars (for example, glucose) that are the primary energy source for many organisms. Others are large polymers of simple sugars, such as starch, which is stored in seeds.

Monosaccharides are simple sugars

Monosaccharides (*mono*, “one”) are relatively simple molecules with up to seven carbon atoms. They differ in their arrangements of carbon, hydrogen, and oxygen atoms (**FIGURE 2.9**).

Pentoses (*pente*, “five”) are five-carbon sugars. Two pentoses are of particular biological importance: the backbones of the nucleic acids RNA and DNA contain ribose and deoxyribose, respectively.

LINK For a description of the nucleic acids RNA and DNA see Concept 3.1

Five-carbon sugars (pentoses)

Ribose and deoxyribose each have five carbons, but very different chemical properties and biological roles.

Six-carbon sugars (hexoses)

These hexoses all have the formula $C_6H_{12}O_6$, but each has distinct biochemical properties.

FIGURE 2.9 Monosaccharides Monosaccharides are made up of varying numbers of carbons. Many have the same kind and number of atoms, but the atoms are arranged differently.

The *hexoses* (*hex*, “six”) all have the formula $C_6H_{12}O_6$. They include glucose, fructose (so named because it was first found in fruits), mannose, and galactose.

yourBioPortal.com

Go to WEB ACTIVITY 2.2
Forms of Glucose

Glycosidic linkages bond monosaccharides

The *disaccharides*, *oligosaccharides*, and *polysaccharides* are all constructed from monosaccharides that are covalently bonded by condensation reactions that form **glycosidic linkages**. A single glycosidic linkage between two monosaccharides forms a **disaccharide**. For example, sucrose—common table sugar—is a major disaccharide formed in plants from a glucose and a fructose:

Another disaccharide is maltose, formed from two glucose units, which is a product of starch digestion (and an important carbohydrate for making beer).

Oligosaccharides contain several monosaccharides bound together by glycosidic linkages. Many oligosaccharides have additional functional groups, which give them special properties. Oligosaccharides are often covalently bonded to proteins and lipids on the outer surfaces of cells, where they serve as recognition signals. For example, the different human blood groups (the ABO blood types) get their specificity from oligosaccharide chains.

Polysaccharides store energy and provide structural materials

Polysaccharides are large polymers of monosaccharides connected by glycosidic linkages (FIGURE 2.10). Polysaccharides are not necessarily linear chains of monomers. Each monomer unit has several sites that are capable of forming glycosidic linkages, and thus branched molecules are possible.

Starches comprise a family of giant molecules that are all polysaccharides of glucose. The different starches can be distin-

guished by the amount of branching in their polymers. Starch is the principal energy storage compound of plants.

Glycogen is a water-insoluble, highly branched polymer of glucose that is the major energy storage molecule in mammals. It is produced in the liver and transported to the muscles. Both glycogen and starch are readily hydrolyzed into glucose monomers, which in turn can be broken down to liberate their stored energy.

If glucose is the major source of fuel, why store it in the form of starch or glycogen? The reason is that 1,000 glucose molecules would exert 1,000 times the *osmotic pressure* of a single glycogen molecule, causing water to enter the cells (see Concept 5.2). If it were not for polysaccharides, many organisms would expend a lot of energy expelling excess water from their cells.

As the predominant component of plant cell walls, *cellulose* is by far the most abundant carbon-containing (*organic*) biological compound on Earth. Like starch and glycogen, cellulose is a polysaccharide of glucose, but its glycosidic linkages are arranged in such a way that it is a much more stable molecule. Whereas starch is easily broken down by chemicals or enzymes to supply glucose for energy-producing reactions, cellulose is an excellent structural material that can withstand harsh environmental conditions without substantial change.

FRONTIERS Cellulose is the most abundant carbon-based material in the living world and is attractive as a source of biofuels, which are plant-derived alternatives to petroleum. It is a significant challenge, however, to find ways to efficiently break down this very stable molecule into simpler fuel molecules.

Do You Understand Concept 2.3?

- Draw the chemical structure of a disaccharide formed by two glucose monosaccharides.
- Examine the glucose molecule shown in Figure 2.9. Identify the functional groups on the molecule.
- Can you see where a large number of hydrogen bonding groups are present in the linear structure of cellulose (see Figure 2.10)? Why is this structure so strong?
- Some sugars have other functional groups in addition to those typically present. Draw the structure of the amino sugar glucosamine, which has an amino group bonded at carbon #2 of glucose. Would this molecule be more or less polar than glucose? Explain why.

(A) Molecular structure

Cellulose is an unbranched polymer of glucose with linkages that are chemically very stable.

Starch and glycogen

Glycogen and starch are polymers of glucose, with branching at carbon 6 (see Figure 2.9).

(B) Macromolecular structure

Linear (cellulose)

Parallel cellulose molecules form hydrogen bonds, resulting in thin fibrils.

Branched (starch)

Branching limits the number of hydrogen bonds that can form in starch molecules, making starch less compact than cellulose.

Highly branched (glycogen)

The high amount of branching in glycogen makes its solid deposits more compact than starch.

(C) Polysaccharides in cells

Layers of cellulose fibrils, as seen in this scanning electron micrograph, give plant cell walls great strength.

Within these potato cells, starch deposits (colored purple in this scanning electron micrograph) have a granular shape.

The dark clumps in this electron micrograph are glycogen deposits in a monkey liver cell.

FIGURE 2.10 Polysaccharides Cellulose, starch, and glycogen are all composed of long chains of glucose but with different levels of branching and compaction.

We have seen that carbohydrates are examples of the monomer–polymer theme in biology. Now we will turn to lipids, which are unusual among the four classes of biological macromolecules in that they are not, strictly speaking, polymers.

concept 2.4 Lipids Are Hydrophobic Molecules

Lipids—colloquially called *fats*—are hydrocarbons (composed of C and H atoms) that are insoluble in water because of their many nonpolar covalent bonds. As you have seen, nonpolar

molecules are hydrophobic and preferentially aggregate together, away from polar water (see Figure 2.6). When nonpolar hydrocarbons are sufficiently close together, weak but additive *van der Waals interactions* (see Table 2.1) hold them together. The huge macromolecular aggregations that can form are not polymers in a strict chemical sense, because the individual lipid molecules are not covalently bonded.

Lipids play several roles in living organisms, including the following:

- They store energy in the C—C and C—H bonds.
- They play important structural roles in cell membranes and on body surfaces, largely because their nonpolar nature makes them essentially insoluble in water.
- Fat in animal bodies serves as thermal insulation.

Fats and oils are triglycerides

The most common units of lipids are **triglycerides**, also known as *simple lipids*. Triglycerides that are solid at room temperature (around 20°C) are called *fats*; those that are liquid at room temperature are called *oils*. A triglyceride contains three *fatty acid* molecules and one *glycerol* molecule. **Glycerol** is a small molecule with three hydroxyl (—OH) groups; thus it is an alcohol. A **fatty acid** consists of a long nonpolar hydrocarbon chain attached to the polar carboxyl (—COOH) group, and it is therefore a carboxylic acid. The long hydrocarbon chain is very hydrophobic because of its abundant C—H and C—C bonds.

Synthesis of a triglyceride involves three condensation reactions (FIGURE 2.11). The resulting molecule has very little polarity and is extremely hydrophobic. That is why fats and oils do not mix with water but float on top of it in separate globules or layers. The three fatty acids in a single triglyceride molecule need not all have the same hydrocarbon chain length or structure; some may be saturated fatty acids, while others may be unsaturated:

- In a **saturated fatty acid**, all the bonds between the carbon atoms in the hydrocarbon chain are single; there are no double bonds. That is, all the available bonds are saturated with hydrogen atoms (FIGURE 2.12A). These fatty acid molecules are relatively rigid and straight, and they pack together tightly, like pencils in a box.
- In an **unsaturated fatty acid**, the hydrocarbon chain contains one or more double bonds. Linoleic acid is an example of a *polyunsaturated* fatty acid that has two double bonds near the middle of the hydrocarbon chain, causing kinks in the chain (FIGURE 2.12B). Such kinks prevent the unsaturated molecules from packing together tightly.

The kinks in fatty acid molecules are important in determining the fluidity and melting point of the lipid. The triglycerides of animal fats tend to have many long-chain saturated fatty acids, which pack tightly together; these fats are usually solid at room temperature and have a high melting point. The triglycerides of plants, such as corn oil, tend to have short or unsaturated fatty acids. Because of their kinks, these fatty acids pack together poorly, have a low melting point, and are usually liquid at room temperature.

FRONTIERS Plant oils can be artificially hydrogenated to make the fatty acids saturated and the lipids less fluid—desirable qualities for cooking certain foods. However, the process also causes double bonds in the “trans” configuration as a side effect: the resulting trans fats have straight-chain, unsaturated fatty acids that for reasons not fully understood lead to coronary artery blockage and heart attacks. While the food industry is racing to improve the hydrogenation process or change formulations to avoid trans fats, many restaurants and cities have banned food containing them as a public health measure.

Fats and oils are excellent storehouses for chemical energy. As you will see in Chapter 6, when the C—H bond is broken, it releases energy that an organism can use for other purposes, such as movement or to build up complex molecules. On a per weight basis, broken-down lipids yield more than twice as much energy as degraded carbohydrates.

Phospholipids form biological membranes

We have mentioned the hydrophobic nature of the many C—C and C—H bonds in a fatty acid. But what about the carboxyl functional group at the end of the molecule? When it ionizes and forms COO[−], it is strongly hydrophilic. So a fatty acid is a molecule with a hydrophilic end and a long hydrophobic tail. It has two opposing chemical properties; the technical term for this is **amphipathic**.

In triglycerides, a glycerol molecule is bonded to three fatty acid chains and the resulting molecule is entirely hydrophobic. **Phospholipids** are like triglycerides in that they contain fatty acids bound to glycerol. However, in phospholipids, a phosphate-containing compound replaces one of the fatty acids, giving these molecules amphipathic properties (FIGURE 2.13A). The phosphate functional group (there are several different kinds in different phospholipids) has a negative electric charge, so this portion of the molecule is hydrophilic, attracting polar water molecules. But the two fatty acids are

FIGURE 2.11 Synthesis of a Triglyceride In living things, the reaction that forms a triglyceride is more complex than the single step shown here.

(A) Palmitic acid

(B) Linoleic acid

FIGURE 2.12 Saturated and Unsaturated Fatty Acids (A) The straight hydrocarbon chain of a saturated fatty acid allows the molecule to pack tightly with other, similar molecules. (B) In unsaturated fatty acids, kinks in the chain prevent close packing.

hydrophobic, so they tend to avoid water and aggregate together or with other hydrophobic substances.

In an aqueous environment, phospholipids line up in such a way that the nonpolar, hydrophobic “tails” pack tightly together and the phosphate-containing “heads” face outward,

where they interact with water. The phospholipids thus form a **bilayer**: a sheet two molecules thick, with water excluded from the core (**FIGURE 2.13B**). Although no covalent bonds link individual lipids in these large aggregations, such stable aggregations form readily in aqueous conditions. Biological membranes have this kind of **phospholipid bilayer** structure, and we will devote Chapter 5 to their biological functions.

(A) Phosphatidylcholine

FIGURE 2.13 Phospholipids (A) Phosphatidylcholine (lecithin) is an example of a phospholipid molecule. In other phospholipids, the amino acid serine, the sugar alcohol inositol, or another compound replaces choline. (B) In an aqueous environment, hydrophobic interactions bring the “tails” of phospholipids together in the interior of a bilayer. The hydrophilic “heads” face outward on both sides of the bilayer, where they interact with the surrounding water molecules.

(B) Phospholipid bilayer

Do You Understand Concept 2.4?

- What is the difference between fats and oils?
- Why are phospholipids amphipathic, and how does this result in a lipid bilayer membrane?
- If fatty acids are carefully put onto the surface of water, they form a single molecular layer. If the mixture is then shaken vigorously, the fatty acids will form hollow, round structures called micelles. Explain these observations.

Molecules such as carbohydrates and lipids are not always stable in living systems. Rather, a hallmark of life is its *ability to transform molecules*. This involves making and breaking covalent bonds, as atoms are removed and others are attached. As part of our introduction to biochemical concepts, we will now turn to these processes of chemical change.

concept 2.5

Biochemical Changes Involve Energy

A **chemical reaction** occurs when atoms have sufficient energy to combine, or change their bonding partners. Consider the hydrolysis of the disaccharide sucrose to its component monomers, glucose and fructose (see p. 25 for the chemical structures). We can express this reaction by a chemical equation:

In this equation, sucrose and water are the **reactants**, and glucose and fructose are the **products**. Electrons and protons are transferred from the reactants to the products. The products of this reaction have very different properties from the reactants. The sum total of all the chemical reactions occurring in a biological system at a given time is called **metabolism**. Metabolic reactions involve energy changes; for example, the energy contained in the chemical bonds of sucrose (reactants) is greater than the energy in the bonds of the two products, glucose and fructose.

What is energy? Physicists define it as the capacity to do work, which occurs when a force operates on an object over a distance. In biochemistry, it is more useful to consider energy as *the capacity for change*. In biochemical reactions, energy changes are usually associated with changes in the chemical composition and properties of molecules.

There are two basic types of energy

Energy comes in many forms: chemical, electrical, heat, light, and mechanical. But all forms of energy can be considered as one of two basic types:

- **Potential energy** is the energy of state or position—that is, stored energy. It can be stored in many forms: in chemical

bonds, as a concentration gradient, or even as an electric charge imbalance.

- **Kinetic energy** is the energy of movement—that is, the type of energy that does work, that makes things change. For example, heat causes molecular motions and can even break chemical bonds.

Potential energy can be converted into kinetic energy and vice versa, and the form that the energy takes can also be converted. Think of reading this book: light energy is converted to chemical energy in your eyes, and then is converted to electrical energy in the nerve cells that carry messages to your brain. When you decide to turn a page, the electrical and chemical energy of nerves and muscles are converted to kinetic energy for movement of your hand and arm.

There are two basic types of metabolism

Energy changes in living systems usually occur as chemical changes, in which energy is stored in or released from chemical bonds.

Anabolic reactions (collectively *anabolism*) link simple molecules to form more complex molecules (for example, the synthesis of sucrose from glucose and fructose). Anabolic reactions require an input of energy—chemists call them *endergonic* or *endothermic* reactions (**FIGURE 2.14A**)—and capture the energy in the chemical bonds that are formed (for example, the glycosidic bond between the two monosaccharides).

Catabolic reactions (collectively *catabolism*) break down complex molecules into simpler ones and release the energy stored in the chemical bonds. Chemists call such reactions *exergonic* or *exothermic* (**FIGURE 2.14B**). For example, when sucrose is hydrolyzed, energy is released.

Catabolic and anabolic reactions are often linked. The energy released in catabolic reactions is often used to drive anabolic reactions—that is, to do biological work. For example, the energy released by the breakdown of glucose (catabolism) is used to drive anabolic reactions such as the synthesis of triglycerides. That is why fat accumulates if you eat food in excess of your energy needs.

Biochemical changes obey physical laws

Recall from the opening of this chapter that we described the mechanistic view of life, whereby living systems obey the same rules that govern the nonliving world. The **laws of thermodynamics** (thermo, “energy”; dynamics, “change”) were derived from studies of the fundamental properties of energy, and the ways energy interacts with matter. These laws apply to all matter and all energy transformations in the universe. Their application to living systems helps us understand how organisms and cells harvest and transform energy to sustain life.

The first law of thermodynamics: Energy is neither created nor destroyed. The first law of thermodynamics states that in any conversion, energy is neither created nor destroyed. Another way of stating this is that the total energy before and after an energy conversion is the same (**FIGURE 2.15A**). [Similarly,

(A) Endergonic reaction

(B) Exergonic reaction

FIGURE 2.14 Energy Changes in Reactions (A) In an endergonic (anabolic) reaction, rolling the ball uphill requires an input of energy. (B) In an exergonic (catabolic) reaction, the reactants behave like a ball rolling down a hill, and energy is released.

(A)

The First Law of Thermodynamics
The total amount of energy before a transformation equals the total amount after a transformation. No new energy is created, and no energy is lost.

(B)

The Second Law of Thermodynamics
Although a transformation does not change the total amount of energy within a closed system (one that is not exchanging matter or energy with the surroundings), after any transformation the amount of energy available to do work is always less than the original amount of energy.

Another statement of the second law is that in a closed system, with repeated energy transformations, free energy decreases and unusable energy (disorder) increases—a phenomenon known as the increase in **entropy**.

FIGURE 2.15 The Laws of Thermodynamics (A) The first law states that energy cannot be created or destroyed. (B) The second law states that after energy transformations, some energy becomes unavailable to do work.

APPLY THE CONCEPT

Biochemical changes involve energy

Chemical reactions in living systems involve changes in energy. These can be expressed as changes in available energy, called free energy (designated G , for Gibbs—the scientist who first described this parameter). The overall direction of a spontaneous chemical reaction is from higher to lower free energy. In other words, if the $G_{\text{reactants}}$ is greater than the G_{products} (negative ΔG), the reaction will be spontaneous; it will tend to go in the direction from reactants to products, and release free energy in the process. Reactions where the $G_{\text{reactants}}$ is less than the G_{products} (positive ΔG) will occur only if additional free energy is supplied.

REACTION	REACTANTS	PRODUCTS	ΔG
Hydrolysis of sucrose:	sucrose + H ₂ O	→ glucose + fructose	7.0
Triglyceride attachment:	glycerol + fatty acid	→ monoglyceride	3.5
Photosynthesis:	6 CO ₂ + 6 H ₂ O	→ glucose + 6 O ₂	686

The table shows some reactions and the absolute values of their associated free energy changes (ΔG).

1. For each reaction, would you expect ΔG to be positive or negative?
2. Which reactions will be spontaneous? Explain your answers.

matter is also conserved: in the hydrolysis of sucrose (see p. 29), there are 12 carbons, 24 hydrogens, and 12 oxygens on both sides of the equation.]

Although the total amount of energy is conserved, chemical reactions involve changes in the amount of (potential) energy stored in chemical bonds. If energy is released during the reaction, it is available to do work—for example, to drive another chemical reaction. In general, reactions that release energy (catabolic, or exergonic reactions) can occur spontaneously.

The second law of thermodynamics: Disorder tends to increase. Although energy cannot be created or destroyed, the second law of thermodynamics implies that when energy is converted from one form to another, some of that energy becomes unavailable for doing work (FIGURE 2.15B). In other words, no physical process or chemical reaction is 100 percent efficient; some of the released energy is lost in a form associated with disorder. Think of disorder as a kind of randomness caused by the thermal motion of particles; this energy is so dispersed that it is unusable. Entropy is a measure of the disorder in a system.

If a chemical reaction increases entropy, its products are more disordered or random than its reactants. The disorder in a solution of glucose and fructose is greater than that in a solution of sucrose, where the glycosidic bond between the two monosaccharides prevents free movement. Conversely, if there are fewer products and they are more restrained in their movements than the reactants, the disorder is reduced. But this requires an energy input to achieve.

The second law of thermodynamics predicts that, as a result of energy transformations, disorder tends to increase; some energy is always lost to random thermal motion (entropy). Chemical changes, physical changes, and biological processes all tend to increase entropy (see Figure 2.15B), and this tendency gives direction to these processes. Changes in entropy are mathematically related to changes in free energy, and thus the second law helps to explain why some reactions proceed in one direction rather than another.

How does the second law of thermodynamics apply to organisms? Consider the human body, with its highly organized

tissues and organs composed of large, complex molecules. This level of complexity appears to be in conflict with the second law, but for two reasons, it is not. First, the construction of complex molecules also generates disorder. The anabolic reactions needed to construct 1 kg of an animal body require the catabolism of about 10 kg of food. So metabolism creates far more disorder (more energy is lost to entropy) than the amount of order stored in flesh. Second, life requires a constant input of energy to maintain order. Without this energy, the complex structures of living systems would break down. Because energy is used to generate and maintain order, there is no conflict with the second law of thermodynamics.

Do You Understand Concept 2.5?

- Describe the forms of energy and changes involved in reading this book.
- What is the difference between potential energy and kinetic energy? Between anabolism and catabolism? Between endergonic and exergonic reactions?
- Predict whether these situations are endergonic or exergonic and explain your reasoning:
 - a. The formation of a lipid bilayer membrane
 - b. Turning on a TV set

Why is the search for water important in the search for life?

ANSWER You have seen throughout this chapter that water is essential for the chemistry of life. Water is composed of two of the most abundant elements (Concept 2.1), and it is a polar molecule (Concept 2.2). This allows biologically important polar molecules such as monosaccharides (Concept 2.3) to dissolve in water. Because of their hydrophobicity,

lipids interact with water to form important biological structures (Concept 2.4). Water molecules participate directly in the formation and breakdown of polymers (Concept 2.2). In short, all of the processes of life as we know it require water.

In the opening essay of this chapter, we described recent evidence for the presence of water on other bodies in our solar system. Could this water harbor life, now or in the past? One way to investigate this possibility is to study how life on Earth may have originated in an aqueous environment. Geological evidence suggests that Earth was formed about 4.5 billion years ago, and that life arose about 3.8 billion years ago. During the time when life originated, there was apparently little oxygen gas (O_2) in the atmosphere. In the 1950s, Stanley Miller and Harold Urey at the University of Chicago set up an experimental “atmosphere” containing various gases thought to be present in Earth’s early atmosphere. Among them were ammonia (NH_3), hydrogen (H_2), methane (CH_4), and (importantly) water vapor (H_2O). Miller and Urey passed an electric spark over the mixture to simulate lightning, providing a source of energy for covalent bond formation. Then they cooled the system so the gases would condense and collect in a watery solution, or “ocean” (FIGURE 2.16). Note that water was essential for this experiment as a source of oxygen atoms.

After several days of continuous operation, the system contained numerous complex molecules, including amino acids, nucleotides, and sugars—the building blocks of life. In later experiments the researchers added other gases, such as carbon dioxide (CO_2), nitrogen (N_2), and sulfur dioxide (SO_2). This resulted in the formation of functional groups such as carboxylic acids, fatty acids, and pentose sugars. Taken together, these data suggest a plausible mechanism for the formation of life’s chemicals in the aqueous environment of early Earth.

Synthesis of Prebiotic Molecules

INVESTIGATION

FIGURE 2.16 Synthesis of Prebiotic Molecules in an Experimental Atmosphere

With an increased understanding of the atmospheric conditions that existed on primitive Earth, the researchers devised an experiment to see if these conditions could lead to the formation of organic molecules.

CONCLUSION

The chemical building blocks of life could have been generated in the probable atmosphere of early Earth.

ANALYZE THE DATA

The following data show the amount of energy impinging on Earth in different forms.

Source	Energy ($\text{cal cm}^{-2} \text{yr}^{-1}$)
Total radiation from sun	260,000
Ultraviolet light	
Wavelength <2500 nm	570
Wavelength <2000 nm	85
Wavelength <1500 nm	3.5
Electric discharges	4
Cosmic rays	0.0015
Radioactivity	0.8
Volcanoes	0.13

- Only a small fraction of the sun’s energy is ultraviolet light (less than 2500 nm). What is the rest of the solar energy?
- The molecules CH_4 , H_2O , NH_3 , and CO_2 absorb light at wavelengths less than 2000 nm. What fraction of total solar radiation is in this range?
- Instead of electric discharges, what other sources of energy could be used in these experiments?

SUMMARY

concept 2.1 Atomic Structure Is the Basis for Life's Chemistry

- Matter is composed of atoms. Each **atom** consists of a positively charged **nucleus** made up of **protons** and **neutrons**, surrounded by **electrons** bearing negative charges.
- The number of protons in the nucleus defines an **element**. There are many elements in the universe, but only a few of them (C, H, O, P, N, and S) make up the bulk of living organisms.
- Electrons are distributed in **electron shells** at varying energy levels away from the nucleus. The first shell has a maximum of two electrons, and subsequent shells have maxima of eight electrons. **Review Figure 2.1**

concept 2.2 Atoms Interact and Form Molecules

- A **chemical bond** is an attractive force that links two atoms together in a molecule. **Review ANIMATED TUTORIAL 2.1**
- **Ions** are electrically charged bodies that form when atoms gain or lose one or more electrons in order to form more stable electron configurations. **Anions** and **cations** are negatively and positively charged ions, respectively. **Ionic bonds** form when ions with opposite charges attract. **Review Figure 2.2**
- A **covalent bond** is a strong bond formed when two atoms share one or more pairs of electrons. **Review Figures 2.3 and 2.4**
- When two atoms of unequal electronegativity bond with each other, a **polar covalent bond** is formed. The two ends, or poles, of the bond have partial charges (δ^+ or δ^-). A **hydrogen bond** is a weak electrical attraction that forms between a δ^+ hydrogen atom in one molecule and a δ^- atom in another molecule (or in another part of a large molecule). Hydrogen bonds are abundant in water. **Review Figure 2.5**
- **Functional groups** are covalently bonded groups of atoms that confer specific properties on biological molecules.
- **Macromolecules** are formed via condensation reactions that link together monomers containing particular functional groups. **Review Figure 2.7, ANIMATED TUTORIAL 2.2, and WEB ACTIVITY 2.1**

concept 2.3 Carbohydrates Consist of Sugar Molecules

- **Carbohydrates** contain carbon bonded to hydrogen and oxygen.
- **Monosaccharides** include pentoses (with five carbons) and hexoses (with six carbons). **Review Figure 2.9 and WEB ACTIVITY 2.2**
- Glycosidic linkages are covalent bonds between saccharides. **Disaccharides** such as sucrose each contain two monosaccharides, whereas **polysaccharides** such as starch and cellulose contain long chains of monomers. **Review Figure 2.10**

concept 2.4 Lipids Are Hydrophobic Molecules

- Fats and oils are **triglycerides**, composed of three **fatty acids** covalently linked to glycerol. **Review Figure 2.11**
- **Saturated fatty acids** have hydrocarbon chains with no double bonds. **Unsaturated fatty acids** contain double bonds in their hydrocarbon chains. **Review Figure 2.12**
- **Phospholipids** contain two fatty acids and a hydrophilic, phosphate-containing polar group attached to glycerol. They are **amphipathic**, with both polar and nonpolar ends. They form into a structural bilayer in water. **Review Figure 2.13**

concept 2.5 Biochemical Changes Involve Energy

- A **chemical reaction** occurs when atoms have sufficient energy to combine or change their bonding partners.
- **Anabolic reactions** are endergonic and require energy. **Catabolic reactions** release energy and are exergonic. **Review Figure 2.14**
- The **laws of thermodynamics** govern biochemical reactions. The first law states that in any transformation, energy is neither created nor destroyed. The second law states that disorder tends to increase. **Review Figure 2.15**

Nucleic Acids, Proteins, and Enzymes

3

Despite suffering from the “ague,” the Reverend Edward Stone went walking in the English countryside. Feverish, tired, with aching muscles and joints, he came across a willow tree. Although apparently unaware that many ancient healers used willow bark extracts to reduce fever, the clergyman knew of the tradition of natural remedies for various diseases. The willow reminded him of the bitter extracts from the bark of South American trees then being sold (at high prices) to treat fevers. Removing some willow bark, Stone sucked on it and found it did indeed taste bitter—and that it relieved his symptoms.

Later he gathered a pound of willow bark and ground it into a powder, which he gave to about 50 people who complained of pain; all said they felt better. Stone reported the results of this “clinical test” in a letter to the Royal Society, England’s most respected scientific body. Stone had discovered salicylic acid, the basis of the most widely used drug in the world. The date of his letter (which still exists) was April 25, 1763.

The chemical structure of salicylic acid (named for *Salix*, the willow genus) was worked out about 70 years later, and soon chemists could synthesize it in the laboratory. Although the compound alleviated pain, its acidity irritated the digestive system. In the late 1890s, the German chemical company Bayer synthesized a milder yet equally effective form, acetylsalicylic acid, which it marketed as aspirin. The new medicine’s success launched Bayer to world prominence as a pharmaceutical company, a position it maintains today.

In the 1960s and 1970s, aspirin use declined when two alternative medications, acetaminophen (Tylenol®) and ibuprofen (Motrin® and Advil®), became widely available. But over this same time, clinical

studies revealed a new use for aspirin: it is an effective anticoagulant, shown to prevent heart attacks and strokes caused by blood clots. Today many people take a daily low dose of aspirin as a preventive against clotting disorders.

Fever, joint pain, headache, blood clots. What do these symptoms have in common? They all are mediated by fatty acid products called prostaglandins and molecules derived from them. Salicylic acid blocks the synthesis of the primary prostaglandin. The exact biochemical mechanism by which aspirin works was described in 1971, and as we will see, it requires understanding protein and enzyme function—two subjects of this chapter.

The bark of the willow tree (*Salix alba*) was the original source of salicylic acid, later modified to aspirin.

How does an understanding of proteins and enzymes help to explain how aspirin works?

KEY CONCEPTS

- 3.1** Nucleic Acids Are Informational Macromolecules
- 3.2** Proteins Are Polymers with Important Structural and Metabolic Roles
- 3.3** Some Proteins Act as Enzymes to Speed up Biochemical Reactions
- 3.4** Regulation of Metabolism Occurs by Regulation of Enzymes

concept 3.1 Nucleic Acids Are Informational Macromolecules

Nucleic acids are polymers specialized for the storage, transmission, and use of genetic information. There are two types of nucleic acids: **DNA** (*deoxyribonucleic acid*) and **RNA** (*ribonucleic acid*). DNA encodes hereditary information, and through RNA intermediates, the information encoded in DNA is used to specify the amino acid sequences of proteins. As you will see later in this chapter, proteins are essential in metabolism and structure. So ultimately, *DNA and the proteins encoded by DNA determine metabolic functions.*

Nucleotides are the building blocks of nucleic acids

Nucleic acids are polymers composed of monomers called nucleotides. A **nucleotide** consists of three components: a nitrogen-containing **base**, a pentose sugar, and one to three phosphate groups (**FIGURE 3.1**). Molecules consisting of a pentose sugar and a nitrogenous base—but no phosphate group—are called *nucleosides*. The nucleotides that make up nucleic ac-

FIGURE 3.1 Nucleotides Have Three Components Nucleotide monomers are the building blocks of DNA and RNA polymers. Nucleotides may have one to three phosphate groups; those in DNA and RNA have one.

Nucleic Acid Building Blocks

TABLE 3.1 Distinguishing RNA from DNA

NUCLEIC ACID	SUGAR	BASES	STRANDS
RNA	Ribose	Adenine	Single
		Cytosine	
		Guanine	
		Uracil	
DNA	Deoxyribose	Adenine	Double
		Cytosine	
		Guanine	
		Thymine	

ids contain just one phosphate group—they are nucleoside *monophosphates*.

The bases of the nucleic acids take one of two chemical forms: a six-membered single-ring structure called a **pyrimidine**, or a fused double-ring structure called a **purine** (see Figure 3.1). In DNA, the pentose sugar is **deoxyribose**, which differs from the **ribose** found in RNA by the absence of one oxygen atom (see Figure 2.9).

During the formation of a nucleic acid, new nucleotides are added to an existing chain one at a time. The pentose sugar and phosphate provide the hydroxyl functional groups for the linkage of one nucleotide to the next. This is done through a condensation reaction (see Figure 2.8), and the resulting bond is called a **phosphodiester linkage**. The linkage reaction always occurs between the phosphate on the new nucleotide (which is located at the 5'-carbon atom on the sugar) and the carbon at the 3' position on the last sugar in the existing chain. Thus, *nucleic acids grow in the 5' to 3' direction* (**FIGURE 3.2**).

Nucleic acids can be oligonucleotides, with about 20 nucleotide monomers, or longer polynucleotides:

- *Oligonucleotides* include RNA molecules that function as “primers” to begin the duplication of DNA; RNA molecules that regulate the expression of genes; and synthetic DNA molecules used for amplifying and analyzing other, longer nucleotide sequences.
- *Polynucleotides*, more commonly referred to as nucleic acids, include DNA and most RNA. Polynucleotides can be very long, and indeed are the longest polymers in the living world. Some DNA molecules in humans contain hundreds of millions of nucleotides.

Base pairing occurs in both DNA and RNA

DNA and RNA differ somewhat in their sugar groups, bases, and general structures (**TABLE 3.1**). Four bases are found in DNA: **adenine (A)**, **cytosine (C)**, **guanine (G)**, and **thymine (T)**. RNA is also made up of four different monomers, but its nucleotides have **uracil (U)** instead of thymine. The sugar in DNA is deoxyribose, whereas the sugar in RNA is ribose. The lack of a hydroxyl group at the 2' position in DNA makes its structure less flexible than that of RNA, which, unlike DNA, can form a variety of structures.

FIGURE 3.2 Linking Nucleotides Together

Growth of a nucleic acid (RNA in this figure) from its monomers occurs in the 5' (phosphate) to 3' (hydroxyl) direction.

The key to understanding the structure and function of nucleic acids is the principle of **complementary base pairing**. In DNA, adenine and thymine always pair (A-T), and cytosine and guanine always pair (C-G):

In RNA, the base pairs are A-U and C-G. Base pairs are held together primarily by *hydrogen bonds*. As you can see, there are polar C=O and N—H covalent bonds in the bases; these can form hydrogen bonds between the δ^- on an oxygen or nitrogen of one base and the δ^+ on a hydrogen of another base.

Individual hydrogen bonds are relatively weak, but there are so many of them in a DNA or RNA molecule that collectively they provide a considerable force of attraction, which can bind together two polynucleotide strands, or a single strand that folds back onto itself. This attraction is not as strong as a covalent bond, however. This means that base pairs are relatively easy to break with a modest input of energy. As you will see, the breaking and making of hydrogen bonds in nucleic acids is vital to their role in living systems.

LINK Hydrogen bonds play an essential role in the chemistry of life; see Concept 2.2

DNA Structure

RNA Usually, RNA is single-stranded (**FIGURE 3.3A**). However, many single-stranded RNA molecules fold up into three-dimensional structures, because of hydrogen bonding between ribonucleotides in separate portions of the molecules (**FIGURE 3.3B**). This results in a three-dimensional surface for the bonding and recognition of other molecules. It is important to realize that this folding occurs by complementary base pairing, and the structure is thus determined by the particular order of bases in the RNA molecule.

In RNA, the bases are attached to ribose. The bases in RNA are the purines adenine (A) and guanine (G) and the pyrimidines cytosine (C) and uracil (U).

FRONTIERS Molecules that interact specifically with a molecule of interest are very important tools in research and medicine. Scientists found recently (and surprisingly) that it is possible to design oligonucleotides in the lab that will fold into specific three-dimensional shapes as a result of complementary base pairing. These shapes are determined by the base sequences of the nucleotide strands. Some of these oligonucleotides, called aptamers, can bind particular small-molecule targets. Aptamers are used in research and are being developed for use as drugs and in diagnostic tests.

DNA Usually, DNA is double-stranded; that is, it consists of two separate polynucleotide strands of the same length (**FIGURE 3.4A**). In contrast to RNA's diversity in three-dimensional structure, DNA is remarkably uniform. The A-T and G-C base pairs are about the same size (each is a purine paired with a pyrimidine), and the two polynucleotide strands form a "ladder" that twists into a double helix (**FIGURE 3.4B**). The sugar-phosphate groups form the sides of the ladder, and the bases with their hydrogen bonds form the rungs on the inside. DNA carries genetic information in its sequence of base pairs rather than in its three-dimensional structure. The key differences among DNA molecules are manifest in their different nucleotide base sequences.

FIGURE 3.3 RNA (A) RNA is usually a single strand. (B) When a single-stranded RNA folds in on itself, hydrogen bonds between complementary sequences can stabilize it into a three-dimensional shape with complicated surface characteristics.

DNA carries information and is expressed through RNA

DNA is a purely *informational* molecule. The information is encoded in the sequence of bases carried in its strands. For example, the information encoded in the sequence TCAGCA is different from the information in the sequence CCAGCA. DNA has two functions in terms of information:

- DNA can be reproduced exactly. This is called *DNA replication*. It is done by polymerization using an existing strand as a base-pairing template.
- Some DNA sequences can be copied into RNA, in a process called *transcription*. The nucleotide sequence in the RNA can then be used to specify a sequence of amino acids in a polypeptide chain. This process is called *translation*. The overall process of transcription and translation is called *gene expression*:

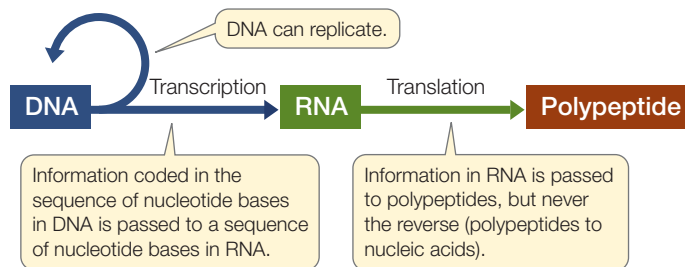

FIGURE 3.4 DNA

(A) DNA usually consists of two strands running in opposite directions that are held together by hydrogen bonds between purines on one strand and pyrimidines on the opposing strand. (B) The two strands in a DNA molecule are coiled in a double helix.

The details of these important processes are described in later chapters, but it is important to realize two things at this point:

1. *DNA replication and transcription depend on the base pairing properties of nucleic acids.* Recall that the hydrogen-bonded base pairs are A-T and G-C in DNA and A-U and G-C in RNA. Consider this double-stranded DNA region:

5'-TCAGCA-3'

3'-AGTCGT-5'

Transcription of the lower strand will result in a single strand of RNA with the sequence 5'-UCAGCA-3'. Can you figure out what the top strand would produce?

2. *DNA replication usually involves the entire DNA molecule.* Since DNA holds essential information, it must be replicated completely so that each new cell or new organism receives a complete set of DNA from its parent (**FIGURE 3.5A**).

The complete set of DNA in a living organism is called its **genome**. However, not all of the information in the genome is needed at all times and in all tissues, and only small sections of the DNA are transcribed into RNA molecules. The sequences of DNA that encode specific proteins and are transcribed into

RNA are called **genes** (**FIGURE 3.5B**). In humans, the gene that encodes the major protein in hair (keratin) is expressed only in skin cells. The genetic information in the keratin-encoding gene is transcribed into RNA and then translated into a keratin polypeptide. In other tissues such as the muscles, the keratin gene is not transcribed, but other genes are—for example, the genes that encode proteins present in muscles but not in skin.

The DNA base sequence reveals evolutionary relationships

Because DNA carries hereditary information from one generation to the next, a theoretical series of DNA molecules stretches back through the lineage of every organism to the beginning of biological evolution on Earth, about 3.8 billion years ago. The genomes of organisms gradually accumulate changes in their DNA base sequences over evolutionary time. Therefore, closely related living species should have more similar base sequences than species that are more distantly related.

LINK The use of DNA sequences to reconstruct the evolutionary history of life is described in Concept 16.2

FIGURE 3.5 DNA Replication and Transcription DNA is completely replicated during cell reproduction (A), but it is only partially transcribed (B). In transcription, the DNA code is copied as RNA, which encodes the genes for specific proteins. Transcription of the many different proteins is activated at different times and, in multicellular organisms, in different cells of the body.

Remarkable developments in sequencing and computer technology have enabled scientists to determine the entire DNA base sequences of whole organisms, including the human genome, which contains about 3 billion base pairs. These studies have confirmed many of the evolutionary relationships that were inferred from more traditional comparisons of body structure, biochemistry, and physiology. Traditional comparisons had indicated that the closest living relative of humans (*Homo sapiens*) is the chimpanzee (genus *Pan*). In fact, the chimpanzee genome shares more than 98 percent of its DNA base sequence with the human genome. Increasingly, scientists turn to DNA analyses to elucidate evolutionary relationships when other comparisons are not possible or are not conclusive. For example, DNA studies revealed a close relationship between starlings and mockingbirds that was not expected on the basis of their anatomy or behavior.

Do You Understand Concept 3.1?

- List the key differences between DNA and RNA and between purines and pyrimidines.
- What are the differences between DNA replication and transcription?
- If one strand of a DNA molecule has the sequence 5'-TTCCGGAT-3', what is the sequence of the other strand of DNA? If RNA is transcribed from the 5'-TTCCGGAT-3' strand, what would be its sequence? And if RNA is transcribed from the other DNA strand, what would be its sequence?
- How can DNA molecules be so diverse when they appear to be structurally similar?

Nucleic acids are largely informational molecules that encode proteins. We now turn to a discussion of proteins—the most structurally and functionally diverse class of macromolecules.

concept 3.2 Proteins Are Polymers with Important Structural and Metabolic Roles

Proteins are the fourth and final type of biological macromolecule we will discuss, and in terms of structural diversity and function, they are at the top of the list. Here are some of the major functions of proteins in living organisms:

- *Enzymes* are catalytic proteins that speed up biochemical reactions.
- *Defensive proteins* such as antibodies recognize and respond to substances or particles that invade the organism from the environment.
- *Hormonal and regulatory proteins* such as insulin control physiological processes.
- *Receptor proteins* receive and respond to molecular signals from inside and outside the organism.
- *Storage proteins* store chemical building blocks—amino acids—for later use.
- *Structural proteins* such as collagen provide physical stability and movement.
- *Transport proteins* such as hemoglobin carry substances within the organism.
- *Genetic regulatory proteins* regulate when, how, and to what extent a gene is expressed.

Clearly, the biochemistry of proteins warrants our attention!

Amino acids are the building blocks of proteins

As we noted in Chapter 2, proteins are polymers made up of monomers called **amino acids**. As their name suggests, the amino acids all contain two functional groups: the nitrogen-containing amino group and the carboxylic acid group.

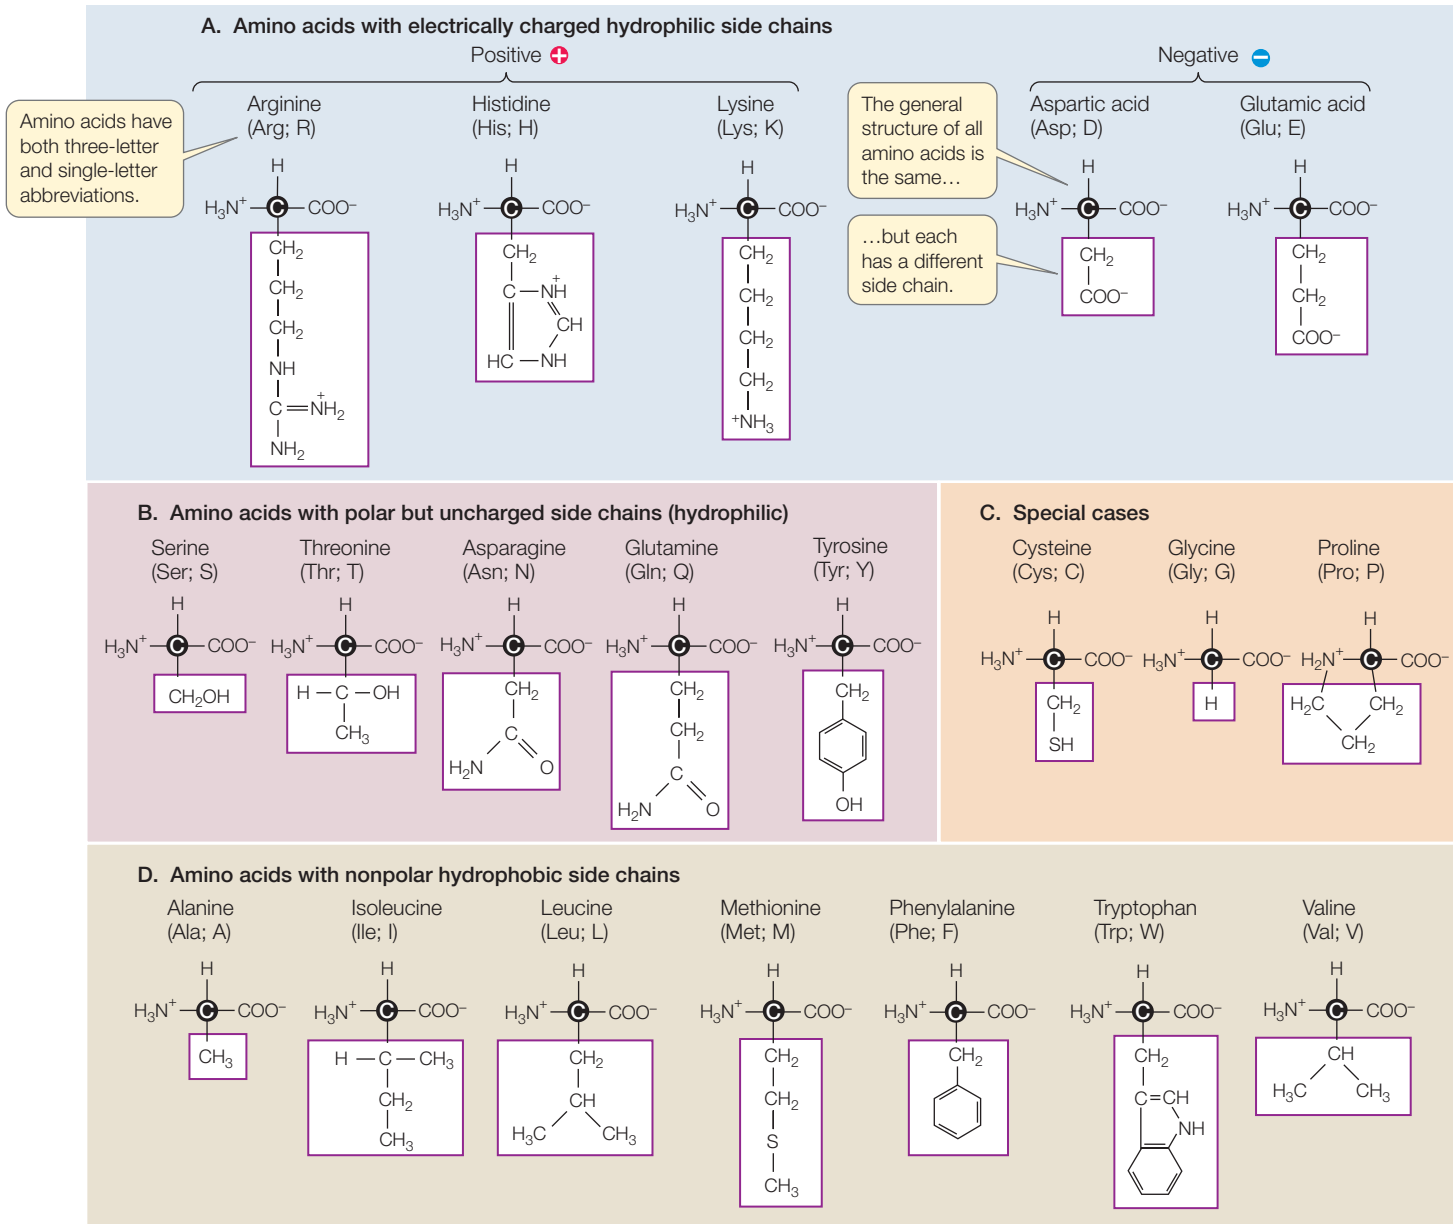

The amino and carboxylic acid groups shown in the diagram are charged. How does this happen? Under the conditions that exist in most living systems, the carboxylic acid group releases a H^+ (a cation), leaving the rest of the group as an anion:

From your studies of chemistry, you may recognize this as an *acid* (hence the name). Conversely, under the same conditions the amino group tends to form a bond with H^+ :

TABLE 3.2 The Twenty Amino Acids in Proteins

Your chemistry knowledge should tell you that this is a *base*. (We will discuss acids and bases in more detail later in this chapter.)

The central carbon atom of an amino acid—the α carbon—has four available electrons for covalent bonding. In all amino acids, two of the electrons are occupied by the two functional groups noted above, and a third is occupied by a hydrogen atom. The fourth bonding electron is shared with a group that differs in each amino acid. This is often referred to as the **R group**, or *side chain*, and is designated by the letter R. Each amino acid is identified by its R group.

There are hundreds of amino acids known in nature, and many of these occur in plants. But *only 20 amino acids* (listed in **TABLE 3.2**) occur extensively in the proteins of all organisms. These 20 amino acids can be grouped according to the properties conferred by their side chains (R groups):

- Five amino acids have electrically charged side chains (+1 or -1), attract water (are hydrophilic), and attract oppositely charged ions of all sorts.
- Five amino acids have polar side chains (δ^+ , δ^-) and tend to form hydrogen bonds with water and other polar or charged substances. These amino acids are also hydrophilic.
- Seven amino acids have side chains that are nonpolar hydrocarbons or very slightly modified hydrocarbons. In the watery environment of the cell, these hydrophobic side chains may cluster together in the interior of the protein. These amino acids are hydrophobic.

Three amino acids—cysteine, glycine, and proline—are special cases, although the side chains of the latter two generally are hydrophobic:

- The *cysteine* side chain, which has a terminal —SH group, can react with another cysteine side chain to form a covalent bond called a **disulfide bridge**, or *disulfide bond* (—S—S—). Disulfide bridges help determine how a polypeptide chain folds.

- The *glycine* side chain consists of a single hydrogen atom and is small enough to fit into tight corners in the interior of a protein molecule, where a larger side chain could not fit.
- Proline* possesses a modified amino group that lacks a hydrogen and instead forms a covalent bond with the hydrocarbon side chain, resulting in a ring structure. This limits both its hydrogen-bonding ability and its ability to rotate. Thus proline often functions to stabilize bends or loops in proteins.

Features of Amino Acids

Amino acids are bonded to one another by peptide linkages

Like nucleotides, amino acids can form short polymers of 20 or fewer amino acids, called *oligopeptides* or simply *peptides*. These include some hormones and other molecules involved in signaling from one part of an organism to another. Even with their relatively short chains of amino acids, oligopeptides have distinctive three-dimensional structures.

More common are the longer polymers called *polypeptides* or *proteins*. Each protein has its own unique proportion and sequence of the 20 amino acids. Proteins range in size from small ones such as insulin, which has a molecular weight of 5,808 daltons and 51 amino acids, to huge molecules such as the muscle protein titin, with a molecular weight of 3,816,188 daltons and 34,350 amino acids. (See p. 17 for a definition of daltons.)

Like nucleic acids, proteins and peptides form via the sequential addition of new amino acids to the ends of existing chains. The amino group of the new amino acid reacts with the carboxyl group of the amino acid at the end of the chain. This condensation reaction forms a **peptide linkage** (also called a *peptide bond*;

FIGURE 3.6). Note that there is directionality here, just as with the nucleic acids. In this case, polymerization takes place in the *amino to carboxyl direction*.

The precise sequence of amino acids in a polypeptide chain constitutes the **primary structure** of a protein. Scientists have determined the primary structures of many proteins. The single-letter abbreviations for amino acids (see Table 3.2) are used to record the amino acid sequences of proteins. Here, for example, are the first 20 amino acids (out of a total of 1,827) in the human protein sucrose:

MARKKFSGLEISLIVLFVIV

The theoretical number of different proteins is enormous. Since there are 20 different amino acids, there could be $20 \times 20 = 400$ distinct dipeptides (two linked amino acids), and $20 \times 20 \times 20 = 8,000$ different tripeptides (three linked amino acids). So for even a small polypeptide of 100 amino acids there are 20^{100} possible sequences, each with its own distinctive primary structure. How large is the number 20^{100} ? Physicists tell us there aren't that many electrons in the entire universe.

FIGURE 3.6 Formation of a Peptide Linkage In living things, the reaction leading to a peptide linkage (also called a peptide bond) has many intermediate steps, but the reactants and products are the same as those shown in this simplified diagram.

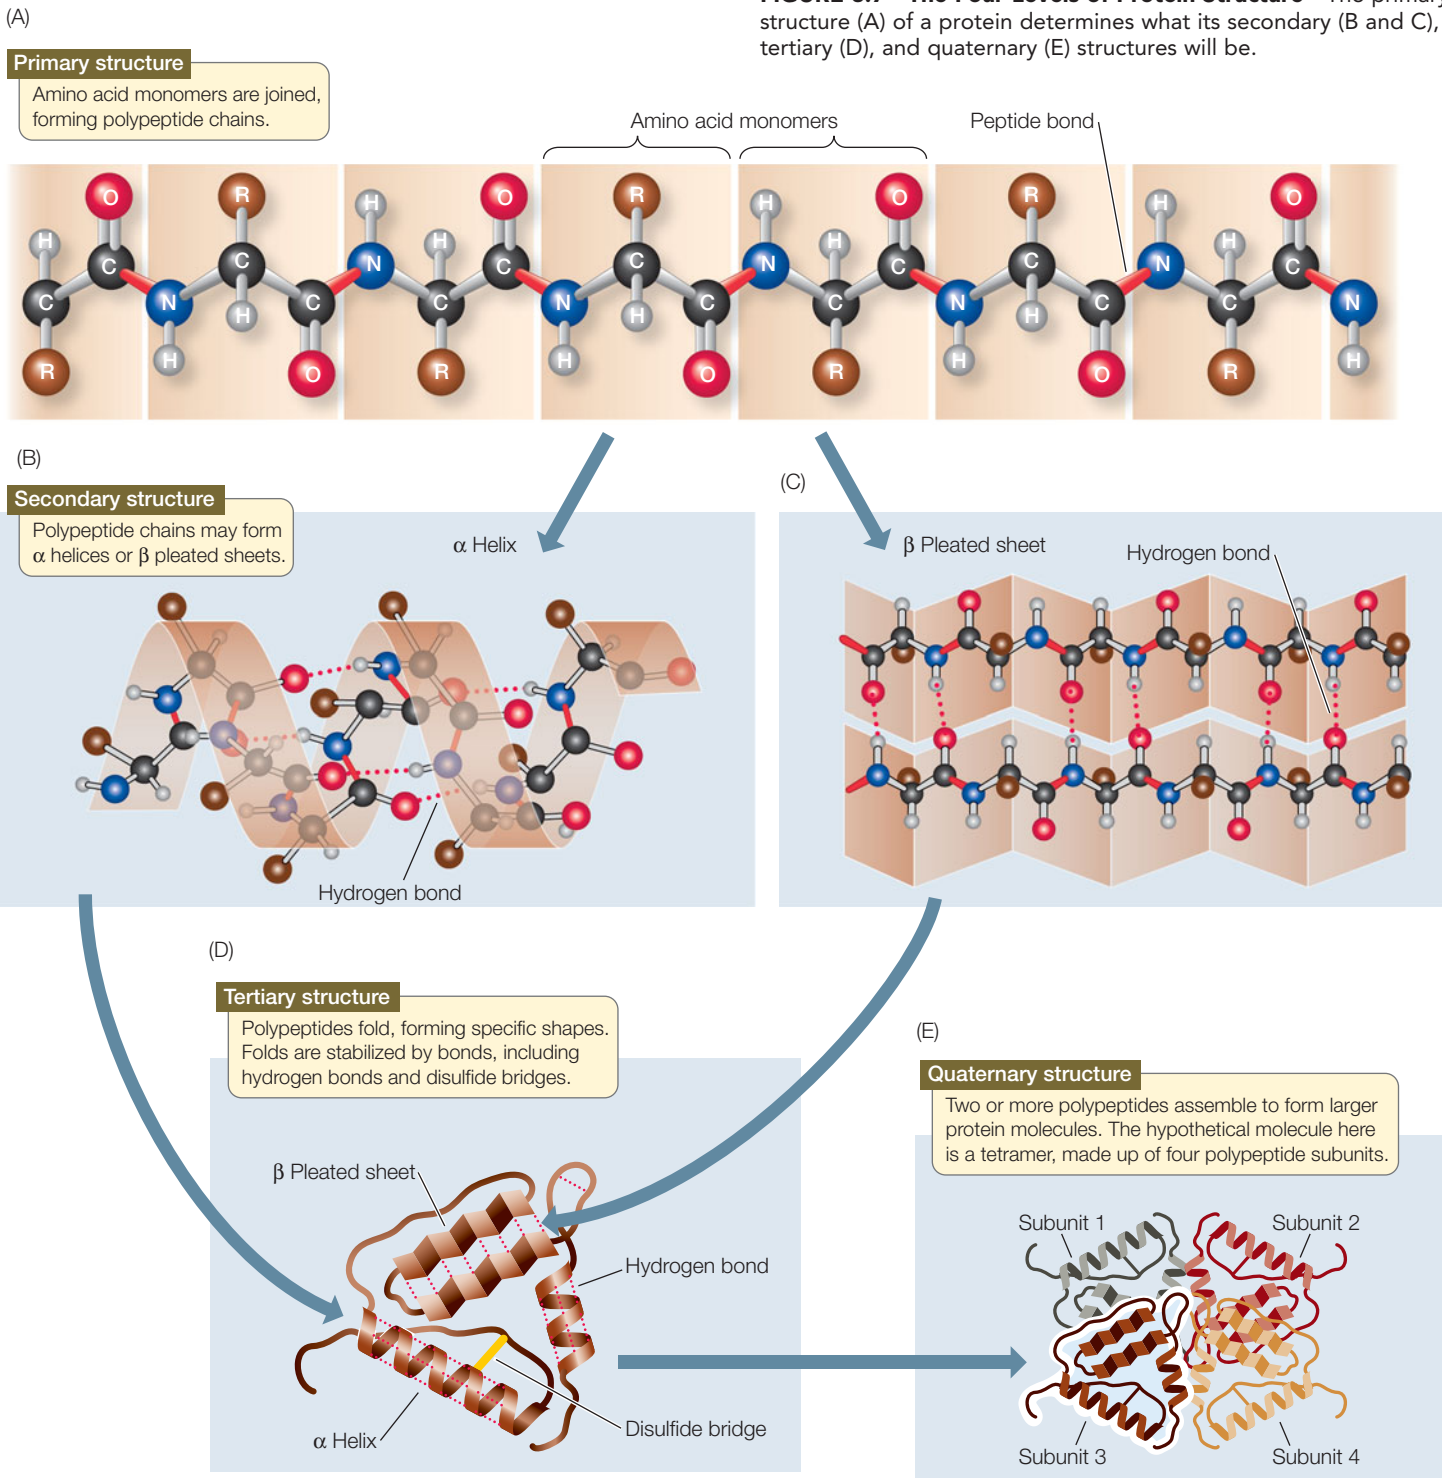

Higher-level protein structure is determined by primary structure

The primary structure of a protein is established by covalent bonds, but higher levels of structure are determined largely by weaker forces, including hydrogen bonds and hydrophobic and hydrophilic interactions. Follow **FIGURE 3.7** as we describe how a protein chain becomes a three-dimensional structure.

SECONDARY STRUCTURE A protein's **secondary structure** consists of regular, repeated spatial patterns in different regions of a polypeptide chain. There are two basic types of secondary structure, both determined by hydrogen bonding between the amino acids that make up the primary structure:

- The **α (alpha) helix** is a right-handed coil that turns in the same direction as a standard wood screw (see Figure 3.7B). The R groups extend outward from the peptide backbone of

FIGURE 3.7 The Four Levels of Protein Structure The primary structure (A) of a protein determines what its secondary (B and C), tertiary (D), and quaternary (E) structures will be.

the helix. The coiling results from hydrogen bonds that form between the N—H group on one amino acid and the C=O group on another within the same turn of the helix.

- The **β (beta) pleated sheet** is formed from two or more polypeptide chains that are extended and aligned. The sheet is stabilized by hydrogen bonds between the N—H groups and the C=O groups on the two chains (see Figure 3.7C). A β pleated sheet may form between separate polypeptide chains or between different regions of a single polypeptide chain that is bent back on itself. Many proteins contain both α helices and β pleated sheets in different regions of the same polypeptide chain.

TERTIARY STRUCTURE In many proteins, the polypeptide chain is bent at specific sites and then folded back and forth, resulting in the **tertiary structure** (see Figure 3.7D). Tertiary structure results in the polypeptide's definitive three-dimensional shape, including a buried interior as well as a surface that is exposed to the environment. The protein's exposed outer surfaces present functional groups capable of interacting with other molecules in the cell. These molecules might be other proteins or smaller chemical reactants (as in enzymes; see below).

Whereas hydrogen bonding between the N—H and C=O groups within and between chains is responsible for a protein's secondary structure, it is the interactions between R groups—the amino acid side chains—that determine tertiary structure (FIGURE 3.8):

- Covalent *disulfide bridges* can form between specific cysteine side chains, holding a folded polypeptide together.
- *Hydrogen bonds* between side chains also stabilize folds in proteins.

FIGURE 3.8 Noncovalent Interactions between Proteins and Other Molecules Noncovalent interactions allow a protein (brown) to bind tightly to another protein (green) with specific properties. Noncovalent interactions also allow regions within the same protein to interact with one another.

- *Hydrophobic* side chains can aggregate together in the interior of a protein, away from water, folding the polypeptide in the process.
- *van der Waals interactions* can stabilize close associations between hydrophobic side chains.
- *Ionic interactions* can form between positively and negatively charged side chains, forming *salt bridges* between amino acids. Ionic bonds can also be buried deep within a protein, away from water.

LINK Review the strong and weak interactions that can occur between atoms, described in Concept 2.2

A complete description of a protein's tertiary structure would specify the location of every atom in the molecule in three-dimensional space, relative to all the other atoms. Many such descriptions are available, including one for the human protein sucrase (FIGURE 3.9).

Remember that both secondary and tertiary structure derive from primary structure. If a protein is heated slowly, the heat energy will disrupt only the weaker interactions, causing the secondary and tertiary structure to break down. The protein is then said to be **denatured**. But in many cases the protein can return to its normal tertiary structure when it cools, demonstrating that all the information needed to specify its unique shape is contained in its primary structure. This was first shown (using chemicals instead of heat to denature the protein) by biochemist Christian Anfinsen for the protein ribonuclease (FIGURE 3.10).

FIGURE 3.9 The Structure of a Protein Sucrase has a specific three-dimensional structure, determined by its primary structure. Sucrase plays a role in digestion in humans.

INVESTIGATION

FIGURE 3.10 Primary Structure Specifies Tertiary Structure Using the protein ribonuclease, Christian Anfinsen showed that proteins spontaneously fold into a functionally correct three-dimensional configuration. As long as the primary structure is not disrupted, the information for correct folding under the right conditions is retained.

HYPOTHESIS

Under controlled conditions that simulate normal cellular environment in the laboratory, the primary structure of a denatured protein can reestablish the protein's three-dimensional structure.

METHOD Chemically denature functional ribonuclease, disrupting disulfide bridges and other intramolecular interactions that maintain the protein's shape, so that only primary structure (i.e., the amino acid sequence) remains. Once denaturation is complete, remove the disruptive chemicals.

RESULTS When the disruptive agents are removed, three-dimensional structure is restored and the protein once again is functional.

CONCLUSION

In normal cellular conditions, the primary structure of a protein specifies how it folds into a functional, three-dimensional structure.

ANALYZE THE DATA

Initially, disulfide bonds (S—S) in RNase A were eliminated because the sulfur atoms in cysteine were reduced (—SH). At time 0, reoxidation began and at various times, the amount of disulfide bond re-formation (blue circles) and the function of ribonuclease (enzyme activity; red circles) were measured by chemical methods. Here are the data:

- At what time did disulfide bonds begin to form?
- At what time did enzyme activity begin to appear?
- Explain the difference between your answers for the times of (A) and (B).

For more, go to Working with Data 3.1 at yourBioPortal.com.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

QUATERNARY STRUCTURE Many functional proteins contain two or more polypeptide chains, called subunits, each folded into its own unique tertiary structure. The protein's **quaternary structure** results from the ways in which these subunits bind together and interact (see Figure 3.7E). Hemoglobin (at right) is an example of a protein with multiple subunits.

Hydrophobic interactions, hydrogen bonds, and ionic interactions all help hold the four subunits together to form a hemoglobin macromolecule. The weak nature of these forces permits small changes in the quaternary structure to aid the

protein's function—which is to carry oxygen in red blood cells. As hemoglobin binds one O₂ molecule, the four subunits shift their relative positions slightly, changing the quaternary structure. Ionic interactions are broken, exposing buried side chains that enhance the binding of additional O₂ molecules. The quaternary structure changes again when hemoglobin releases its O₂ molecules to the cells of the body.

FRONTIERS Spiderwebs are composed of a protein that is very strong—possibly the strongest material in the living world—because the web must support the weight of the spider and its prey and stretch without breaking. The protein's strength comes from its multiple interlocking β pleated sheets. It is difficult to collect this protein from spiders, so biologists are using genetic engineering to produce it in more tractable organisms such as goats. The mass-produced spider silk will have uses ranging from surgical threads to bulletproof vests.

Environmental conditions affect protein structure

Because they are held together by weak forces, the three-dimensional structures of proteins are influenced by environmental conditions. Conditions that would not break covalent bonds can disrupt the weaker, noncovalent interactions that determine secondary and tertiary structure. Such alterations may affect a protein's shape and thus its function. Various conditions can alter the weak, noncovalent interactions:

- *Increases in temperature* cause more rapid molecular movements and thus can break hydrogen bonds and hydrophobic interactions.
- *Alterations in the concentration of H⁺* can change the patterns of ionization of the exposed carboxyl and amino groups, thus disrupting the patterns of ionic attractions and repulsions.
- *High concentrations of polar substances* such as urea can disrupt the hydrogen bonding that is crucial to protein structure.

- *Nonpolar substances* may also denature a protein in cases where hydrophobic groups are essential for maintaining the protein's structure.

Denaturation can be irreversible when amino acids that were buried in the interior of the protein become exposed at the surface, or vice versa, causing a new structure to form, or causing different molecules to bind to the protein. Boiling an egg denatures its proteins and is, as you know, not reversible.

Do You Understand Concept 3.2?

- What attributes of an amino acid's R group would make it hydrophobic? Hydrophilic?
- Sketch the bonding of two amino acids, glycine and leucine, by a peptide linkage. Now add a third amino acid, alanine, in the position it would have if added within a biological system. What is the directionality of this process?
- Examine the structure of sucrase (see Figure 3.9). Where in the protein might you expect to find the following amino acids: valine, proline, glutamic acid, and threonine? Explain your answers.
- Detergents disrupt hydrophobic interactions by coating hydrophobic molecules with a molecule that has a hydrophilic surface. When hemoglobin is treated with a detergent, the four polypeptide chains separate and become random coils. Explain these observations.

We have discussed the remarkable diversity in protein structures. These structures expose atoms that can allow the proteins to interact with other molecules. In the next section we will see how these interactions can result in catalysis, the remarkable speeding up of biochemical reactions.

APPLY THE CONCEPT

Proteins are polymers with important structural and metabolic roles

Biological systems contain “supermolecular complexes” (for example, the ribosome; see Chapter 4), which are composed of individual molecules of RNA and protein that fit together noncovalently. These complexes can be split apart with detergents that disrupt hydrophobic interactions. Based on the concepts discussed in this chapter, fill in the table at right to indicate which of the observations are characteristic of RNA, which are characteristic of protein, and which are characteristic of both. Explain your answers.

OBSERVATION	CHARACTERISTIC OF:	
	PROTEIN	RNA
Has three-dimensional (3-D) structure		
3-D structure destroyed by heat		
Monomers connected by N—C bonds		
Contains sulfur atoms		
Contains phosphorus atoms		

concept 3.3 Some Proteins Act as Enzymes to Speed up Biochemical Reactions

In Chapter 2 we introduced the concepts of biological energetics. We showed that some metabolic reactions are exergonic and some are endergonic, and that biochemistry obeys the laws of thermodynamics (see Figures 2.14 and 2.15). Knowing whether energy is supplied or released in a particular reaction tells us whether the reaction *can* occur in a living system. But it does not tell us *how fast* the reaction will occur.

Living systems depend on reactions that occur spontaneously, but at such slow rates the cells would not survive without ways to speed them up. That is the role of **catalysts**: substances that speed up reactions without themselves being permanently altered. A catalyst does not cause a reaction to occur that would not proceed without it, *but it increases the rate of the reaction*. This is an important point: *No catalyst makes a reaction occur that cannot otherwise occur*.

Most biological catalysts are proteins called *enzymes*. Although we will focus here on proteins, a few important catalysts are RNA molecules called *ribozymes*. A biological catalyst, whether protein or RNA, provides a molecular structure that binds the reactants and can participate in the reaction itself. However, this participation does not permanently change the enzyme. At the end of the reaction, the catalyst is unchanged and available to catalyze additional, similar reactions.

To speed up a reaction, an energy barrier must be overcome

An exergonic reaction may release free energy, but without a catalyst it will take place very slowly. This is because there is an *energy barrier* between reactants and products. Think about the hydrolysis of sucrose, which we described in Concept 2.5.

In humans, this reaction is part of the process of digestion. Even if water is abundant, the sucrose molecule will not bind the H atom and -OH group of water at the appropriate locations to break the covalent bond between glucose and fructose *unless there is an input of energy to initiate the reaction*. Such an input of energy will place the sucrose into a reactive mode called the **transition state**. The energy input required for sucrose to reach this state is called the **activation energy** (E_a). The following example will help illustrate the ideas of activation energy and transition state:

A spark is needed to excite the molecules in the fireworks so they will react with oxygen in the air. Once the transition state is reached, the reaction occurs (**FIGURE 3.11**).

Where does the activation energy come from? In any collection of reactants at room or body temperature, the molecules are moving around. A few are moving fast enough that their kinetic energy can overcome the energy barrier, enter the transition state, and react. So the reaction takes place—but very

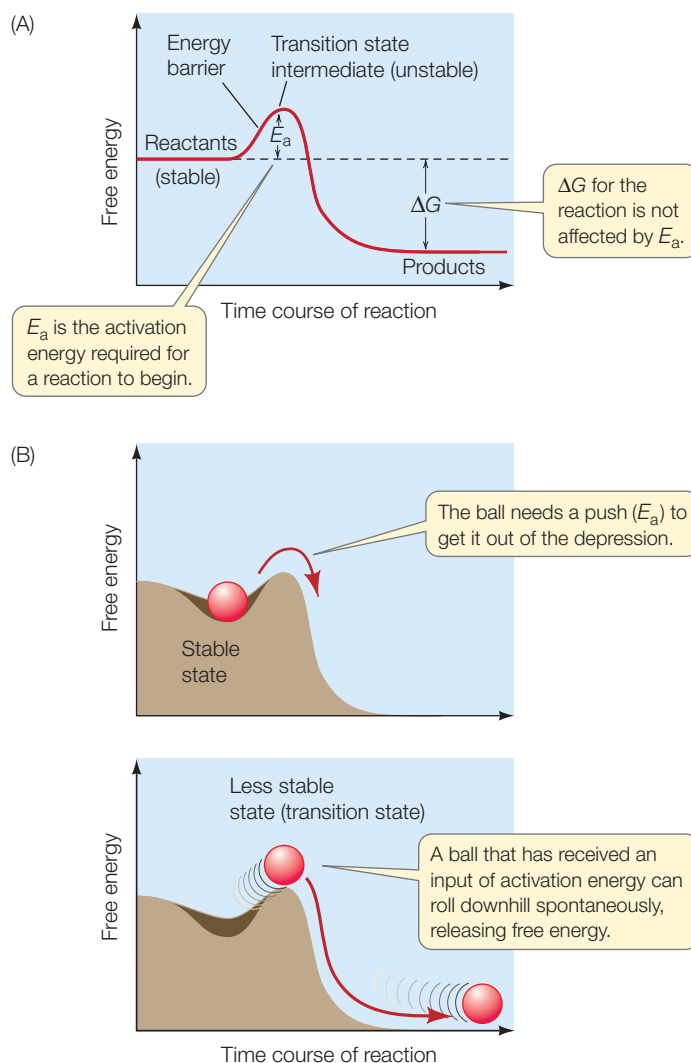

FIGURE 3.11 Activation Energy Initiates Reactions (A) In any chemical reaction, an initial stable state must become less stable before change is possible. (B) A ball on a hillside provides a physical analogy to the biochemical principle graphed in A. Although these graphs show an exergonic reaction, activation energy is needed for endergonic reactions as well.

slowly. If the system is heated, all the reactant molecules move faster and have more kinetic energy, and the reaction speeds up. You have probably used this technique in the chemistry laboratory.

Adding enough heat to increase the average kinetic energy of the molecules would not work in living systems, however. Such a nonspecific approach would accelerate all reactions, including destructive ones such as the denaturation of proteins.

An enzyme lowers the activation energy for the reaction—it offers the reactants an easier path so they can come together and react more easily (**FIGURE 3.12**). In this way, an enzyme can change the rate of a reaction substantially. For example, if a molecule of sucrose just sits in solution, hydrolysis may occur in about 15 days; with sucrase present, the same reaction occurs in 1 second!

FIGURE 3.12 Enzymes Lower the Energy Barrier Although the activation energy (E_a) is lower in an enzyme-catalyzed reaction than in an uncatalyzed reaction, the energy released is the same with or without catalysis. A lower activation energy means the reaction will take place at a faster rate.

Free Energy Changes

Enzymes bind specific reactants at their active sites

Catalysts increase the rates of chemical reactions. Most nonbiological catalysts are nonspecific. For example, powdered platinum catalyzes virtually any reaction in which molecular hydrogen (H_2) is a reactant. In contrast, most biological catalysts are highly specific. An enzyme usually recognizes and binds to only one or a few closely related reactants, and it catalyzes only a single chemical reaction.

In an enzyme-catalyzed reaction, the reactants are called **substrates**. Substrate molecules bind to a particular site on the enzyme, called the **active site**, where catalysis takes place (FIGURE 3.13). The specificity of an enzyme results from the exact three-dimensional shape and chemical properties of its active site. Only a narrow range of substrates, with specific shapes, functional groups, and chemical properties, can fit properly and bind to the active site. The names of enzymes reflect their functions and often end with the suffix “ase.” For example, the enzyme *sucrase* catalyzes the hydrolysis of sucrose, and we write the reaction as follows:

The binding of a substrate to the active site of an enzyme produces an **enzyme-substrate complex (ES)** that is held together by one or more means, such as hydrogen bonding, electrical attraction, or temporary covalent bonding. The enzyme-substrate complex gives rise to product and free enzyme:

where E is the enzyme, S is the substrate, P is the product, and ES is the enzyme-substrate complex. The free enzyme (E) is

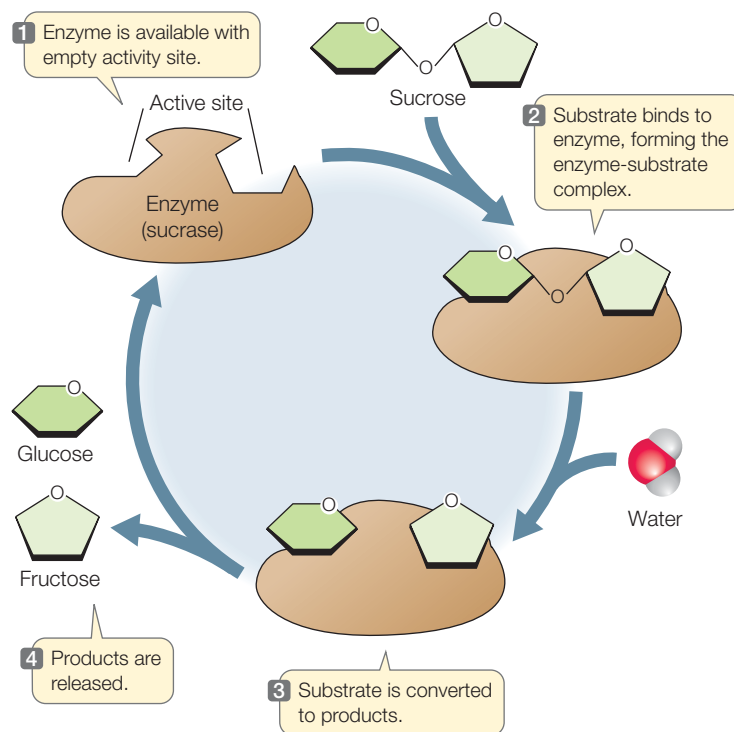

FIGURE 3.13 Enzyme Action Sucrase catalyzes the hydrolysis of sucrose. After the reaction, the enzyme is unchanged and is ready to accept another substrate molecule.

in the same chemical form at the end of the reaction as at the beginning. While bound to the substrate, it may change chemically, but by the end of the reaction it has been restored to its initial form and is ready to bind more substrate (see Figure 3.13).

HOW ENZYMES WORK During and after the formation of the enzyme-substrate complex, chemical interactions occur. These interactions contribute directly to the breaking of old bonds and the formation of new ones. In catalyzing a reaction, an enzyme may use one or more mechanisms:

- **Inducing strain:** Once the substrate has bound to the active site, the enzyme causes bonds in the substrate to stretch, putting it in an unstable transition state:

- **Substrate orientation:** When free in solution, substrates are moving from place to place randomly while at the same time vibrating, rotating, and tumbling. They only rarely have the

proper orientation to react when they collide. The enzyme lowers the activation energy needed to start the reaction, by bringing together specific atoms so that bonds can form.

- **Adding chemical groups:** The side chains (R groups) of an enzyme's amino acids may be directly involved in the reaction. For example, in *acid–base catalysis*, the acidic or basic side chains of the amino acids in the active site transfer H^+ ions to or from the substrate, destabilizing a covalent bond in the substrate and permitting the bond to break.

The active site is usually only a small part of the enzyme protein. But its three-dimensional structure is so specific that it binds only one or a few related substrates. The binding of the substrate to the active site depends on the same relatively weak forces that maintain the tertiary structure of the enzyme: hydrogen bonds, the attraction and repulsion of electrically charged groups, and hydrophobic interactions. Scientists used to think of substrate binding as being similar to a lock and key fitting together. Actually, for most enzymes and substrates the relationship is more like a baseball and a catcher's mitt: the substrate first binds, and then the active site changes slightly to make the binding tight. **FIGURE 3.14** illustrates this “induced fit” phenomenon.

Induced fit at least partly explains why enzymes are so large. The rest of the macromolecule has at least three roles:

- It provides a framework so the amino acids of the active site are properly positioned in relation to the substrate(s).
- It participates in the changes in protein shape and structure that result in induced fit.
- It provides binding sites for regulatory molecules (see Concept 3.4).

FIGURE 3.14 Some Enzymes Change Shape When Substrate Binds to Them Shape changes result in an induced fit between enzyme and substrate, improving the catalytic ability of the enzyme. Induced fit can be observed in the enzyme hexokinase, seen here with and without its substrates, glucose (green) and ATP (yellow).

TABLE 3.3

Some Examples of Nonprotein “Partners” of Enzymes

TYPE OF MOLECULE	ROLE IN CATALYZED REACTIONS
Cofactors	
Iron (Fe^{2+} or Fe^{3+})	Oxidation/reduction
Copper (Cu^+ or Cu^{2+})	Oxidation/reduction
Zinc (Zn^{2+})	Helps bind NAD
Coenzymes	
Biotin	Carries $-COO^-$
Coenzyme A	Carries $-CO-CH_3$
NAD	Carries electrons
FAD	Carries electrons
ATP	Provides/extracts energy
Prosthetic groups	
Heme	Binds ions, O_2 , and electrons; contains iron cofactor
Flavin	Binds electrons
Retinal	Converts light energy

NONPROTEIN PARTNERS FOR ENZYMES Some enzymes require ions or other molecules in order to function (**TABLE 3.3**):

- **Cofactors** are inorganic ions such as copper, zinc, and iron that bind to certain enzymes. For example, the cofactor zinc binds to the enzyme alcohol dehydrogenase.
- A **coenzyme** is a carbon-containing molecule that is required for the action of one or more enzymes. It is usually relatively small compared with the enzyme to which it temporarily binds, and it adds or removes chemical groups from the substrate. A coenzyme is like a substrate in that it does not permanently bind to the enzyme; it binds to the active site, changes chemically during the reaction, and then separates from the enzyme to participate in other reactions. A coenzyme differs from a substrate in that it can participate in many different reactions, with different enzymes.
- **Prosthetic groups** are distinctive, non–amino acid atoms or molecular groupings that are permanently bound to their enzymes. An example is a flavin nucleotide, which binds to succinate dehydrogenase, an important enzyme in energy metabolism.

FRONTIERS Just as proteins can act as catalysts by providing a surface (the active site) that has a particular arrangement of chemical groups, so too can nucleic acids, particularly RNA. Because RNA can also carry genetic information, this has led to the idea that in the evolution of life on Earth, RNA preceded proteins: there was an “RNA world.” Recent research supports this theory by showing that both pyrimidines and purines (attached to ribose) can arise from conditions thought to have existed billions of years ago on Earth.

FIGURE 3.15 Catalyzed Reactions Reach a Maximum

Rate Because there is usually less enzyme than substrate present, the reaction rate levels off when the enzyme becomes saturated.

RATE OF REACTION The rate of an uncatalyzed reaction is directly proportional to the concentration of the substrate. The higher the concentration, the more reactions per unit of time. As we have seen, the addition of the appropriate enzyme speeds up the reaction, but it also changes the shape of the plot of rate versus substrate concentration (FIGURE 3.15). For a given concentration of enzyme, the rate of the enzyme-catalyzed reaction initially increases as the substrate concentration increases from zero, but then it levels off.

Why does this happen? The concentration of an enzyme is usually much lower than that of its substrate and does not change as substrate concentration changes. When all the enzyme molecules are bound to substrate molecules, the enzyme is working at its maximum rate. Under these conditions the active sites are said to be *saturated*.

The maximum rate of a catalyzed reaction can be used to measure how efficient the enzyme is—that is, how many molecules of substrate are converted into product by an individual enzyme molecule per unit of time, when there is an excess of substrate present. This *turnover number* ranges from 1 molecule every second for sucrase to an amazing 40 million molecules per second for the liver enzyme catalase.

Do You Understand Concept 3.3?

- Explain how the structure of an enzyme makes that enzyme specific.
- What is activation energy? How does an enzyme lower the activation energy needed to start a reaction?
- Compare coenzymes with substrates. How do they work together in enzyme catalysis?
- Compare the state of an enzyme active site at a low substrate concentration and at a high substrate concentration. How does this affect the rate of the reaction?

Now that you understand more about how enzymes function, let's see how different enzymes work in the metabolism of living organisms.

concept 3.4 Regulation of Metabolism Occurs by Regulation of Enzymes

The enzyme-catalyzed reactions we have been discussing operate within *metabolic pathways* in which the product of one reaction is a substrate for the next. For example, the pathway for the catabolism of sucrose begins with sucrose and ends many reactions later with the production of CO_2 and H_2O . Energy is released along the way. Each step of this catabolic pathway is catalyzed by a specific enzyme:

Other enzymes participate in anabolic pathways, which produce relatively complex molecules from simpler ones. A typical cell contains hundreds of enzymes, which are part of many interconnecting metabolic pathways.

A major characteristic of life is *homeostasis*—the maintenance of stable internal conditions (see Chapter 29). How does a cell maintain a relatively constant internal environment while thousands of chemical reactions are going on?

One way a cell can regulate metabolism is to control the *amount* of an enzyme. For example, the product of a metabolic pathway may be available from the cell's environment in adequate amounts. In this case, it would be energetically wasteful for the cell to continue making large proteins (as most enzymes are) that it doesn't need. For this reason, cells often have the ability to turn off the synthesis of certain enzymes.

LINK The regulation of enzyme synthesis is described in Chapter 11

The consequences of *too little* enzyme can be significant. For example, in humans sucrase is important in digestion. If the enzyme is not present, as in rare cases of infants with congenital sucrase deficiency, the pathway that begins with sucrose is essentially blocked. If such infants ingest fruits or juices containing sucrose, then the sucrose accumulates rather than being catabolized and the infant gets diarrhea and stomach cramps. In some cases, this leads to slower growth. Treatment for sucrase deficiency is to limit sucrose consumption or use a tablet that contains the enzyme at every meal.

Cells can also maintain homeostasis by regulating the *activity* of enzymes. An enzyme protein may be present continuously, but it may be active or inactive depending on the circumstances. Regulation of enzyme activity allows cells to fine-tune metabolism relatively quickly in response to changes in their environment by regulating the functions of particular enzymes. In this section, we will describe how enzyme regulation occurs.

FIGURE 3.16 Irreversible Inhibition DIPF forms a stable covalent bond with the amino acid serine at the active site of the enzyme acetylcholinesterase, thus irreversibly disabling the enzyme.

work. In some cases the inhibitor binds the enzyme irreversibly, and the enzyme becomes permanently inactivated. In other cases the inhibitor has reversible effects; it can separate from the enzyme, allowing the enzyme to function fully as before.

IRREVERSIBLE INHIBITION If an inhibitor covalently binds to an amino acid side chain *at the active site* of an enzyme, the enzyme is permanently inactivated because it cannot interact with its substrate. An example of an irreversible inhibitor is DIPF (diisopropyl phosphorofluoridate), which reacts with serine (**FIGURE 3.16**). DIPF is an irreversible inhibitor of acetylcholinesterase, an important enzyme that functions in the nervous system. The widely used insecticide malathion is a derivative of DIPF that inhibits only insect acetylcholinesterase, not the mammalian enzyme. The irreversible inhibition of enzymes is of practical use to humans, but this form of regulation is not common in the cell, because the enzyme is permanently inactivated and cannot be recycled. Instead, cells use reversible inhibition.

Enzymes can be regulated by inhibitors

Various chemical inhibitors can bind to enzymes, slowing down the rates of the reactions they catalyze. Some inhibitors occur naturally in cells; others can be made in laboratories. Naturally occurring inhibitors regulate metabolism; artificial ones can be used to treat disease, kill pests, or study how enzymes

(A) Competitive inhibition

(B) Noncompetitive inhibition

REVERSIBLE INHIBITION In some cases, an inhibitor is similar enough to a particular enzyme's natural substrate that it can bind noncovalently to the active site, yet different enough that no chemical reaction occurs. This is analogous to a key that inserts into a lock but does not turn it. When such a molecule is bound to the enzyme, the natural substrate cannot enter the active site and the enzyme is unable to function. Such a molecule is called a **competitive inhibitor** because it competes with the natural substrate for the active site (**FIGURE 3.17A**). In this case, the inhibition is reversible. When the concentration of the competitive inhibitor is reduced, the active site is less likely to be occupied by the inhibitor, and the enzyme regains activity.

A **noncompetitive inhibitor** binds to an enzyme at a site distinct from the active site. This binding causes a change in the shape of the enzyme that alters its activity (**FIGURE 3.17B**). The active site may no longer bind the substrate, or if it does, the rate of product formation may be reduced. Like competitive inhibitors, noncompetitive inhibitors can become unbound, so their effects are reversible.

FIGURE 3.17 Reversible Inhibition (A) A competitive inhibitor binds temporarily to the active site of an enzyme. (B) A noncompetitive inhibitor binds temporarily to the enzyme at a site away from the active site. In both cases, the enzyme's function is disabled for only as long as the inhibitor remains bound.

Enzyme Catalysis

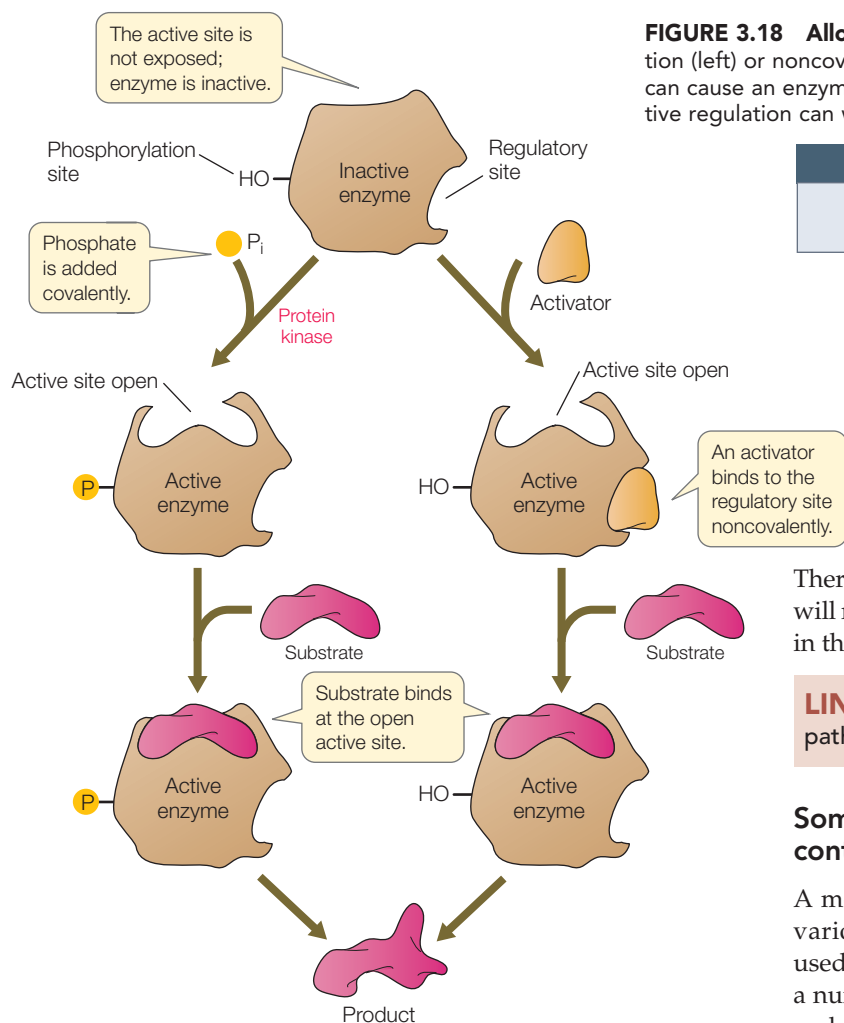

FIGURE 3.18 Allosteric Regulation of Enzyme Activity Covalent modification (left) or noncovalent binding of a regulator (in this case an activator; right) can cause an enzyme to change shape and expose an active site. Note that negative regulation can work this way as well, with the active site becoming hidden.

yourBioPortal.com

Go to ANIMATED TUTORIAL 3.3
Allosteric Regulation of Enzymes

An example of allosteric regulation is the activation of *protein kinases*, an important class of enzymes that regulate responses to the environment by organisms. Protein kinases can have profound effects on cell metabolism and are therefore subject to tight allosteric regulation. The active form of a protein kinase in turn regulates the activity of other enzymes, by phosphorylating allosteric or active sites on the other enzymes.

There are hundreds of different protein kinases in humans. We will return to the exact functions of protein kinases many times in this book.

LINK The role of protein kinases in intracellular signaling pathways is described in Chapter 5

An allosteric enzyme is regulated via changes in its shape

The change in enzyme shape that is due to noncompetitive inhibitor binding is an example of allostery (*allo*, “different”; *stereos*, “shape”). **Allosteric regulation** occurs when a non-substrate molecule binds or modifies a site other than the active site of an enzyme (called the *allosteric site*), inducing the enzyme to change its shape. The change in shape alters the chemical attraction (affinity) of the active site for the substrate, and so the rate of the reaction is changed. Allosteric regulation can result in the activation of a formerly inactive enzyme, or the inactivation of an enzyme (as in the case of the noncompetitive inhibitor).

An enzyme can have more than one allosteric site, and these may be modified by either covalent or noncovalent binding (**FIGURE 3.18**):

- **Covalent modification:** For example, an amino acid residue can be covalently modified by the addition of phosphate (in a process called *phosphorylation*). If this occurs in a hydrophobic region of the enzyme, it makes that region hydrophilic, because phosphate carries a negative charge. The protein twists, and this can expose or hide the active site.
- **Noncovalent binding:** A regulatory molecule may bind noncovalently to an allosteric site, causing the enzyme to change shape. This can either activate or inhibit the enzyme’s function.

Some metabolic pathways are usually controlled by feedback inhibition

A metabolic pathway typically involves a starting material, various intermediate products, and an end product that is used for some purpose by the cell. In each pathway there are a number of reactions, each forming an intermediate product and each catalyzed by a different enzyme. In many pathways the first step is the *commitment step*, meaning that once this enzyme-catalyzed reaction occurs, the “ball is rolling,” and the other reactions happen in sequence, leading to the end product. But as we pointed out earlier, it is energetically wasteful for the cell to make something it does not need.

One way to regulate a metabolic pathway is by having the final product inhibit the enzyme that catalyzes the commitment step (**FIGURE 3.19**). When the end product is present at a high concentration, some of it binds to a site on the commitment step enzyme, thereby causing it to become inactive. The end product may bind to the active site on the enzyme (as a competitive inhibitor) or an allosteric site (as a noncompetitive inhibitor). This mechanism is known as **feedback inhibition** or *end-product inhibition*. We will describe many other examples of such inhibition in later chapters.

FRONTIERS When a plant is subjected to adverse conditions such as drought, it makes a hormone called abscisic acid, which directs the plant’s adaptive responses. For example, it closes tiny holes (stomata) in the plant’s leaves to reduce water loss. Key to this drought response is the enzyme that catalyzes the commitment step of the pathway for abscisic acid synthesis. By understanding the regulation of this enzyme, scientists hope to develop crop plants that can tolerate dry conditions.

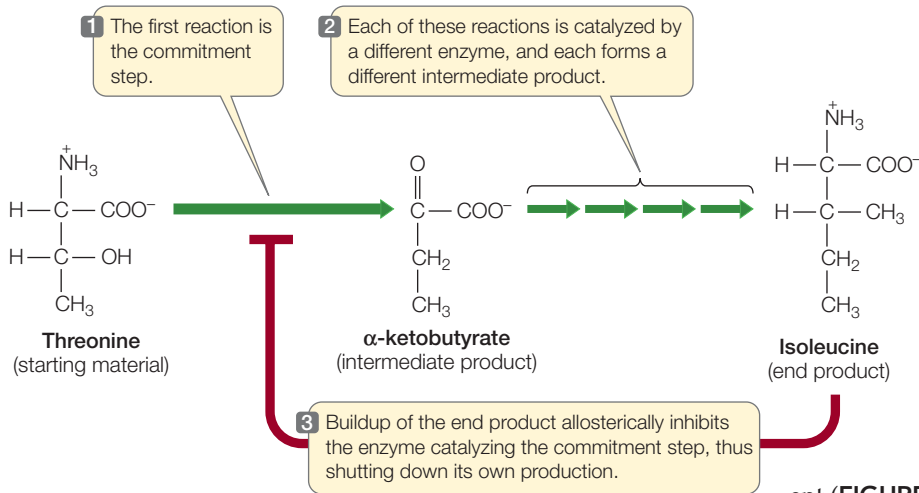

FIGURE 3.19 Feedback Inhibition of Metabolic Pathways The first reaction in a metabolic pathway is referred to as the commitment step. Often the end product of the pathway can inhibit the enzyme that catalyzes the commitment step. The specific pathway shown here is the synthesis of isoleucine from threonine in bacteria. It is typical of many enzyme-catalyzed biosynthetic pathways.

Enzymes are affected by their environments

The specificity and activity of an enzyme depend on its three-dimensional structure, and this in turn depends on weak forces such as hydrogen bonds (see Figure 3.7). In living systems, two environmental factors can change protein structure and thereby enzyme activity.

pH AFFECTS ENZYME ACTIVITY We introduced the concept of acids and bases when we discussed amino acids. Some amino acids have side chains that are acidic or basic (see Table 3.2). That is, they either generate H^+ and become anions, or attract H^+ and become cations. These reactions are often reversible. For example:

The ionic form of this amino acid (right) is far more hydrophilic than the nonionic form (left).

From your studies of chemistry, you may recall the *law of mass action*. In this case the law implies that the higher the H^+ concentration, the more the reaction will be driven to the left (to the nonionic form of glutamic acid). Therefore, changes in the H^+ concentration can alter the level of hydrophobicity of some regions of a protein and thus affect its shape. To generalize, protein tertiary structure, and therefore enzyme activity, is very sensitive to the concentration of H^+ in the aqueous environment. You may also recall that H^+ concentration is measured by pH (the negative logarithm of the H^+ concentration).

Although the water inside cells is generally at a neutral pH of 7, this can change, and different biological environments have different pH values. Each enzyme has a tertiary structure and amino acid sequence that make it optimally active at a particular pH; its activity decreases as the solution is made more acidic or more basic than this ideal (optimal) pH (FIGURE 3.20A). As an example, consider the human digestive system (see Concept 39.3). The pH inside the human stomach is highly acidic, about pH 1.5. Many enzymes that hydrolyze macromolecules in the intestine, such as proteases, have pH optima in the neutral range. So when food enters the small intestine, a buffer (bicarbonate) is secreted into the intestine to raise the pH to 6.5. This allows the hydrolytic enzymes to be active and digest the food.

TEMPERATURE AFFECTS ENZYME ACTIVITY In general, warming increases the rate of a chemical reaction because a greater proportion of the reactant molecules have enough kinetic energy to provide the activation energy for the reaction. Enzyme-catalyzed reactions are no different (FIGURE 3.20B). However, temperatures that are too high inactivate enzymes, because at high temperatures the enzyme molecules vibrate and twist so rapidly that some of their non-covalent bonds break. When an enzyme's tertiary structure is changed by heat, the enzyme loses its function. Some enzymes denature at temperatures only slightly above that of the human

FIGURE 3.20 Enzyme Activity Is Affected by the Environment (A) The activity curve for each enzyme peaks at its optimal pH. For example, pepsin is active in the acidic environment of the stomach, whereas chymotrypsin is active in the small intestine. (B) Similarly, there is an optimal temperature for each enzyme. At higher temperatures the enzyme becomes denatured and inactive; this explains why the activity curve falls off abruptly at temperatures that are above optimal.

APPLY THE CONCEPT

Regulation of metabolism occurs by regulation of enzymes

The concept of enzymes as biological catalysts has many applications. In a pile of clothes in your garage, you notice there are bacteria growing on some socks made of this synthetic polymer:

You make a protein extract from the bacteria and isolate what you think is an enzyme that can cleave the monomers from the polymer. You also synthesize the dipeptide glycine-glycine (see Table 3.2) to test as a possible inhibitor of the enzyme. The table shows the results from several of your experiments.

EXPERIMENT	CONDITION	RATE OF POLYMER CLEAVAGE
1	No enzyme	0.505
2	Enzyme	825.0
3	Enzyme pre-boiled at 100°C	0.520
4	Enzyme + RNA	799.0
5	Enzyme + dipeptide	0.495

1. Explain the results of each experiment.
2. How do you think the dipeptide works? How would you test your hypothesis?

body, but a few are stable even at the boiling point (or freezing point) of water. All enzymes have an optimal temperature for activity.

Individual organisms adapt to changes in the environment in many ways, one of which is based on groups of enzymes called *isozymes* that catalyze the same reaction but have different chemical compositions and physical properties. Different isozymes within a given group may have different optimal temperatures. The rainbow trout, for example, has several isozymes of the enzyme acetylcholinesterase. If a rainbow trout is transferred from warm water to near-freezing water (2°C), the fish produces a different isozyme of acetylcholinesterase. The new isozyme has a lower optimal temperature, allowing the fish's nervous system to perform normally in the colder water.

In general, enzymes adapted to warm temperatures do not denature at those temperatures because their tertiary structures are held together largely by covalent bonds such as disulfide bridges, instead of the more heat-sensitive weak chemical interactions.

Do You Understand Concept 3.4?

- Explain and give examples of irreversible and reversible enzyme inhibitors.
- The amino acid lysine (see Table 3.2) is at the active site of an enzyme. Normally the enzyme is active at pH 7. At pH 5 (higher concentration of H⁺), the enzyme is inactive. Explain these observations.
- An enzyme is subject to allosteric regulation. How would you design an inhibitor of the enzyme that was competitive? Noncompetitive? Irreversible?
- Some organisms thrive at a pH of 2; other organisms thrive at a temperature of 65°C. Yet mammals cannot tolerate either environment in their tissues. Explain.

How does an understanding of proteins and enzymes help to explain how aspirin works?

ANSWER The mechanism by which aspirin works exemplifies many of the concepts introduced in this chapter. Robert Vane showed that aspirin binds to a protein with a specific three-dimensional structure (Concept 3.2), and that target is the enzyme cyclooxygenase (Concept 3.3). Aspirin acts as an irreversible inhibitor of the enzyme (Concept 3.4), thus shutting down the metabolic pathway for which cyclooxygenase is a commitment step. Follow the description below carefully, as it illustrates these important concepts.

Cyclooxygenase catalyzes the conversion of a fatty acid with 20 carbon atoms, arachidonic acid, to a structure with a ring (thus the "cyclo" in the name of the enzyme). O₂ is a cofactor (thus the "oxygen"; **FIGURE 3.21**). The product of

FIGURE 3.21 Aspirin: An Enzyme Inhibitor Aspirin inhibits a key enzyme in the metabolic pathways leading to inflammation and blood clotting.

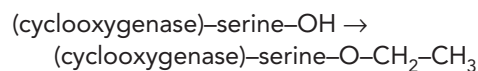

FIGURE 3.22 Inhibition by Covalent Modification Aspirin inhibits cyclooxygenase by covalent modification of an amino acid at the active site of the enzyme.

this reaction (prostaglandin H_2) is the starting material for the biochemical pathways that produce two types of molecules:

- *Prostaglandins*, which are involved in inflammation and pain, and
- *Thromboxanes*, which stimulate blood clotting and constriction of blood vessels.

Aspirin binds at the active site of cyclooxygenase and transfers an acetyl group to the exposed hydroxyl group of a nearby serine residue (**FIGURE 3.22**):

This covalent modification changes the exposed, polar serine to a less polar molecule, and it becomes slightly more hydrophobic. The shape of the active site changes and becomes inaccessible to the substrate, arachidonic acid. The enzyme is inhibited, and the pathways leading to prostaglandins and thromboxanes are shut down. Less pain, inflammation, and blood clotting are the result. Small wonder that aspirin is taken as a pain reliever and a preventive medicine for heart attacks and strokes. It has come a long way from Edward Stone's walk in the woods.

SUMMARY

concept 3.1 Nucleic Acids Are Informational Macromolecules

- The nucleic acids—DNA and RNA—are used mainly for information storage and expression.
- Nucleic acids are polymers of nucleotides. A **nucleotide** consists of one to three phosphate groups, a pentose sugar (**ribose** in RNA and **deoxyribose** in DNA), and a nitrogen-containing **base**. **Review Figure 3.1 and WEB ACTIVITY 3.1**
- In DNA, the nucleotide bases are **adenine (A)**, **guanine (G)**, **cytosine (C)**, and **thymine (T)**. **Uracil (U)** replaces thymine in RNA. The nucleotides are joined by **phosphodiester linkages** between the sugar of one and the phosphate of the next. RNA is usually single-stranded, whereas DNA is double-stranded. **Review Figure 3.2**
- **Complementary base pairing**, based on hydrogen bonds between A and T, A and U, and G and C, occurs in RNA and DNA. In RNA the hydrogen bonds result in a folded molecule;

in DNA the hydrogen bonds connect two strands into a double helix. **Review Figures 3.3 and 3.4 and WEB ACTIVITY 3.2**

- DNA is expressed as RNA in the process of **transcription**. RNA can then specify the amino acid sequence of a protein in the process of **translation**.

See ANIMATED TUTORIAL 3.1

concept 3.2 Proteins Are Polymers with Important Structural and Metabolic Roles

- The functions of proteins include support, protection, catalysis, transport, defense, regulation, storage, and movement.
- **Amino acids** are the monomers from which polymeric proteins are made by **peptide linkages**. There are 20 different amino acids in proteins, each distinguished by a **side chain (R group)** that confers specific properties. **Review Table 3.2 and WEB ACTIVITY 3.3**

- The **primary structure** of a protein is the sequence of amino acids in the polypeptide chain. This chain is folded into a **secondary structure**, which in different parts of the protein may take the form of an **α helix** or a **β pleated sheet**. **Review Figure 3.7**
- **Disulfide bridges** and noncovalent interactions between amino acids cause polypeptide chains to fold into three-dimensional **tertiary structures**. Multiple polypeptides can interact to form **quaternary structures**. A protein's unique shape and chemical structure allow it to bind specifically to other molecules.
- Heat and certain chemicals can result in a protein becoming **denatured**, which involves the loss of tertiary or secondary structure. **Review Figure 3.10 and WORKING WITH DATA 3.1**

concept 3.3 Some Proteins Act as Enzymes to Speed up Biochemical Reactions

- A chemical reaction must overcome an energy barrier to get started. An enzyme is a protein catalyst that affects the rate of a biological reaction by lowering the **activation energy** needed to initiate the reaction. **Review Figure 3.12 and WEB ACTIVITY 3.4**
- A **substrate** binds to the enzyme's **active site**—the site of catalysis—forming an **enzyme–substrate complex**. Enzymes are highly specific for their substrates.
- At the active site, a substrate enters its **transition state**, and the reaction proceeds.

- Substrate binding causes many enzymes to change shape, exposing their active site(s) and allowing catalysis. **Review Figure 3.14**
- Some enzymes require nonprotein “partners” to carry out catalysis. **Review Table 3.3**
- Substrate concentration affects the rate of an enzyme-catalyzed reaction. At the maximum rate, the enzyme is saturated with substrate. **Review Figure 3.15**

concept 3.4 Regulation of Metabolism Occurs by Regulation of Enzymes

- Metabolism is organized into pathways in which the product of one reaction is a substrate for the next reaction. Each reaction in the pathway is catalyzed by a specific enzyme.
- Enzyme activity is subject to regulation. Some inhibitors bind irreversibly to enzymes. Other inhibitors bind reversibly. **Review Figures 3.16 and 3.17 and ANIMATED TUTORIAL 3.2**
- In **allosteric regulation**, a molecule binds to a site on the enzyme other than the active site. This changes the overall structure of the enzyme (including that of its active site) and results in either activation or inhibition of the enzyme's catalytic activity. **Review Figure 3.18 and ANIMATED TUTORIAL 3.3**
- The end product of a metabolic pathway may inhibit an enzyme that catalyzes the “commitment step” of that pathway. This is called **feedback inhibition**. **Review Figure 3.19**
- Environmental pH and temperature affect enzyme activity. **Review Figure 3.20**

Cells: The Working Units of Life

4

In 1818, a 19-year-old London writer, Mary Shelley, published a novel that shocked a society in the midst of the Industrial Revolution. In Shelley's story, Dr. Victor Frankenstein discovers how to use electricity to reanimate dead creatures. Collecting body parts from graves and medical labs, the fictional doctor assembles them into a huge 8-foot-tall body and uses his secret method to bring it to life. The results are disastrous, and the novel became a cautionary tale about the limits of science.

Almost 200 years later, in 2010, biologists Craig Venter and Hamilton Smith also gave new life to an "empty shell." In this case, the "shell" was a cell of the tiny bacterium *Mycoplasma discoides*, in which the DNA had been destroyed by hydrolysis. Without DNA to direct the synthesis of its proteins, the cell would die. The scientists used a computer to design an artificial DNA sequence that had all the genes necessary for bacterial life, plus some unique sequences. Then they went into the chemistry lab and made the DNA from individual nucleotides. They inserted this synthetic genome (similar to the genome of the closely related bacterium *Mycoplasma mycoides*) into the bacterium, where it replaced the bacterium's normal DNA, which was hydrolyzed. The new DNA directed the cell to perform all the biochemical characteristics of life, including cell reproduction. Since the new genome had some distinctive DNA sequences devised by the scientists, it was an entirely new organism, called *Mycoplasma mycoides* JVC1-syn1.0.

Why did Venter and Smith need to start with a pre-existing cell? The chemical reactions of metabolism, polymerization, and replication cannot occur in a dilute aqueous environment; it would be too unlikely for reactants and enzymes to collide with one another. Life requires

a compartment that brings together and concentrates the molecules involved in these events, which ultimately are directed by the DNA genome.

After several cell divisions (40, by Venter and Smith's estimate), the cells of the new organism no longer had any of the original cell's proteins or small molecules. The cells had used substances in the environment to synthesize their own small and large molecules. They were truly individuals of a new organism, whose "parent" was a computer.

The practical aim of this research is to create cells with new capabilities, such as synthesizing clean-burning fuels. But it also puts cells into broader focus as the basic units of biological structure and function.

What do the characteristics of modern cells indicate about how the first cells originated?

Cells of *Mycoplasma mycoides* JVC1-syn1.0. These are the first synthetic cells.

KEY CONCEPTS

- 4.1 Cells Provide Compartments for Biochemical Reactions
- 4.2 Prokaryotic Cells Do Not Have a Nucleus
- 4.3 Eukaryotic Cells Have a Nucleus and Other Membrane-Bound Compartments
- 4.4 The Cytoskeleton Provides Strength and Movement
- 4.5 Extracellular Structures Allow Cells to Communicate with the External Environment

concept 4.1 Cells Provide Compartments for Biochemical Reactions

Cells contain water and other small and large molecules, which we examined in Chapters 2 and 3. Each cell contains at least 10,000 different types of molecules, most of them present in many copies. Cells use these molecules to transform matter and energy, to respond to their environments, and to reproduce. As we mentioned in the essay above, these biological processes would be impossible outside the enclosure of a cell.

The **cell theory**, developed in the nineteenth century, recognizes this basic fact about life. It was the first unifying principle of biology and has three critical components:

- Cells are the fundamental units of life.
- All living organisms are composed of cells.
- All cells come from preexisting cells.

Cell theory has two important conceptual implications:

- *Studying cell biology is in some sense the same as studying life.* The principles that underlie the functions of a single bacterial cell are similar to those governing the approximately 60 trillion cells in an adult human.
- *Life is continuous.* All those human cells came from a single cell, a zygote (or fertilized egg). The zygote was formed when two cells fused: a sperm from the father and an egg from the mother. The cells of the parents' bodies were all derived from their parents, and so on back through the generations—all the way back to the evolution of the first living cells.

Cell size is limited by the surface area-to-volume ratio

Most cells are tiny. Their volumes range from 1 to 1,000 cubic micrometers (**FIGURE 4.1**). There are some exceptions: the eggs of birds are single cells that are, relatively speaking, enormous, and individual cells of several types of algae and bacteria are large enough to be viewed with the unaided eye.

Small cell size is a practical necessity arising from the decrease in the **surface area-to-volume ratio** of any object as it increases in size. As an object increases in volume, its surface area also increases, but not as quickly (**FIGURE 4.2**). This phenomenon has great biological significance for two reasons:

- The *volume* of a cell determines the amount of metabolic activity it carries out per unit of time.
- The *surface area* of a cell determines the amount of substances that can enter it from the outside environment, and the amount of waste products that can exit to the environment.

As a living cell grows larger, its metabolic activity, and thus its need for resources and its rate of waste production, increases faster than its surface area. In addition, substances must move from one location to another within the cell; the smaller the cell, the more easily this is accomplished. The large surface area-to-volume ratio represented by the many small cells of a multicellular organism enables it to carry out the many different functions required for survival.

yourBioPortal.com

Go to WEB ACTIVITY 4.1
The Scale of Life

FIGURE 4.1 The Scale of Life This logarithmic scale shows the relative sizes of molecules, cells, and multicellular organisms.

Most cell diameters are in the range of 1–100 μm .

This scale is logarithmic. Each unit is 10 times bigger than the previous unit.

FIGURE 4.2 Why Cells Are Small As an object grows larger, its volume increases more rapidly than its surface area. Cells must maintain a large surface area-to-volume ratio in order to function. This explains why multicellular organisms must be composed of many small cells rather than a few large ones.

Cells can be studied structurally and chemically

The small sizes of most cells necessitate special instruments to study them and their constituents. For *visualizing cells*, there are two types of microscopes (**FIGURE 4.3**):

- *Light microscopes* use glass lenses and visible light to form images. The smallest detail that can be seen with such a microscope is about 0.2 μm in diameter, which is about 1,000 times smaller than an object the human eye can see. Light microscopes are used to visualize living cells and general cell structure.
- *Electron microscopes* use an electron beam focused by magnets. The size limit is 2 nm, which is 100,000 times smaller than something the human eye can see. Electron microscopes can be used to visualize most structures within preserved cells.

The *chemical analysis* of cells usually begins with breaking them open to make a *cell-free extract*. This can be done physically, using a blender or other homogenizing machinery, or osmotically, by placing the cell in a chemical environment where it swells and bursts (see Figure 5.3). In either case, the resulting extract can be analyzed in terms of its composition and chemical reactions. For example, specific enzyme activities may be measured. If conditions are right in this test tube system, the *properties of the cell-free extract are the same as those inside the cell*. This last statement is of great importance, because it allows biologists to study the chemical processes that occur inside cells in the test tube, so that chemical changes can be easily measured.

A cell's internal structures and even some of its macromolecules can be separated according to their sizes in a centrifuge (**FIGURE 4.4**). Once the subcellular structures are separated from one another, they are much easier to study.

The plasma membrane forms the outer surface of every cell

As we described in the opening of this chapter, a key to the origin of cells was the enclosure of biochemical functions within

RESEARCH TOOLS

a membrane. We will describe the **plasma membrane** in more detail in Chapter 5, but for now, note that it consists of phospholipid bilayers with proteins, and that there is both compositional and functional diversity within this general framework. Unless stained for light microscopy, the very thin (7 nm) plasma membrane is visible only in electron microscopy. It has several important roles:

- The plasma membrane acts as a *selectively permeable barrier*, preventing some substances from crossing it while permitting other substances to enter and leave the cell. In doing so, it allows the cell to maintain homeostasis, a stable internal environment that is distinct from the surrounding environment. This explains why a red blood cell contains the pigmented molecule hemoglobin but the surrounding blood plasma does not.
- As the cell's boundary with the outside environment, the plasma membrane is important in *communicating* with adjacent cells and receiving signals from the environment.
- The plasma membrane often has proteins protruding from it that are responsible for *binding and adhering* to adjacent cells or to a surface. Thus the plasma membrane plays an important structural role and contributes to cell shape.

RESEARCH TOOLS

FIGURE 4.4 Centrifugation Structures within cells can be separated from one another on the basis of size and density, and the isolated structures can then be analyzed chemically.

Cells are classified as either prokaryotic or eukaryotic

Biologists classify all living things into three domains: Archaea, Bacteria, and Eukarya. The organisms in Archaea and Bacteria are collectively called **prokaryotes** because they have in common a prokaryotic cellular organization. A prokaryotic cell typically does not have membrane-enclosed internal compartments; in particular, it does not have a *nucleus*.

Eukaryotic cell organization is found in members of the domain Eukarya—the **eukaryotes**—which includes the protists (a diverse group of microorganisms), plants, fungi, and animals. In contrast to the prokaryotes, eukaryotes contain membrane-enclosed compartments called **organelles** where specific metabolic functions occur. The most notable of these is the cell **nucleus**, where most of the cell's DNA is located and where gene expression begins:

Just as a cell is an enclosed compartment, separating its contents from the surrounding environment, so each organelle provides a compartment that separates certain molecules and biochemical reactions from the rest of the cell. This impressive “division of labor” provides possibilities for regulation and efficiency that were important in the evolution of complex organisms.

LINK Eukaryotes arose from prokaryotes by endosymbiosis; see Concept 20.1

Do You Understand Concept 4.1?

- In considering the origin of cells, why do biologists focus on the origin of the plasma membrane?
- Figure 4.2 shows cube-shaped representations of cells. Many cells, however, are spherical. The surface area of a sphere is $4\pi r^2$ and the volume is $(4/3)(\pi r^3)$. What is the surface area-to-volume ratio of a spherical cell with a diameter of $2\ \mu\text{m}$ and one with a diameter of $3\ \mu\text{m}$? What are the implications of this difference between the two cells for cell function?
- What evolutionary advantages does a eukaryotic cell have compared with a prokaryotic cell?

As we mentioned in this section, there are two structural themes in cell architecture: prokaryotic and eukaryotic. We'll turn now to the organization of prokaryotic cells.

concept 4.2 Prokaryotic Cells Do Not Have a Nucleus

In terms of sheer numbers and diversity, prokaryotes are the most successful organisms on Earth. As we generalize about the features of these cells, bear in mind that there are vast numbers of prokaryotic species, and that the Bacteria and Archaea can be distinguished from one another in numerous ways. These differences, and the vast diversity of organisms in these two domains, are the subject of Chapter 19.

The volume of a prokaryotic cell is typically about one-fiftieth of the volume of a eukaryotic cell. Prokaryotic cells range from about 1 to $10\ \mu\text{m}$ in length, width, and diameter. While some prokaryotes exist as single cells, other types form chains or small clusters of cells, and in some cases certain cells in a group perform specialized functions.

Prokaryotic cells share certain features

All prokaryotes have the same basic structure (**FIGURE 4.5**):

- The plasma membrane encloses the cell, separating its interior from the external environment, and regulates the traffic of materials into and out of the cell.
- The **nucleoid** is a region in the cell where the DNA is located. As we described in Chapter 3, DNA is the hereditary material that controls cell growth, maintenance, and reproduction.

The rest of the material enclosed in the plasma membrane is called the **cytoplasm**. The cytoplasm has two components:

- The **cytosol** consists mostly of water containing dissolved ions, small molecules, and soluble macromolecules such as proteins.
- Within the cytosol are insoluble suspended particles, including ribosomes. **Ribosomes** are complexes of RNA and proteins that are about 25 nm in diameter. They can be visualized only with the electron microscope. They are the sites of protein synthesis, where the information encoded by nucleic acids directs the sequential linking of amino acids to form proteins.

The cytoplasm is not a static region. Rather, the substances in this environment are in *constant motion*. For example, a typical protein moves around the entire cell within a minute, and it collides with many other molecules along the way. This constant motion helps ensure that biochemical reactions proceed at sufficient rates to meet the needs of the cell. Prokaryotes may look simple, but in reality they are functionally complex, carrying out thousands of biochemical reactions.

Specialized features are found in some prokaryotes

As they evolved, some prokaryotes developed specialized structures that gave them a selective advantage in their particular environments. These cells were better able to survive and reproduce than cells lacking the specialized structures.

CELL WALLS Most prokaryotes have a cell wall located outside the plasma membrane. The rigidity of the cell wall supports the cell and determines its shape. The cell walls of most bacteria, but not those of archaea, contain *peptidoglycan*, a polymer of amino sugars that are cross-linked by covalent bonds to peptides, forming a single giant molecule that surrounds the entire cell. In some bacteria, another layer, the outer membrane (a polysaccharide-rich phospholipid membrane), encloses the peptidoglycan layer (see Figure 4.4). Unlike the plasma membrane, this outer membrane is relatively permeable, allowing the movement of molecules across it.

Enclosing the cell wall of some bacteria is a slimy layer composed mostly of polysaccharides, referred to as the *capsule*. In some cases these capsules protect the bacteria from attack by white blood cells in the animals they infect. Capsules also help keep the cells from drying out, and sometimes they help bacteria attach to other cells. Many prokaryotes produce no capsule, and those that do have capsules can survive even if they lose them, so the capsule is not essential to prokaryotic life.

INTERNAL MEMBRANES Some groups of bacteria—including the cyanobacteria—carry out photosynthesis: they use energy from the sun to convert carbon dioxide and water into carbohydrates. These bacteria have an internal membrane system that contains molecules needed for photosynthesis. The development of photosynthesis, which requires membranes, was an important event in the early evolution of life on Earth. Other prokaryotes have internal membrane folds that are attached to the plasma membrane. These folds may function in cell division or in various energy-releasing reactions.

FIGURE 4.5 A Prokaryotic Cell The bacterium *Pseudomonas aeruginosa* illustrates the typical structures shared by all prokaryotic cells. This bacterium also has a protective outer membrane and a capsule, which are not present in all prokaryotes.

FIGURE 4.6 Prokaryotic Flagella (A) Flagella contribute to the movement and adhesion of prokaryotic cells. (B) Complex protein ring structures anchored in the plasma membrane form a motor unit that rotates the flagellum and propels the cell.

A bacterium with enclosed compartments would have several evolutionary advantages. Chemicals could be concentrated within particular regions of the cell, allowing chemical reactions to proceed more efficiently. Certain biochemical activities could be segregated within compartments with more favorable conditions for those reactions, such as a different pH from the rest of the cell.

FLAGELLA Some prokaryotes swim by using appendages called **flagella**, which sometimes look like tiny corkscrews (FIGURE 4.6A). In bacteria, flagella are made of a protein called *flagellin*. A complex motor protein spins each flagellum on its axis like a propeller, driving the cell along. The motor protein is anchored to the plasma membrane and, in some bacteria, to the outer membrane of the cell wall (FIGURE 4.6B). We know that flagella cause the motion of cells because if they are removed, the cells do not move.

CYTOSKELETON Some prokaryotes, especially rod-shaped bacteria, have a helical network of filamentous structures that extend down the length of the cell just inside the plasma membrane. The proteins that make up this structure are similar to actin in eukaryotic cells (which we will discuss next). The helical filaments in these prokaryotes play a role in maintaining their rodlike cell shape.

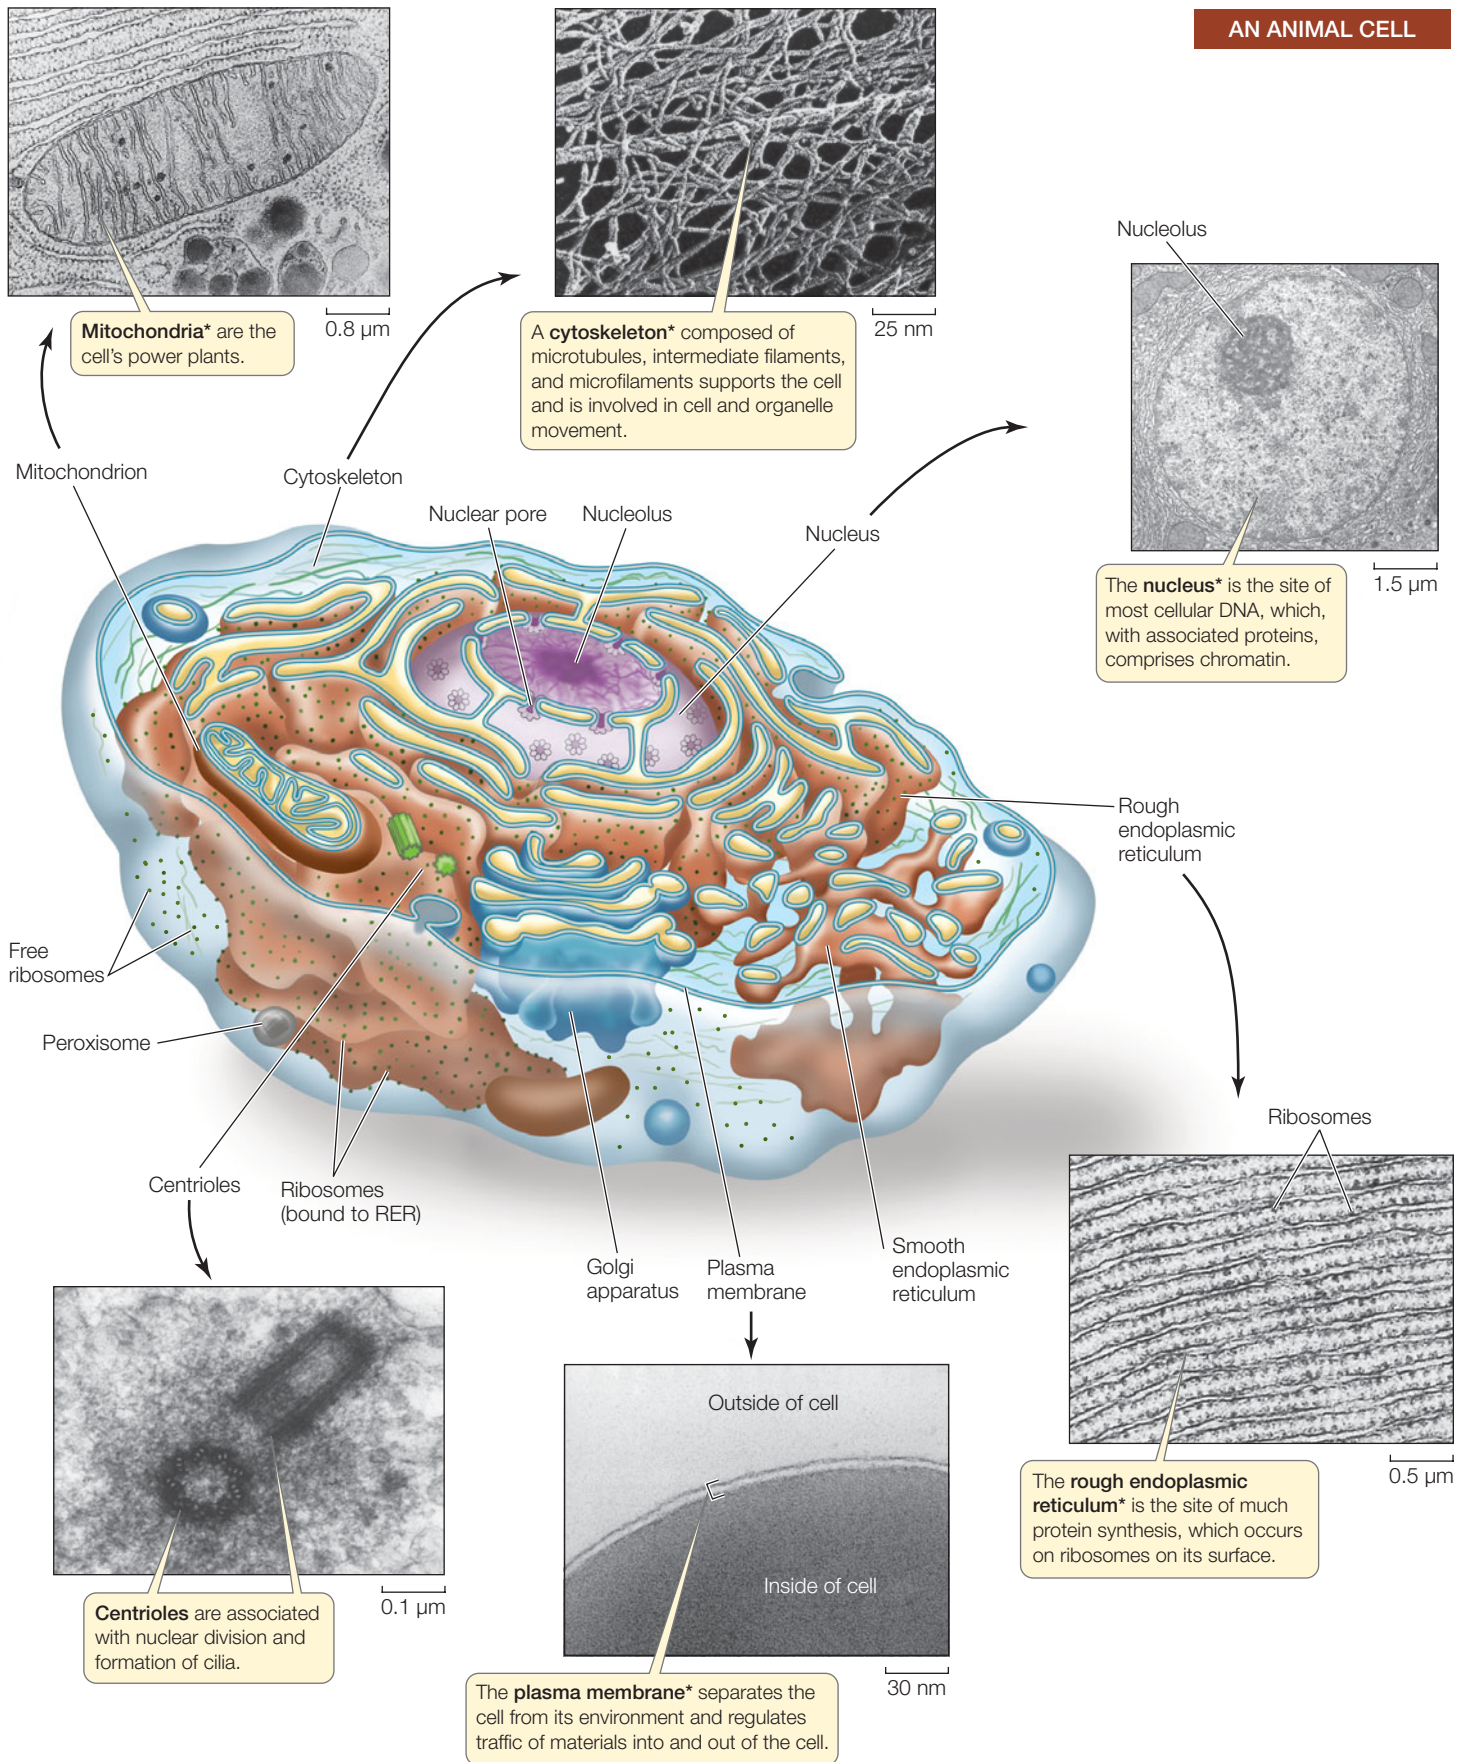

Do You Understand Concept 4.2?

- Describe the structures that are present in all prokaryotic cells.
- Compare the structures and functions of bacterial cell walls with those of bacterial cytoskeletons.
- Flagella are made up of proteins that have other functions, and are present in all prokaryotes. What is the evolutionary advantage of a bacterium that has flagella over bacteria that do not?

As we mentioned earlier, the prokaryotic cell is one of two broad types of cells recognized in cell biology. The other is the eukaryotic cell. Eukaryotic cells, and multicellular eukaryotic organisms, are more structurally and functionally complex than prokaryotic cells.

concept 4.3 Eukaryotic Cells Have a Nucleus and Other Membrane-Bound Compartments

Like prokaryotic cells, eukaryotic cells have a plasma membrane, cytoplasm, and ribosomes. But as you learned earlier in this chapter, eukaryotic cells also have organelles within the cytoplasm whose interiors are separated from the cytosol by membranes (FIGURE 4.7).

AN ANIMAL CELL

Mitochondria* are the cell's power plants.

A cytoskeleton* composed of microtubules, intermediate filaments, and microfilaments supports the cell and is involved in cell and organelle movement.

The nucleus* is the site of most cellular DNA, which, with associated proteins, comprises chromatin.

The rough endoplasmic reticulum* is the site of much protein synthesis, which occurs on ribosomes on its surface.

Centrioles are associated with nuclear division and formation of cilia.

The plasma membrane* separates the cell from its environment and regulates traffic of materials into and out of the cell.

Eukaryotic Cell Tour

Compartmentalization is the key to eukaryotic cell function

Each type of organelle has a specific role in the cell. Some organelles have been characterized as factories that make specific products. Others are like power plants that take in energy in one form and convert it into a more useful form. In addition to these organelles, eukaryotic cells have some structures that are analogous to those seen in prokaryotes. For example, they have a cytoskeleton composed of protein fibers, and outside the plasma membrane, an extracellular matrix.

When animal and plant cells are examined using electron microscopy, they have many organelles and structures in common—the most obvious is the cell nucleus. But they also have some differences—for example, many plant cells have chloroplasts that are colored green by the pigment used in photosynthesis. Figure 4.7 shows diagrams of an animal and a plant cell, with electron micrographs of some of the subcellular structures.

Ribosomes are factories for protein synthesis

The ribosomes of both prokaryotes and eukaryotes consist of one larger and one smaller subunit; the sizes of the subunits differ between the two cell types. Each subunit consists of one to three large RNA molecules called ribosomal RNA (rRNA) and multiple smaller protein molecules that are bound noncovalently to one another and to the rRNA. The ribosome is an amazingly precise structure. If the individual macromolecules are separated by disruption of their hydrophobic interactions, they will spontaneously reassemble into a functional complex.

The role of ribosomes is to translate the nucleotide sequence of a messenger RNA molecule into a polypeptide chain.

LINK Protein synthesis is described in more detail in Concept 10.4

Unlike other organelles, ribosomes are not membrane-enclosed compartments. In prokaryotic cells, ribosomes float freely in the cytoplasm. In eukaryotic cells they are found in the cytoplasm, where they may be free or attached to the surface of the endoplasmic reticulum (a membrane-enclosed organelle; see below), and also inside certain organelles—namely the mitochondria and the chloroplasts.

FRONTIERS Ribosomes are prototypical “macromolecular machines”—large aggregates of macromolecules, bound together noncovalently, that perform complex functions in the cell. Other such aggregates include the chromatin inside the nucleus and the cytoskeleton. Biologists and chemists are currently working to understand how these aggregates fit together, at both the atomic and macromolecular levels. This understanding will lead to greater insights into cell function and into the design of drugs targeted at the aggregates that inhibit protein synthesis.

The nucleus contains most of the DNA

As we noted in Chapter 3, hereditary information is stored in the sequence of nucleotides in DNA molecules. In eukaryotic cells, most of the DNA is in the nucleus. Most cells have a single nucleus, and it is usually the largest organelle; at 5 μm in diameter, the nucleus is substantially larger

than most prokaryotic cells. The nucleus has several functions:

- It is the location of the DNA and of DNA replication.
- It is where DNA is transcribed to RNA (see Concept 3.1).
- It contains the **nucleolus**, a region where ribosomes begin to be assembled from RNA and proteins.

If you look carefully at the diagrams and electron micrograph of the nucleus in Figure 4.7, you will see that the nucleus is enclosed by not one but *two membranes*—two lipid bilayers—that together form the *nuclear envelope*. Functionally, this barrier separates DNA transcription (which occurs in the nucleus) from translation (which occurs in the cytoplasm). The two membranes of the nuclear envelope are perforated by thousands of *nuclear pores*, each measuring approximately 9 nm in diameter, which connect the interior of the nucleus to the cytoplasm. The pores regulate the traffic between these two cellular compartments by allowing some molecules to enter or leave the nucleus and by blocking others. This allows the nucleus to regulate its information-processing functions.

Inside the nucleus, DNA is combined with proteins to form a fibrous complex called *chromatin*. Chromatin occurs in the form of exceedingly long, thin threads called *chromosomes*. Different eukaryotic organisms have different numbers of chromosomes (ranging from two in one kind of Australian ant to hundreds in some plants). These DNA–protein complexes become much more compact during cell division, as you will see in Concept 7.2. You can see in Figure 4.7 that the outer membrane of the nuclear envelope folds outward into the cytoplasm and is continuous with the membrane of another organelle, the endoplasmic reticulum, which we will discuss next.

The endomembrane system is a group of interrelated organelles

Much of the volume of many eukaryotic cells is taken up by an extensive **endomembrane system**. This interconnected system of membrane-enclosed compartments includes the nuclear envelope, endoplasmic reticulum, Golgi apparatus, and lysosomes, which are derived from the Golgi. Tiny, membrane-surrounded droplets called **vesicles** shuttle substances between the various components of the endomembrane system, as well as the plasma membrane (**FIGURE 4.8**). In drawings and electron micrographs this system appears static, but in the living cell, membranes and the materials they contain are in constant motion. Membrane components have been observed to shift from one organelle to another within the endomembrane system. This suggests that all these membranes must be functionally related.

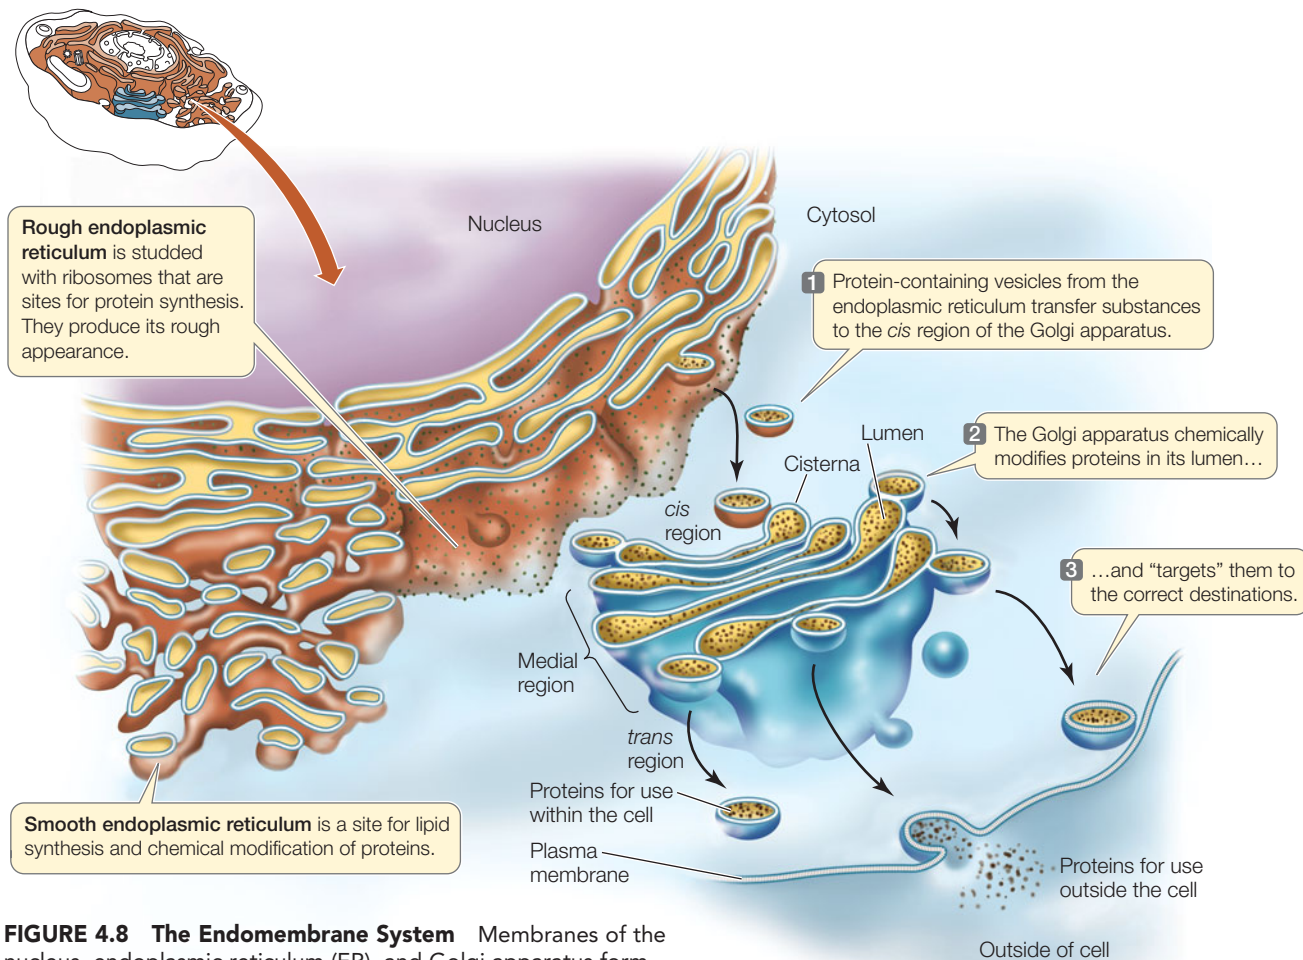

FIGURE 4.8 The Endomembrane System Membranes of the nucleus, endoplasmic reticulum (ER), and Golgi apparatus form a network that is connected by vesicles. Parts of the membrane move between these organelles. Membrane synthesized in the smooth ER becomes sequentially part of the rough ER, then the Golgi, then vesicles formed from the Golgi. These vesicles may eventually fuse with, and become part of, the plasma membrane.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 4.2**
The Golgi Apparatus

ENDOPLASMIC RETICULUM Electron micrographs of eukaryotic cells reveal networks of interconnected membranes branching throughout the cytoplasm, forming tubes and flattened sacs. These membranes are collectively called the **endoplasmic reticulum**, or **ER**. The interior compartment (*lumen*) of the ER is separate and distinct from the surrounding cytoplasm (see Figure 4.8). The ER can enclose up to 10 percent of the interior volume of the cell, and its extensive folding results in a surface area many times greater than that of the plasma membrane. There are two types of ER: rough and smooth.

The **rough endoplasmic reticulum (RER)** is called "rough" because of the many ribosomes attached to the outer surface of the membrane, giving it a rough appearance in electron micrographs. These ribosomes are not permanently

attached to the ER but become attached when they begin synthesizing proteins destined for modification within the RER:

- A protein enters the RER only if it contains a specific short sequence of amino acids that signals the ribosome to attach to the RER.
- Once inside the RER, proteins are chemically modified to alter their functions and to chemically "tag" them for delivery to specific cellular destinations.
- The RER participates in transporting these proteins to other locations in the cell. The proteins are transported in vesicles that pinch off from the ER. All secreted proteins pass through the RER.
- Most membrane-bound proteins are made on the RER.

A polypeptide that is synthesized on the RER surface is transported across the membrane and into the lumen while it is being translated. Once inside, it undergoes several changes, including the formation of disulfide bridges and folding into its tertiary structure. Many proteins are covalently linked to carbohydrate groups in the RER, thus becoming *glycoproteins*. These carbohydrate groups often have roles in recognition—for example, they identify proteins destined for transfer to specific cellular locations (such as the lysosome; see Figure 4.9). This "addressing" system is very important for ensuring that proteins arrive at

their correct destinations. For example, the enzymes within the lysosomes (see below) are highly destructive and could destroy the cell if they were released into the cytosol.

The **smooth endoplasmic reticulum (SER)** is connected to portions of the RER but lacks ribosomes and is more tubular (less like flattened sacs) than the RER. Some of the proteins synthesized on the RER are transported to the lumen of the SER, where they are chemically modified. The SER has three other important roles:

- It is responsible for the chemical modification of small molecules taken in by the cell, including drugs and pesticides. These modifications make the targeted molecules more polar, so they are more water-soluble and more easily removed.
- It is the site for glycogen degradation in animal cells.
- It is the site for the synthesis of lipids and steroids.

Cells that synthesize a lot of protein for export are usually packed with RER. Examples include glandular cells that secrete digestive enzymes and white blood cells that secrete antibodies. In contrast, cells that carry out less protein synthesis (such as storage cells) contain less RER. Liver cells, which modify molecules (including toxins) that enter the body from the digestive system, have abundant SER.

GOLGI APPARATUS The **Golgi apparatus** (or Golgi complex) is named after its discoverer, Camillo Golgi. It has two components: flattened membranous sacs called *cisternae* (singular *cisterna*), which are piled up like saucers, and small membrane-enclosed vesicles (see Figure 4.8). The entire apparatus is about 1 μm long.

When protein-containing vesicles from the RER fuse with the Golgi membrane, the proteins are released into the lumen of a Golgi cisterna, where they may be further modified. The Golgi has several roles:

- It concentrates, packages, and sorts proteins before they are sent to their cellular or extracellular destinations.
- It adds some carbohydrates to proteins.
- It is where some polysaccharides for the plant cell wall are synthesized.

FRONTIERS Storage proteins in seeds are a major source of food, but sometimes these proteins are deficient in certain essential amino acids. Crop plants can be genetically engineered to make more nutritious storage proteins; however, the Golgi often packages the altered proteins incorrectly. This makes the proteins unstable, leading to seeds with low protein content. Understanding how proteins are packaged by the Golgi is important for increasing the nutritional value of foods.

The cisternae of the Golgi apparatus have three functionally distinct regions: the *cis* region lies nearest to the nucleus or a patch of RER, the *trans* region lies closest to the plasma

membrane, and the *medial* region lies in between (see Figure 4.8). (The terms *cis*, *trans*, and *medial* derive from Latin words meaning “on the same side,” “on the opposite side,” and “in the middle,” respectively.) These three parts of the Golgi apparatus contain different enzymes and perform different functions.

Protein-containing vesicles from the ER fuse with the *cis* membrane of the Golgi apparatus. Other vesicles may transport proteins from one cisterna to the next, although it appears that some proteins move between cisterna through tiny channels. Vesicles budding off from the *trans* region carry their contents away from the Golgi apparatus. These vesicles go to the plasma membrane or to the lysosome.

LYSOSOMES The **primary lysosomes** originate from the Golgi apparatus. They contain hydrolases (digestive enzymes), and they are the sites where macromolecules—proteins, polysaccharides, nucleic acids, and lipids—are hydrolyzed into their monomers (see Chapter 2). A lysosome is about 1 μm in diameter; it is surrounded by a single membrane and has a densely staining, featureless interior (**FIGURE 4.9**). There may be dozens of lysosomes in a cell.

Some macromolecules that are hydrolyzed in lysosomes enter from the environment outside the cell by a process called *phagocytosis* (*phago*, “eat”; *cytosis*, “cellular”). In this process, a pocket forms in the plasma membrane and then deepens and encloses material from outside the cell. The pocket becomes a small vesicle containing macromolecules (e.g., proteins), called a *phagosome*, which breaks free of the plasma membrane to move into the cytoplasm. The phagosome fuses with a primary lysosome to form a **secondary lysosome**, in which hydrolysis occurs. The products of digestion (e.g., amino acids) pass through the membrane of the lysosome, providing monomers for other cellular processes. The “used” secondary lysosome, now containing undigested particles, then moves to the plasma membrane, fuses with it, and releases the undigested contents to the environment.

Phagocytes are specialized cells whose major role is to take in and break down materials; they are found in nearly all animals and many protists. However, lysosomes are active even in cells that do not perform phagocytosis. All cells continually break down some of their components and replace them with new ones. The programmed destruction of cell components is called *autophagy*, and lysosomes are where the cell breaks down its own materials, even entire organelles, hydrolyzing their constituents.

How important is autophagy? An entire class of human diseases called *lysosomal storage diseases* occur when lysosomes fail to digest internal components; these diseases are often very harmful or fatal. An example is Tay-Sachs disease, in which a particular lipid called a ganglioside is not broken down in the lysosomes and instead accumulates in brain cells and damages them. In the most common form of this disease, a baby starts exhibiting neurological symptoms and becomes blind, deaf, and unable to swallow after six months of age. Death occurs before age four.

Plant cells do not appear to contain lysosomes, but the central vacuole of a plant cell (which we will describe below) may

APPLY THE CONCEPT

Eukaryotic cells have a nucleus and other membrane-bound compartments

Proteins can be tagged with radioactivity and specific molecules (antibodies) so they can be detected in particular cell fractions. Liver cells were exposed to radioactive amino acids for 3 minutes, which made all proteins being synthesized during that period radioactive. Then the radioactive amino acids were removed and, at 5-minute intervals, portions of the cells were broken open and fractionated—the organelles were separated from one another as shown in Figure 4.3B. An antibody to the protein lipase was used to distinguish lipase from all the other proteins present. The percentage of radioactively labeled lipase in several cell compartments was determined. The table shows the results.

TIME (MIN)	PERCENTAGE OF RADIOACTIVE LIPASE			
	ER LUMEN	GOLGI	LYSOSOMES	RIBOSOMES
5	5	0	0	95
10	25	10	0	65
15	75	20	5	0
20	25	55	20	0
25	0	65	35	0
30	0	25	75	0
35	0	0	100	0

1. What can you conclude about the pathway of lipase in the cell after it is synthesized?
2. Look up the function of lipase in Concept 39.3. Why is its organelle destination appropriate?

FIGURE 4.9 Lysosomes Isolate Digestive Enzymes from the Cytoplasm Lysosomes are sites for the hydrolysis of material taken into the cell by phagocytosis.

yourBioPortal.com

Go to **WEB ACTIVITY 4.2**
Lysosomal Digestion

function in an equivalent capacity because it, like lysosomes, contains many digestive enzymes.

Some organelles transform energy

A cell requires energy to make the molecules it needs for activities such as growth, reproduction, responsiveness, and movement. *Mitochondria* (found in all eukaryotic cells) harvest chemical energy, while *chloroplasts* (found in plants and other photosynthetic cells) harvest energy from sunlight.

MITOCHONDRIA In eukaryotic cells, the breakdown of energy-rich molecules such as the monosaccharide glucose begins in the cytosol. The molecules that result from this partial degradation enter the **mitochondrion** (plural *mitochondria*), whose primary function is to convert the chemical energy of those molecules into a form the cell can use, namely the energy-rich nucleotide ATP (adenosine triphosphate; see Concept 6.1).

A typical mitochondrion is somewhat less than 1.5 μm in diameter and 2–8 μm in length—about the size of many bacteria. It can divide independently of the central nucleus. The number of mitochondria per cell ranges from one gigantic organelle in some unicellular protists to a few hundred thousand in large egg cells. An average human liver cell contains more than 1,000 mitochondria. Cells that are active in movement and growth require the most chemical energy, and these tend to have the most mitochondria per unit of volume.

Mitochondria have two membranes. The outer membrane has large pores, and most substances can pass through it. The inner membrane separates the biochemical processes of the mitochondrion from the surrounding cytosol. The inner membrane is extensively folded into structures called *cristae*, and the fluid-filled region inside the inner membrane is referred to as the mitochondrial *matrix*. The mitochondrion contains many enzymes for energy metabolism, as well as DNA and ribosomes for the synthesis of a small proportion of the mitochondrial proteins.

PLASTIDS Plastids are present in the cells of plants and algae, and like mitochondria, they can divide autonomously. Plastids can differentiate into a variety of organelles, some of which are used for the storage of pigments (as in flowers), carbohydrates (as in potatoes), lipids, or proteins. An important type of plastid is the **chloroplast**, which contains the green pigment chlorophyll and is the site of photosynthesis (see Concepts 6.5 and 6.6). Photosynthesis is an anabolic process that converts light energy into the chemical energy contained in bonds between the atoms of carbohydrates.

A chloroplast is enclosed within two membranes. In addition, it contains a series of internal membranes that look like stacks of flat, hollow discs, called *thylakoids*. Each stack of thylakoids is called a *granum* (plural *grana*). Light energy

is converted to chemical energy on the thylakoid membranes. The aqueous fluid surrounding the thylakoids is called the *stroma*, and it is there that carbohydrates are synthesized. Like the mitochondrial matrix, the chloroplast stroma contains ribosomes and DNA, which are used to synthesize some of the chloroplast proteins.

Several other membrane-enclosed organelles perform specialized functions

There are several other kinds of membrane-bound organelles with specialized functions: peroxisomes, glyoxysomes, and vacuoles, including contractile vacuoles.

PEROXISOMES **Peroxisomes** are small (0.2–1 μm diameter) organelles that accumulate toxic peroxides, such as hydrogen peroxide (H_2O_2), which occur as the by-products of some biochemical reactions in all eukaryotes. These peroxides can be safely broken down inside the peroxisomes without mixing with other components of the cell. A peroxisome has a single membrane and a granular interior containing specialized enzymes.

GLYOXYSOMES **Glyoxysomes** are found only in plants. They are most abundant in young plants and are the locations where stored lipids are converted into carbohydrates for transport to growing cells.

VACUOLES **Vacuoles** occur in many eukaryotic cells, but particularly those of plants and fungi (see Figure 4.6). Plant vacuoles have several functions:

- **Storage:** Like all cells, plant cells produce a variety of toxic by-products and waste products. Plants store many of these in vacuoles. Because they are poisonous or distasteful, these stored materials deter some animals from eating the plants, and may thus contribute to the plants' defenses and survival.
- **Structure:** In many plant cells, enormous vacuoles take up more than 90 percent of the cell volume and grow as the cell grows. The presence of dissolved substances in the vacuole causes water to enter it from the cytoplasm (which in turn takes up water from outside the cell), making the vacuole swell like a water-filled balloon. (This osmotic effect is illustrated in Figure 5.3.) The plant cell wall resists the swelling, causing the cell to stiffen from the increase in water pressure. This pressure is called *turgor pressure*, and it helps support the plant.
- **Reproduction:** Some pigments in the petals and fruits of flowering plants are contained in vacuoles. These pigments—the red, purple, and blue anthocyanins—are visual cues that help attract animals, which assist in pollination and seed dispersal.
- **Catabolism:** In the seeds of some plants, the vacuoles contain enzymes that hydrolyze stored seed proteins into monomers. The developing plant seedling uses these monomers as building blocks and sources of energy.

Many freshwater protists have *contractile vacuoles*. Their function is to get rid of the excess water that rushes into the cell because of the imbalance in solute concentration between the interior of the cell and its freshwater environment. The contractile vacuole enlarges as water enters, and then abruptly contracts, forcing the water out of the cell through a special pore structure.

Do You Understand Concept 4.3?

- Make a table that summarizes eukaryotic cell organelles with regard to size, numbers per cell, and functions.
- What are some functions of the cell nucleus? What are the advantages of confining these functions within the nucleus, separated from the cytoplasm?
- Compare the structural and functional differences between rough and smooth endoplasmic reticulum.
- In I-cell disease, an enzyme in the endomembrane system that normally adds phosphorylated sugar groups to proteins is lacking, and the proteins are not targeted to the lysosomes as they would be in normal cells. The “I” stands for inclusion bodies that appear in the cells. What do you think these inclusions are, and why do they accumulate?

So far, we have discussed numerous membrane-enclosed organelles. Now we’ll turn to a group of cytoplasmic structures without membranes.

concept 4.4

The Cytoskeleton Provides Strength and Movement

The interior of the cell has a meshwork of protein filaments. Each type of filament is a polymer, made up of monomers that are proteins (which in turn are polymers of amino acids). This **cytoskeleton** fills several important roles:

- It supports the cell and maintains its shape.
- It controls the positions and movements of organelles within the cell.
- It is involved with bulk movements of the cytoplasm, called *cytoplasmic streaming*.
- It interacts with extracellular structures, helping to anchor the cell in place.

There are three components of the cytoskeleton: microfilaments (smallest diameter), intermediate filaments, and microtubules (largest diameter). These filaments have very different functions.

Microfilaments are made of actin

Microfilaments (FIGURE 4.10A) are usually in bundles. Each filament is about 7 nm in diameter and up to several micrometers long. Microfilaments have two major roles:

- They help the entire cell or parts of the cell to move.
- They determine and stabilize cell shape.

(A) **Microfilaments**
Made up of strands of the protein actin; often interact with strands of other proteins.

(B) **Intermediate filaments**
Made up of fibrous proteins organized into tough, ropelike assemblages that stabilize a cell's structure and help maintain its shape.

(C) **Microtubules**
Long, hollow cylinders made up of many molecules of the protein tubulin. Tubulin consists of two subunits, α -tubulin and β -tubulin.

FIGURE 4.10 The Cytoskeleton Three highly visible and important structural components of the cytoskeleton are shown here in detail. Specific stains were used to visualize them in a single cell.

These structures maintain and reinforce cell shape and contribute to cell movement.

Microfilaments are assembled from *actin* monomers that attach to the filament at one end (the “plus end”) and detach at the other (the “minus end”). In an intact filament, assembly and detachment are in equilibrium. But sometimes the filaments can shorten (more detachment) or lengthen (more assembly):

$$\text{actin polymer (filament)} \rightleftharpoons \text{actin monomers}$$

This property of **dynamic instability** is a hallmark of the cytoskeleton. Portions of it can be made and broken down rather quickly, depending on cell function. Actin-associated proteins work at both ends of the filament to catalyze assembly and disassembly.

In the muscle cells of animals, actin filaments are associated with another protein, the motor protein *myosin*, and the interactions of these two proteins account for the contraction of muscles. In non-muscle cells, actin filaments are associated with localized changes in cell shape. For example, microfilaments are involved in the flowing movement of the cytoplasm called cytoplasmic streaming, in amoeboid movement, and in the “pinching” contractions that divide an animal cell into two daughter cells. Microfilaments are also involved in the formation of cellular extensions called pseudopodia (*pseudo*, “false”; *podia*, “feet”) that enable some cells (such as *Amoeba*, see Figure 4.14) to move.

Intermediate filaments are diverse and stable

There are at least 50 different kinds of **intermediate filaments** (FIGURE 4.10B), many of them specific to just a few cell types. They generally fall into six molecular classes (based on amino acid sequence) that share the same general structure. One of these classes consists of fibrous proteins of the keratin family, which also includes the proteins in hair and fingernails. The intermediate filaments are tough, ropelike protein assemblages 8–12 nm in diameter. Intermediate filaments are more permanent than the other two types of filaments and do not show dynamic instability. Intermediate filaments have two major structural functions:

- They anchor cell structures in place. In some cells, intermediate filaments radiate from the nuclear envelope and help maintain the positions of the nucleus and other organelles in the cell.
- They resist tension. For example, they maintain rigidity in body surface tissues by extending through the cytoplasm and connecting specialized membrane structures called desmosomes (see Figure 4.18).

Microtubules are the thickest elements of the cytoskeleton

Microtubules are the largest diameter components of the cytoskeletal system (FIGURE 4.10C). They are long, hollow, unbranched cylinders about 25 nm in diameter and up to several micrometers long. Microtubules have two roles:

- They form a rigid internal skeleton for some cells or cell regions.

- They act as a framework along which motor proteins can move structures within the cell.

Microtubules are assembled from dimers of the protein *tubulin*. The dimers consist of one molecule each of α -tubulin and β -tubulin. Thirteen chains of tubulin dimers surround the hollow microtubule. Like microfilaments, microtubules show dynamic instability, with (+) and (–) ends and associated proteins.

$$\text{microtubule} \rightleftharpoons \text{tubulin monomers}$$

Tubulin polymerization results in a rigid structure, and tubulin depolymerization leads to its collapse. Microtubules often form an interior skeleton for projections that come out of the plasma membrane, such as cilia and flagella (see below).

FRONTIERS In a search for inhibitors of cell division for treating cancer, the molecule taxol was purified from the Pacific yew, an evergreen tree. Taxol works by blocking the disassembly of microtubules at their minus ends—the exact mechanism remains unclear. Treated microtubules are stable, and this prevents chromosome separation during cell division. Unfortunately, taxol is not very soluble in tissue fluids, and it has adverse side effects. There is a major effort to synthesize and test chemically modified taxol to overcome these problems.

Cilia and flagella provide mobility

Microtubules line movable cell appendages: the **cilia** (singular *cilium*; FIGURE 4.11) and the flagella (see Concept 4.2). Many eukaryotic cells have one or both of these appendages, which are projections of the plasma membrane lined with microtubules and their associated proteins:

- Cilia are only 0.25 μm in length. They are present by the hundreds and move stiffly to either propel a cell (for example, in protists) or to move fluid over a stationary cell (as in the human respiratory system).
- Flagella are much longer—100 to 200 μm in length—and occur singly or in pairs. They can push or pull the cell through its aqueous environment.

The microtubules that line cilia and flagella do more than just make them rigid. Microtubules and their associated proteins are responsible for the movement of these organelles by bending.

In cross section, a typical cilium or eukaryotic flagellum is surrounded by the plasma membrane and contains a “9 + 2” array of microtubules. As Figure 4.11B shows, nine fused pairs of microtubules—called doublets—form an outer cylinder, and one pair of unfused microtubules runs up the center. A spoke radiates from one microtubule of each doublet and connects the doublet to the center of the structure. These structures are essential to the bending motions of both cilia and flagella. How does this occur?

The motion of cilia and flagella results from the sliding of the microtubule doublets past each other. This sliding is driven by a motor protein called *dynein*, which can change its three-dimensional shape. (All motor proteins work by undergoing

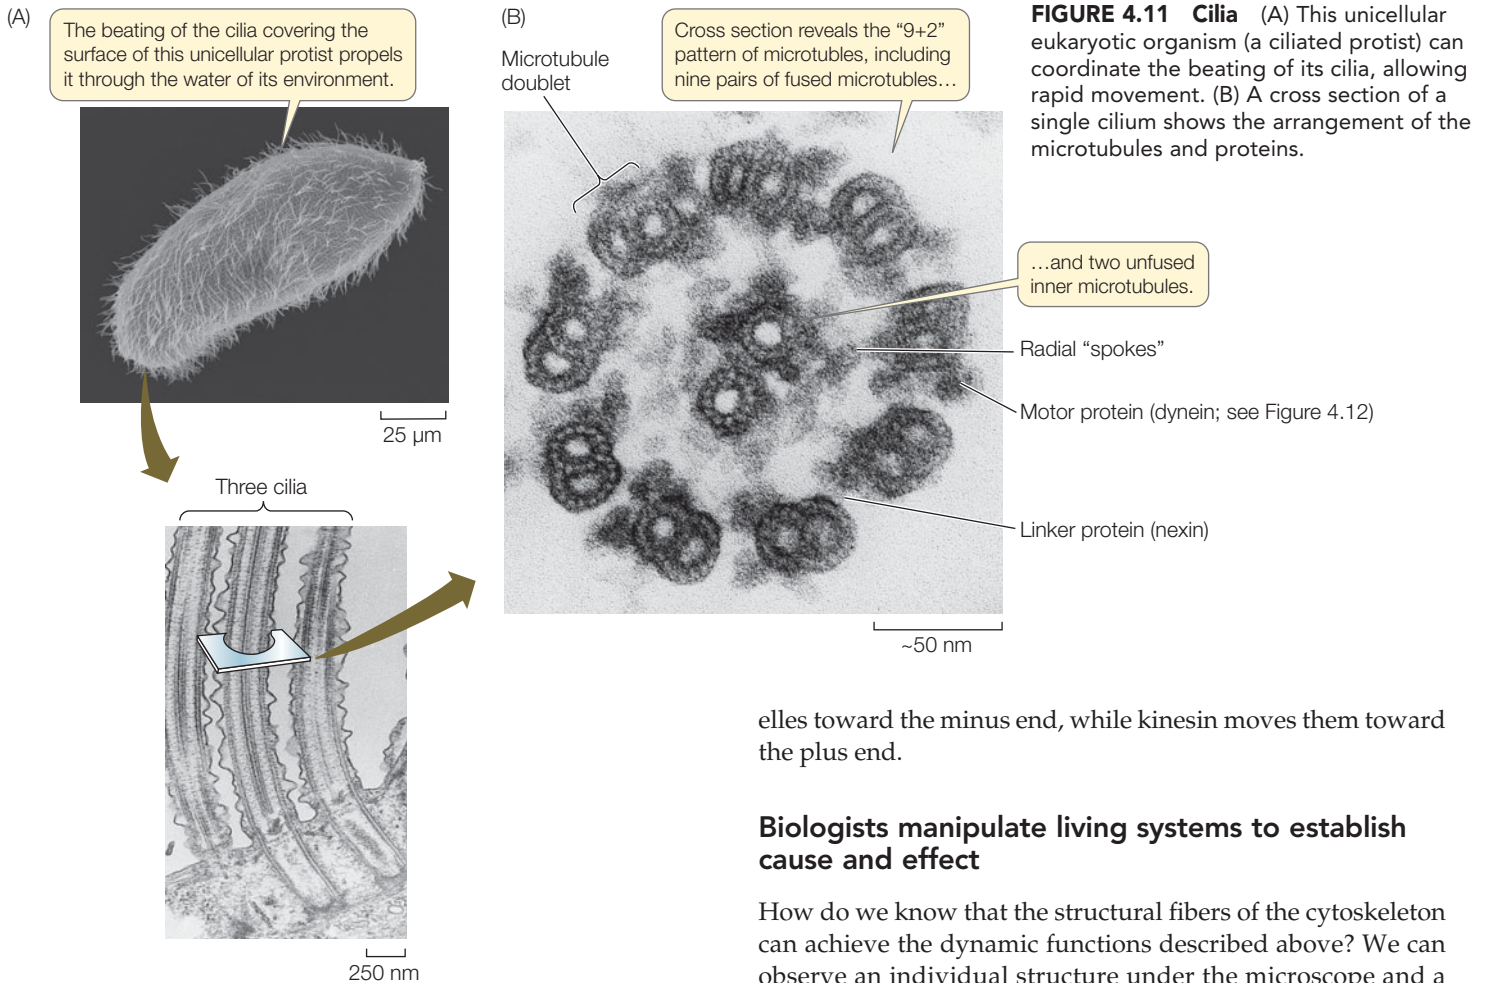

FIGURE 4.11 Cilia (A) This unicellular eukaryotic organism (a ciliated protist) can coordinate the beating of its cilia, allowing rapid movement. (B) A cross section of a single cilium shows the arrangement of the microtubules and proteins.

elles toward the minus end, while kinesin moves them toward the plus end.

Biologists manipulate living systems to establish cause and effect

How do we know that the structural fibers of the cytoskeleton can achieve the dynamic functions described above? We can observe an individual structure under the microscope and a function in a living cell that contains that structure. These simultaneous observations suggest that the structure may carry out that function, but in science, mere *correlation does not establish cause and effect*. For example, light microscopy of living cells reveals the movement of the cytoplasm within the cell. The observed presence of cytoskeletal components *suggests, but does not prove*, their role in this process. Science seeks to show the specific links that relate a structure or molecule (“A”) to a

reversible shape changes powered by energy from ATP hydrolysis.) Dynein molecules bind between two neighboring microtubule doublets. As the dynein molecules change shape, they move the doublets past one another (**FIGURE 4.12**). Another protein, *nexin*, can cross-link the doublets and prevent them from sliding past one another; in this case, the cilium bends.

Motor proteins, including *kinesin*, carry protein-laden vesicles from one part of the cell to another (**FIGURE 4.13**). These proteins bind to a vesicle or other organelle, then “walk” it along a microtubule by a repeated series of shape changes. A slightly different form of dynein from the one that moves cilia also performs this function. Recall that microtubules are directional, with a plus end and a minus end. Dynein moves attached organ-

FIGURE 4.12 A Motor Protein Moves Microtubules in Cilia and Flagella The motor protein dynein causes microtubule doublets to slide past one another. If the protein nexin is present to anchor the microtubule doublets together, the flagellum or cilium bends.

In isolated cilia without nexin cross-links, movement of dynein motor proteins causes microtubule doublets to slide past one another.

When nexin is present to cross-link the doublets, they cannot slide and the force generated by dynein movement causes the cilium to bend.

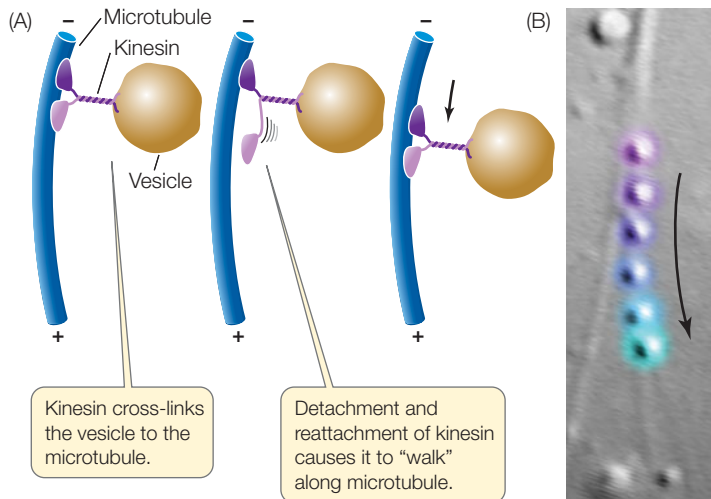

FIGURE 4.13 A Motor Protein Drives Vesicles along Microtubules (A) Kinesin delivers vesicles or organelles to various locations in the cell by moving along microtubule "railroad tracks." (B) The process is seen by time-lapse photography at half-second intervals in the protist *Dictyostelium*.

function ("B"). Two manipulative approaches are commonly used in cell biology:

- **Inhibition:** Use a drug that inhibits A, and see if B still occurs. If B does not occur, then A is probably a causative factor for B. **FIGURE 4.14** shows an experiment in which an inhibitor is used to demonstrate cause and effect in the case of the cytoskeleton and cell movement.
- **Mutation:** Examine a cell or organism that lacks the gene (or genes) for A, and see if B still occurs. If it does not, then A is probably a causative factor for B. You will see many examples of this experimental approach later in this book.

Do You Understand Concept 4.4?

- Make a table that compares the three major components of the cytoskeleton with regard to composition, structure, and function.
- The neuron (nerve cell) has a long extension called an axon. Molecules made in the cell's main body must travel a long distance to reach the end of the axon. The axon is lined with microtubules. Explain how motor proteins, vesicles, and microtubules move these molecules along the axon.
- In a dividing cell, the chromosomes become very compact, and then the duplicated sets of chromosomes move along the microtubules to opposite ends of the cell. How would you use an inhibitor to show that microtubules are essential for this chromosomal separation? What control experiments would you suggest?

All cells interact with their environments, and many eukaryotic cells are part of multicellular organisms and must interact with other cells. The plasma membrane plays a crucial role in these interactions, but other structures outside that membrane are

INVESTIGATION

FIGURE 4.14 The Role of Microfilaments in Cell Movement: Showing Cause and Effect in Biology In test tubes, the drug cytochalasin B prevents microfilament formation from monomeric precursors. This led to the question: Will the drug work like this in living cells and inhibit the movement of *Amoeba*?

HYPOTHESIS

Amoeboid cell movements are caused by the cytoskeleton.

METHOD

Amoeba proteus is a single-celled eukaryote that moves by extending its membrane.

Cytochalasin B is a drug that blocks the formation of microfilaments, part of the cytoskeleton.

Amoeba treated with cytochalasin B

RESULTS

Treated *Amoeba* is alive but rounds up and does not move

Control *Amoeba* continues to move

CONCLUSION

Microfilaments of the cytoskeleton are essential for amoeboid cell movement

ANALYZE THE DATA

Several important controls were done to validate the conclusions of this experiment. The experiment was repeated in the presence of the following drugs: cycloheximide, which inhibits new protein synthesis; dinitrophenol, which inhibits new ATP formation (energy); and colchicine, which inhibits the polymerization of microtubules. Here are the results:

Condition	Rounded cells (%)
No drug	3
Cytochalasin B	95
Colchicine	4
Cycloheximide	3
Cycloheximide + cytochalasin B	94
Dinitrophenol	5
Dinitrophenol + cytochalasin B	85

Explain each experiment. What can you conclude about *Amoeba* and the cytoskeleton?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

involved as well. We now turn to these extracellular structures in animals and plants

concept 4.5

Extracellular Structures Allow Cells to Communicate with the External Environment

Although the plasma membrane is the functional barrier between the inside and the outside of a cell, molecules are produced by cells and secreted to the outside of the plasma membrane, where they form structures that play essential roles in protecting, supporting, or attaching cells to each other. Because they are outside the plasma membrane, these structures are said to be *extracellular*. In eukaryotes, these structures are made up of two components:

- A prominent fibrous macromolecule
- A gel-like medium in which the fibers are embedded

The plant cell wall is an extracellular structure

The plant **cell wall** is a semirigid structure outside the plasma membrane (FIGURE 4.15). The *fibrous* component is the polysaccharide cellulose (see Figure 2.10), and the *gel-like matrix* contains extensively cross-linked polysaccharides and proteins. The wall has three major roles:

FIGURE 4.15 The Plant Cell Wall The semirigid cell wall provides support for plant cells. It is composed of cellulose fibers embedded in a matrix of polysaccharides and proteins.

- It provides support for the cell and limits the volume of a mature cell by remaining rigid.
- It acts as a barrier to infection by fungi and other organisms that can cause plant diseases.
- It contributes to plant form by controlling the direction of cell expansion during growth and development.

Because of their thick cell walls, plant cells viewed under a light microscope appear to be entirely isolated from one another. But electron microscopy reveals that this is not the case. The cytoplasm of adjacent plant cells are connected by numerous plasma membrane-lined channels, called **plasmodesmata**, that are about 20–40 nm in diameter and extend through the cell walls (see Figure 4.7). Plasmodesmata allow water, ions, small molecules, hormones, and even some RNA and protein molecules to move between connected cells. In this way, energy-rich molecules such as sugars can be shared among cells, and plant hormones can affect growth at sites far from where they were synthesized. This intercellular communication integrates a plant organ composed of thousands of cells.

FRONTIERS In most plants, cellulose is synthesized by a complex of enzymes at the plasma membrane and then secreted into the cell wall. The orientation of the cellulose fibers determines the final shape of a cell and, in aggregate, the shapes of plant organs such as leaves and roots. Cytoplasmic microtubules appear to be important in orienting the fibers, possibly by interacting with the synthesis complex. However, it is not yet clear how the orientation of the microtubules themselves is determined.

The extracellular matrix supports tissue functions in animals

Animal cells lack the semirigid wall that is characteristic of plant cells, but many animal cells are surrounded by, or in contact with, an **extracellular matrix** (FIGURE 4.16). The *fibrous component* of the extracellular matrix is the protein **collagen**, and the gel-like matrix consists of **proteoglycans**, which are glycoproteins with long carbohydrate side chains. A third group of proteins links the collagen and the proteoglycan matrix together.

The extracellular matrices of animal cells have several roles:

- They hold cells together in tissues.
- They contribute to the physical properties of cartilage, skin, and other tissues. For example, the mineral component of bone is laid down on an organized extracellular matrix.
- They help filter materials passing between different tissues. This is especially important in the kidney.
- They help orient cell movements during embryonic development and during tissue repair.

Proteins connect the cell's plasma membrane to the extracellular matrix. These proteins (for example, *integrin*) span the plasma membrane and have two binding sites: one on the interior of the cell, usually to microfilaments in the cytoplasm just

FIGURE 4.16 An Extracellular Matrix Cells in the kidney secrete an extracellular matrix called the basal lamina that separates them from nearby blood vessels. The basal lamina filters materials that pass between the kidney and the blood.

below the cell surface, and the other to collagen in the extracellular matrix. These binding sites are noncovalent and reversible. When a cell moves its location in an organism, the first step is for integrin to change its three-dimensional structure so that it detaches from the collagen (**FIGURE 4.17**).

Cell junctions connect adjacent cells

In a multicellular animal, specialized structures protrude from adjacent cells to “glue” them together. These **cell junctions** are most evident in electron micrographs of *epithelial tissues*, which are layers of cells that line body cavities or cover body surfaces (examples are skin and the lining of the windpipe leading to the lungs). These surfaces are often exposed to environmental factors that might disrupt the integrity of the tissues, so it is particularly important that their cells stick together tightly. There are three types of junctions (**FIGURE 4.18**):

- *Tight junctions* prevent substances from moving through spaces between cells. For example, the epithelium of the urinary bladder contains tight junctions to prevent urine from leaking out into the body.
- *Desmosomes* hold adjacent cells together with stable protein connections, but materials can still move around in the extracellular matrix. This provides mechanical stability for tissues such as skin that receive physical stress.
- *Gap junctions* are like plant plasmodesmata: they are channels that run between membrane pores in adjacent cells, allowing substances to pass between cells. In the heart, for example, gap junctions allow the rapid spread of electric current mediated by ions so the heart muscle cells can beat in unison.

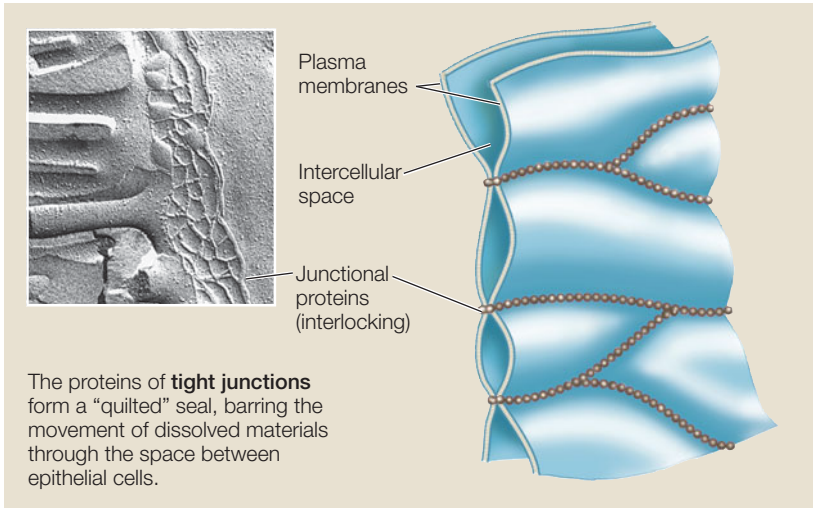

FIGURE 4.18 Junctions Link Animal Cells Although all three types of junctions are shown in the cell at right, they don’t necessarily all occur in the same cell.

Do You Understand Concept 4.5?

- Compare the extracellular matrix of plant cells and animal cells.
- What kinds of cell junctions would you expect to find, and why, in the following situations?
 - a. In the digestive system, where material must pass through cells and not go through the extracellular material, to get from the intestine to the blood vessels.
 - b. In a small animal, where a chemical signal passes rapidly through cells to go from the head to the tail.
 - c. In the lining of the intestine, where cells in the lining are constantly jostled by the churning of the underlying muscle
- When cancer spreads from its primary location to other parts of the body (a process called metastasis), tumor cells detach from their original location and then reattach at a different location. How would the integrin-collagen system be involved in this process?

What do the characteristics of modern cells tell us about how the first cells originated?

ANSWER Ideas about how the first cells may have formed focus on two questions: how and when. As to how cells could arise from a chemical-rich environment, most biologists assume that a cell membrane formed first and was necessary to provide a compartment for the chemical transformations of life to occur, separated from the environment (Concept 4.1). Biologists also assume that the first cells were relatively simple prokaryotes (Concept 4.2), without the organelles that define eukaryotic cells (Concept 4.3).

Jack Szostak, a Nobel laureate at Harvard University, builds synthetic cell models that give insights into the origin of cells. He and his colleagues make small membrane-lined droplets by putting fatty acids into water and then shaking the mixture. The lipids form water-filled droplets, each surrounded by a lipid bilayer “membrane” (see Figure 2.13). With water (and other molecules of the scientists’ choosing) trapped inside, these spheres have many properties characteristic of modern cells—so many that they have been called *protocells* (FIGURE 4.19). For example, the membrane barrier determines what goes in and out of a protocell, by excluding macromolecules like RNA but allowing smaller molecules such as nucleotides

FIGURE 4.19 A Protocell A protocell can be made in the lab and can carry out some functions of modern cells—in particular, it provides a compartment for biochemical reactions.

to pass through. Moreover, RNA inside the protocell can act as a catalyst, replicating itself from nucleotides that enter the protocell. The spheres are somewhat unstable, and under the microscope they can be seen to grow, elongate, and break, a possible precursor of more precise cell division.

Is this really a cell, possibly like the one where life started? Certainly not: it cannot fully reproduce itself, and its capacities for metabolism are limited. But by providing a compartment for biochemical reactions with a boundary that separates it from the environment, the protocell is a model for the first cell.

When did the first cells on Earth appear? According to geologists, Earth is about 4.5 billion years old. Heat and atmospheric conditions precluded life for at least a half-billion years after Earth formed. The oldest fossils of multicellular organisms date from about 1.2 billion years ago.

In all probability, life began with single-celled organisms resembling modern bacteria. Unfortunately, such cells lack the structures that are typically preserved in fossils, and so they die without a trace. Recently, however, geochemist and paleontologist William Schopf at the University of California, Los Angeles used a new method of microscopy called confocal laser scanning microscopy, combined with chemical analyses, to identify fossil cells that are about 800 million years old. Some of these look like Szostak’s protocells. These were probably not the first cells, as there is chemical evidence in some rocks that life was present about 3.8 billion years ago. But so far, Schopf’s fossilized cells are the oldest cells that anyone has been able to find.

4

SUMMARY

concept 4.1 Cells Provide Compartments for Biochemical ReactionsSee **WEB ACTIVITY 4.1**

- Cell theory states that the cell is the fundamental unit of biological structure and function.
- Cells are small because a cell's surface area must be large compared with its volume to accommodate exchanges between the cell and its environment. **Review Figure 4.2**
- All cells are enclosed by a selectively permeable **plasma membrane** that separates their contents from the external environment.

concept 4.2 Prokaryotic Cells Do Not Have a Nucleus

- Prokaryotic cells usually have no internal compartments, but have a **nucleoid** containing DNA, and a **cytoplasm** containing **cytosol**, **ribosomes** (the sites of protein synthesis), proteins, and small molecules. Many have an extracellular **cell wall**. **Review Figure 4.5**
- Some prokaryotes have folded membranes, for example photosynthetic membranes, and some have **flagella** for motility. **Review Figure 4.6**

concept 4.3 Eukaryotic Cells Have a Nucleus and Other Membrane-Bound Compartments

- Eukaryotic cells contain many membrane-enclosed **organelles** that compartmentalize their biochemical functions. **Review Figure 4.7 and ANIMATED TUTORIAL 4.1**
- The **nucleus** contains most of the cell's DNA.
- The **endomembrane system**—consisting of the nuclear envelope, **endoplasmic reticulum**, **Golgi apparatus**, and **lysosomes**—is a series of interrelated compartments enclosed by membranes. It segregates proteins and modifies them. Lysosomes contain many digestive enzymes. **Review Figures 4.8 and 4.9, ANIMATED TUTORIAL 4.2, and WEB ACTIVITY 4.2**

- **Mitochondria** and **chloroplasts** are semiautonomous organelles that process energy.
- A **vacuole** is prominent in many plant cells. It is a membrane-enclosed compartment full of water and dissolved substances.

concept 4.4 The Cytoskeleton Provides Strength and Movement

- The **microfilaments**, **intermediate filaments**, and **microtubules** of the **cytoskeleton** provide the cell with shape, strength, and movement. **Review Figure 4.10**
- Microfilaments and microtubules have **dynamic instability** and can grow or shrink in length rapidly.
- **Cilia** and **flagella** are microtubule-lined extensions of the plasma membrane that produce movements of cells or their surrounding fluid medium. **Review Figures 4.11 and 4.12**
- Motor proteins move cellular components, such as vesicles, around the cell by “walking” along microtubules. **Review Figure 4.13**
- Biologists establish cause-and-effect relationships by manipulating biological systems. **Review Figure 4.14**

concept 4.5 Extracellular Structures Allow Cells to Communicate with the External Environment

- The plant **cell wall** consists principally of **cellulose**. Cell walls are pierced by **plasmodesmata** that join the cytoplasm of adjacent cells. **Review Figure 4.15**
- In animals, the **extracellular matrix** consists of different kinds of proteins, including collagen and proteoglycans. Integrins connect the cell cytoplasm with the extracellular matrix. **Review Figures 4.16 and 4.17**
- Specialized cell junctions connect cells in animal tissues. These include **tight junctions**, **desmosomes**, and **gap junctions**. The last are involved in intercellular communication. **Review Figure 4.18 and WEB ACTIVITY 4.3**

Cell Membranes and Signaling

5

If you are like most people, you consume a significant amount of caffeine every day. In fact, more than 90 percent of North Americans and Europeans drink coffee or tea to get their “caffeine fix.” Coffee and tea plants contain caffeine as a defense against the insects that eat them. Caffeine acts as an insecticide in plant parts that are particularly vulnerable to insect attacks, such as seeds, young seedlings, and leaves. But it is not toxic to humans.

Legend has it that about 5,000 years ago, a Chinese emperor found out by accident that a pleasant beverage could be made by boiling tea leaves. About 1,000 years ago, monks living in what is now Ethiopia found that roasting coffee seeds (“beans”) gave a similarly pleasant effect and that the beverage kept them awake during long periods of prayer. Caffeine is now the most widely consumed psychoactive molecule in the world, but unlike other psychoactive drugs, it is not subject to government regulation.

Most people know from personal experience what caffeine does to the body: because it keeps us awake, it obviously affects the brain. In fact, it is often given to premature babies in the hospital nursery when they stop breathing. But it also affects other parts of the body—for example, it increases urination and speeds up the heart. How does this molecule work?

The key to understanding caffeine’s action is to understand how it interacts with the cell membrane. In Chapter 4 we introduce the concept of the membrane as a structural boundary between the inside of a cell and the surrounding environment.

The plasma membrane physically separates the cell cytoplasm from its surroundings and helps maintain chemical differences between these two environments. The same can be said of the membranes that surround cell organelles, separating them from the cytoplasmic environment.

When caffeine arrives at a cell in the body, it first encounters the plasma membrane. The properties of this membrane determine whether and how the cell will react to caffeine. Will it cross the membrane boundary and enter the cell? What determines whether it crosses the membrane? If it does not, how can caffeine’s interactions with membrane components lead to changes in cell function?

What role does the cell membrane play in the body’s response to caffeine?

Many people rely on caffeine to wake themselves up and to keep their minds alert.

KEY CONCEPTS

- 5.1** Biological Membranes Have a Common Structure and Are Fluid
- 5.2** Some Substances Can Cross the Membrane by Diffusion
- 5.3** Some Substances Require Energy to Cross the Membrane
- 5.4** Large Molecules Cross the Membrane via Vesicles
- 5.5** The Membrane Plays a Key Role in a Cell’s Response to Environmental Signals
- 5.6** Signal Transduction Allows the Cell to Respond to Its Environment

concept 5.1 Biological Membranes Have a Common Structure and Are Fluid

The evolution of cellular life required the presence of a boundary, a way to separate the inside of the cell from the surrounding environment. This need was—and still is—fulfilled by biological membranes. Like many of the basic processes of life at the cellular level, the functions of membranes are carried out by a molecular structure shared by most organisms.

A biological membrane's structure and functions are determined by the chemical properties of its constituents: lipids, proteins, and carbohydrates. An important concept that emerges from our consideration of these molecules is polarity and how polarity influences the way a molecule interacts with water. The nonpolar regions of phospholipids and membrane proteins interact to form an insoluble barrier. The phospholipid bilayer serves as a lipid "lake" in which a variety of proteins "float" (FIGURE 5.1). This general design is known as the **fluid mosaic model**.

Membranes contain a wide array of proteins, some of which are noncovalently embedded in the phospholipid bilayer. These proteins are held within the membrane by their hydrophobic regions, or *domains*, while the proteins' hydrophilic domains are exposed to the watery conditions on one or both sides of the bilayer. Membrane proteins have several functions: they move materials through the membrane and receive chemical signals from the cell's external environment.

The carbohydrates associated with membranes are attached to either lipids or protein molecules. They are generally located on the outside of the cell, where they interact with substances in the external environment. Like some membrane proteins,

FIGURE 5.1 Membrane Molecular Structure The general molecular structure of biological membranes is a continuous phospholipid bilayer in which proteins are embedded. The phospholipid bilayer separates two aqueous regions, the external environment outside the cell and the cell cytoplasm.

yourBioPortal.com

Go to WEB ACTIVITY 5.1
Membrane Molecular Structure

carbohydrates are crucial for recognizing specific molecules, such as those on the surfaces of adjacent cells.

Each membrane is made up of constituents that are suitable for the specialized functions of the cell or organelle it surrounds. As you read about the different molecules in membranes, keep in mind that some membranes contain many protein molecules, others are lipid-rich, others have significant amounts of *cholesterol* or other sterols, and still others are rich in carbohydrates.

Lipids form the hydrophobic core of the membrane

The lipids in biological membranes are usually *phospholipids*. Recall from Concept 2.2 that some compounds are hydrophilic ("water-loving") and others are hydrophobic ("water-hating"), and that a phospholipid molecule has regions of both kinds:

- **Hydrophilic regions.** The phosphorus-containing "head" of a phospholipid is electrically charged and therefore associates with polar water molecules.
- **Hydrophobic regions.** The long, nonpolar fatty acid "tails" of a phospholipid associate with other nonpolar materials, but they do not dissolve in water or associate with hydrophilic substances.

Because of these properties, one way in which phospholipids can coexist with water is to form a *bilayer*, with the fatty acid “tails” of the two layers interacting with each other, and the polar “heads” facing the outside, aqueous environment:

LINK The properties of phospholipid bilayers are described in Concept 2.4

The thickness of a biological membrane is about 8 nm (0.008 μm), which is twice the length of a typical phospholipid. This thickness is about 8,000 times thinner than the page you are reading.

As we note in Chapter 4, in the laboratory it is possible to make artificial bilayers with the same organization as natural membranes. Small holes in such bilayers seal themselves spontaneously. The capacity of phospholipids to associate with one another and maintain a bilayer organization helps biological membranes fuse during vesicle formation, phagocytosis, and related processes (see Concept 4.3, especially Figure 4.9).

Although biological membranes all share a similar structure, there are many different kinds of phospholipids, and membranes from different cells or organelles may differ greatly in their *lipid composition*. Not only do membranes contain many different kinds of phospholipids, but also a significant proportion of the lipid content in an animal cell membrane may be cholesterol.

Phospholipids can differ in terms of fatty acid chain length (number of carbon atoms), degree of unsaturation (number of double bonds) in the fatty acids, and the kinds of polar (phosphate-containing) groups present. The most common fatty acids in membranes have chains with 16–18 carbon atoms and 0–2 double bonds. Saturated fatty acid chains (those with no

double bonds) allow close packing of phospholipids in the bilayer, whereas the “kinks” in the unsaturated fatty acids (see Figure 2.12) make for a less dense, more fluid packing.

Up to 25 percent of the lipid content of an animal cell plasma membrane may be cholesterol. When present, cholesterol is important for membrane integrity; the cholesterol in your membranes is not hazardous to your health. A molecule of cholesterol is usually situated next to an unsaturated fatty acid.

The fatty acids of the phospholipids make the membrane somewhat fluid—about as fluid as lightweight machine oil. This fluidity permits some molecules to move laterally within the plane of the membrane. A given phospholipid molecule in the plasma membrane can travel from one end of the cell to the other in a little more than one second! However, it is rare for a phospholipid molecule in one half of the bilayer to spontaneously flip over to the other side. For that to happen, the polar part of the molecule would have to move through the hydrophobic interior of the membrane. Since spontaneous flip-flops are rare, the inner and outer halves of the bilayer may be quite different in the kinds of phospholipids they contain.

Membrane fluidity is affected by several factors, two of which are particularly important:

- **Lipid composition.** Cholesterol and long-chain, saturated fatty acids pack tightly together, resulting in less fluid membranes. Unsaturated fatty acids or those with shorter chains tend to increase membrane fluidity. Some anesthetics are nonpolar and act by inserting into the membrane, where they reduce the fluidity of nerve cell membranes, and thereby decrease nerve activity.
- **Temperature.** Membrane fluidity declines under cold conditions because molecules move more slowly at lower temperatures. For example, when your fingers get numb after contact with ice, it is due to a reduction in membrane fluidity in nerve cells. To address this problem, some organisms simply change the lipid composition of their membranes when their environment gets cold, replacing saturated with unsaturated fatty acids and using fatty acids with shorter chains. These changes play a role in the survival of plants, bacteria, and hibernating animals during the winter.

APPLY THE CONCEPT

Biological membranes have a common structure and are fluid

The membrane lipids of a cell can be labeled with a fluorescent tag so the entire surface of the cell will glow evenly under ultraviolet light. If a strong laser light is then shone on a tiny region of the cell, that region gets bleached (the strong light destroys the fluorescent tag) and there is a “hole” in the cell surface fluorescence. After the laser is turned off, the hole gradually fills in with fluorescent lipids that diffuse in from other parts of the membrane. The time it takes for the hole to disappear is a measure of membrane fluidity. The table shows some data for cells with altered membrane compositions. Explain the effect of each alteration.

CONDITION	TIME (SEC) FOR “HOLE” TO BECOME FLUORESCENT
No alteration	65
Decreased length of fatty acid chains	38
Increased cholesterol	88
Increased desaturation of fatty acid chains	42
Increased membrane protein content	90

Go to INTERACTIVE TUTORIAL 5.1
Lipid Bilayer: Temperature Effects on Composition

Membrane proteins are asymmetrically distributed

All biological membranes contain proteins. Typically, plasma membranes have about 1 protein molecule for every 25 phospholipid molecules. This ratio varies depending on membrane function. In the inner membrane of the mitochondrion, which is specialized for energy processing, there is 1 protein for every 5 lipids. By contrast, myelin—a membrane that encloses portions of some neurons (nerve cells) and acts as an electrical insulator—has only 1 protein for every 70 lipids.

Recall from Table 3.2 that some amino acids contain nonpolar, hydrophobic R groups, while others contain polar (charged), hydrophilic R groups. The arrangement of these amino acids in a membrane protein determines whether the membrane protein will insert into the nonpolar lipid bilayer and how it will be positioned:

There are two general types of membrane proteins:

- **Peripheral membrane proteins** lack exposed hydrophobic groups and are not embedded in the bilayer. Instead, they have polar or charged regions that interact with exposed parts of integral membrane proteins, or with the polar heads of phospholipid molecules (see Figure 5.1).
- **Integral membrane proteins** are at least partly embedded in the phospholipid bilayer (see Figure 5.1). Like phospholipids, these proteins have both hydrophilic and hydrophobic regions.

Membrane proteins and lipids generally interact only noncovalently. The polar ends of proteins can interact with the polar ends of lipids, and the nonpolar regions of both molecules can interact hydrophobically. However, some membrane proteins have fatty acids or other lipid groups covalently attached to them. Proteins in this subgroup of integral membrane proteins are referred to as *anchored membrane proteins*, because it is their hydrophobic lipid components that anchor them in the phospholipid bilayer.

Proteins are asymmetrically distributed on the inner and outer surfaces of membranes. An integral membrane protein

that extends all the way through the phospholipid bilayer and protrudes on both sides is known as a **transmembrane protein**. In addition to one or more *transmembrane domains* that extend through the bilayer, such a protein may have domains with other specific functions on the inner and outer sides of the membrane. Transmembrane proteins are always oriented the same way—domains with specific functions inside or outside the cell are always found on the correct side of the membrane. Peripheral membrane proteins are localized on one side of the membrane or the other. This asymmetrical arrangement gives the two surfaces of the membrane different properties. As we will soon see, these differences have great functional significance.

Like lipids, some membrane proteins move relatively freely within the phospholipid bilayer. Cell fusion experiments illustrate this migration dramatically. When two cells fuse, a single continuous membrane forms around both cells, and some proteins from each cell distribute themselves uniformly around this membrane (FIGURE 5.2).

Although some proteins are free to migrate throughout the membrane, others appear to be contained within specific regions. These membrane regions are like a corral of horses on a farm: the horses are free to move around within the fenced area but not outside it. For example, a muscle cell protein that recognizes a chemical signal from a neuron is normally found only within a specific region of the plasma membrane, where the neuron meets the muscle cell.

How does this happen? Proteins inside the cell can restrict the movement of proteins within a membrane. Components of the cytoskeleton may be attached to membrane proteins protruding into the cytoplasm (see Figure 5.1). The stability of the cytoskeleton may thus restrict the movement of attached membrane proteins.

Plasma membrane carbohydrates are recognition sites

In addition to lipids and proteins, the plasma membrane contains carbohydrates. The carbohydrates are located on the outer surface of the plasma membrane and serve as recognition sites for other cells and molecules. Membrane-associated carbohydrates may be covalently bonded to lipids or to proteins:

- A **glycolipid** consists of a carbohydrate covalently bonded to a lipid. Extending outside the cell surface, the carbohydrate may serve as a recognition signal for interactions between cells. For example, the carbohydrates on some glycolipids change when cells become cancerous. This change may allow white blood cells to target cancer cells for destruction.
- A **glycoprotein** consists of a carbohydrate covalently bonded to a protein. The bound carbohydrate is an oligosaccharide of 15 or fewer monosaccharide units (see Concept 2.3). These oligosaccharides often function as signaling sites, as do the carbohydrates attached to glycolipids.

The “alphabet” of monosaccharides on the outer surfaces of membranes can generate a large diversity of messages. There may be linear or branched oligosaccharides with many different three-dimensional shapes. An oligosaccharide of a specific

shape on one cell can bind to a complementary shape on an adjacent cell. This binding is the basis of cell–cell adhesion:

FRONTIERS As an animal embryo develops, cells detach from one region, move, and then reattach at another region. This requires that cell membrane glycoproteins with binding specificities for adjacent cells are replaced by new ones with different specificities, so the cells can bind to their new neighbors. To investigate embryonic development, scientists are making genetically modified organisms whose embryonic cell membranes lack one or another surface binding component.

Membranes are constantly changing

Membranes in eukaryotic cells are constantly forming, transforming from one type to another, fusing with one another, and breaking down. As we discuss in Concept 4.3, fragments of membrane move (in the form of vesicles) from the endoplasmic reticulum (ER) to the Golgi apparatus, and from the Golgi apparatus to the plasma membrane (see Figure 4.7). Secondary lysosomes form when primary lysosomes from the Golgi apparatus fuse with phagosomes from the plasma membrane (see Figure 4.8).

Because all membranes have a similar appearance under the electron microscope, and because they interconvert readily, we might expect all subcellular membranes to be chemically identical. However, that is not the case, for *there are major chemical differences among the membranes of even a single cell*. Membranes are changed chemically when they form parts of certain organelles. In the Golgi apparatus, for example, the membranes of the *cis* face closely resemble those of the endoplasmic reticulum in chemical composition, but those of the *trans* face are more similar to the plasma membrane.

Do You Understand Concept 5.1?

- What are the differences between peripheral and integral membrane proteins?
- Why do phospholipids shaken in a water environment assemble into vesicles surrounded by a lipid bilayer?
- What is the evidence for membrane fluidity?
- If cells that recognize and attach to one another are separated, they reaggregate because of binding between their membrane glycoproteins. What would happen if the same experiment were conducted with cells treated to remove cell surface carbohydrates?

INVESTIGATION

FIGURE 5.2 Rapid Diffusion of Membrane Proteins

A human cell can be fused to a mouse cell in the laboratory, forming a single large cell (heterokaryon). This phenomenon was used to test whether membrane proteins can diffuse independently in the plane of the plasma membrane.

HYPOTHESIS

Proteins embedded in a membrane can diffuse freely within the membrane.

METHOD

- 1 The cells are fused together to create a heterokaryon.

RESULTS

CONCLUSION

Membrane proteins can diffuse rapidly in the plane of the membrane.

ANALYZE THE DATA

The experiment was repeated at various temperatures with the following results:

Temperature (°C)	Cells with mixed proteins (%)
0	0
15	8
20	42
26	77

Plot these data on a graph of Percentage Mixed vs. Temperature. Explain these data, relating the results to the concepts of diffusion and membrane fluidity.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

Now that you understand the structure of biological membranes, let's see how their components function. In the sections that follow, we will focus on the plasma membrane (the cell membrane). We'll look at how the plasma membrane regulates the passage of substances that enter or leave a cell. Bear in mind that these principles also apply to the membranes that surround organelles.

concept 5.2 Some Substances Can Cross the Membrane by Diffusion

An important property of all life is the ability to regulate the internal composition of a cell, distinguishing it from the surrounding environment. Biological membranes allow some substances, but not others, to pass through them. This characteristic of membranes is called **selective permeability**.

There are two fundamentally different processes by which substances cross biological membranes:

- The processes of **passive transport** do not require direct input of metabolic energy to drive them.
- The processes of **active transport** require the input of metabolic (chemical) energy from an outside source.

This section focuses on passive transport across membranes. The energy for the passive transport of a substance is found in the difference between its concentration on one side of the membrane and its concentration on the other. Passive transport can occur by either of two types of diffusion: *simple diffusion* through the phospholipid bilayer, or *facilitated diffusion* through channel proteins or by means of carrier proteins.

Diffusion is the process of random movement toward a state of equilibrium

In a solution, there is a tendency for all of the components to be evenly distributed. You can see this when a drop of ink is allowed to fall into a gelatin suspension (a "gel"). Initially the pigment molecules are very concentrated, but they will move about at random, slowly spreading until the intensity of color is exactly the same throughout the gel:

A solution in which the solute molecules are uniformly distributed is said to be at *equilibrium*. This does not mean the molecules have stopped moving; it just means they are moving in such a way that their overall distribution does not change.

Diffusion is the process of random movement toward a state of equilibrium. In effect, it is a net movement from regions of greater concentration to regions of lesser concentration. Diffusion is generally a *very slow process in living tissues*, especially when we consider the gel-like consistency of the cell cytoplasm. For example, it would take about 3 years for a molecule

of oxygen gas (O_2) to diffuse from the human lung to a cell at the fingertip! So it is not surprising that as plants and animals evolved and became larger and multicellular, those with circulatory systems to distribute vital molecules such as O_2 had a distinct advantage over organisms relying on simple diffusion.

How fast a substance diffuses depends on three factors:

- The *diameter* of the molecules or ions: smaller molecules diffuse faster.
- The *temperature* of the solution: higher temperatures lead to faster diffusion because the heat provides more energy for movement.
- The *concentration gradient* in the system—that is, the change in solute concentration with distance in a given direction. The greater the concentration gradient, the more rapidly a substance diffuses.

What does this mean for a cell surrounded by a membrane? The cytoplasm is largely a water-based (aqueous) solution, and so is the surrounding environment. In a complex solution (one with many different solutes), the diffusion of each solute depends only on its own concentration, not the concentrations of other solutes. So one might expect a substance with a higher concentration inside the cell to diffuse out, and one with a higher concentration outside the cell to diffuse in. Indeed, this does occur for some molecules.

Simple diffusion takes place through the phospholipid bilayer

Some small molecules can pass through the phospholipid bilayer of the membrane by **simple diffusion**. A molecule that is hydrophobic and soluble in lipids can enter the membrane readily and pass through it. The more lipid-soluble the molecule is, the more rapidly it diffuses through the lipid bilayer.

In contrast, electrically charged or polar molecules, such as amino acids, sugars, ions, and water, do not pass readily through a membrane, for two reasons. First, these molecules are not very soluble in the hydrophobic interior of the bilayer. Second, charged molecules will form hydrogen bonds with water and ions in the aqueous environment on either side of the membrane. The multiplicity of these hydrogen bonds prevents the substances from moving into the hydrophobic interior of the membrane.

FRONTIERS The effectiveness of many anesthetics in reducing feeling or sensation is directly related to their membrane lipid solubility. But it is not clear exactly what happens after the drug dissolves in the membrane. Scientists are investigating this by measuring the physical properties of membrane components after an anesthetic is added. Understanding how membrane lipids and proteins are affected by anesthetics may help in designing more specific drugs with fewer side effects.

Osmosis is the diffusion of water across membranes

Water molecules pass through specialized channels in membranes (see below) by a diffusion process called **osmosis**. This process depends on the relative concentrations of water

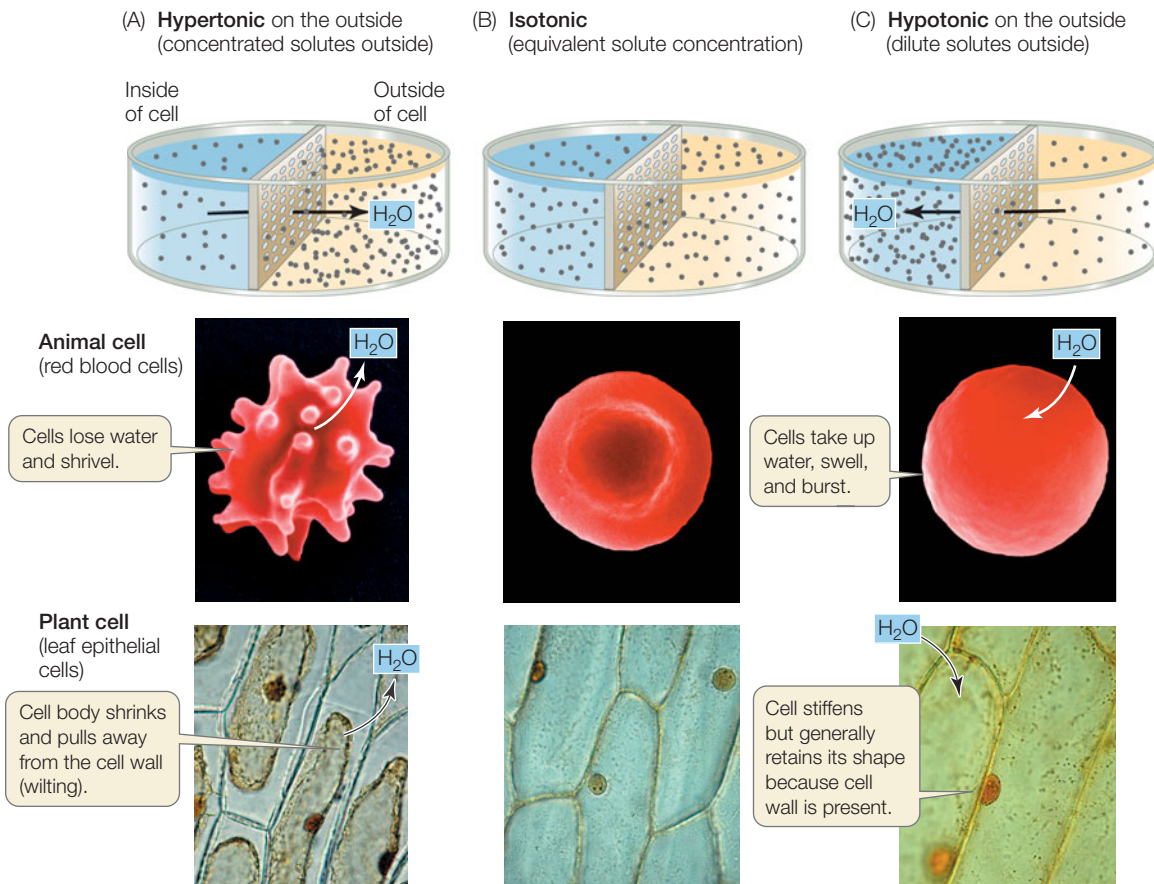

FIGURE 5.3 Osmosis Can Modify the Shapes of Cells (A) In a solution that is hypertonic to the cytoplasm of a plant or animal cell, water flows out of the cell. (B) In a solution that is isotonic with the cytoplasm, the cell maintains a consistent, characteristic shape because there is no net movement of water into or out of the cell. (C) In a solution that is hypotonic to the cytoplasm, water enters the cell. An animal cell will swell and may burst under these conditions; a plant cell will not swell too much because of its rigid cell wall.

molecules on both sides of the membrane. In a particular solution, the higher the *total* solute concentration, the lower the concentration of water molecules. Consider a situation where a membrane separating two different solutions allows water, *but not solutes*, to pass through. The water molecules will move across the membrane toward the solution with the higher solute concentration and the lower concentration of water molecules.

Here we are referring to the *net* movement of water. Since it is so abundant, water is constantly moving (through protein channels) across the plasma membrane, into and out of cells. But if there is a concentration difference between the two sides of the membrane, the overall movement will be greater in one direction or the other.

Three terms are used to compare the solute concentrations of two solutions separated by a membrane:

- A **hypertonic** solution has a higher solute concentration than the other solution (FIGURE 5.3A).
- **Isotonic** solutions have equal solute concentrations (FIGURE 5.3B).
- A **hypotonic** solution has a lower solute concentration than the other solution (FIGURE 5.3C).

The concentration of solutes in the environment determines the direction of osmosis in all animal cells. A red blood cell takes up water from a solution that is hypotonic to the cell's contents. If this happens, the cell bursts because its plasma membrane cannot withstand the pressure created by the water entry and the resultant swelling (see Figure 5.3C). The integrity of blood

cells is absolutely dependent on the maintenance of a constant solute concentration in the surrounding blood plasma—the plasma must be isotonic to the blood cells. Regulation of the solute concentrations of body fluids is thus an important process for organisms without cell walls.

In contrast to animal cells, the cells of plants, archaea, bacteria, fungi, and some protists have cell walls that limit their volumes and keep them from bursting. Cells with sturdy walls take up a limited amount of water, and in so doing they build up internal pressure against the cell wall, which prevents further water from entering. This pressure within the cell is called **turgor pressure**; it keeps the green parts of plants upright and is the driving force for enlargement of plant cells (see Concept 25.3). It is a normal and essential component of plant growth. If enough water leaves the cells, turgor pressure drops and the plant wilts. Turgor pressure reaches about 100 pounds per square inch (0.7 kg/cm²), which is many times greater than the pressure in auto tires.

Diffusion may be aided by channel proteins

As we saw earlier, polar or charged substances such as water, amino acids, sugars, and ions do not readily diffuse across membranes. But they can cross the hydrophobic phospholipid bilayer passively (that is, without the input of energy) in one of two ways, depending on the substance:

- **Channel proteins** are integral membrane proteins that form channels across the membrane through which certain substances can pass.

- Some substances can bind to membrane proteins called **carrier proteins** that speed up their diffusion through the phospholipid bilayer.

Both of these processes are forms of **facilitated diffusion**. The substances diffuse according to their concentration gradients, but their diffusion is made easier by channel or carrier proteins. Particular channel or carrier proteins allow diffusion both into and out of a cell or organelle. In other words, they can operate in both directions.

We will focus here on two examples of channel proteins and discuss carrier proteins in the next section.

ION CHANNELS The best-studied channel proteins are the **ion channels**. As you will see in later chapters, the movement of ions across membranes is important in many biological processes, including respiration within the mitochondria, the electrical activity of the nervous system, and the opening of the pores that allow gas exchange with the environment. Several types of ion channels have been identified, each of them specific for a particular ion. All of them show the same basic structure of a hydrophilic pore that allows a particular ion to move through it.

Just as a fence may have a gate that can be opened or closed, most ion channels are gated: they can be opened or closed to ion passage. A **gated channel** opens when a stimulus causes a change in the three-dimensional shape of the channel. In some cases, this stimulus is the binding of a chemical signal, or **ligand**. Channels controlled in this way are called *ligand-gated channels* (FIGURE 5.4). In contrast, a *voltage-gated channel* is stimulated to open or close by a change in the voltage (electrical charge difference) across the membrane.

AQUAPORINS FOR WATER Water crosses membranes at a much faster rate than would be expected if it simply diffused through the phospholipid bilayer. One way it does this is by “hitchhiking” with some ions, such as Na^+ , as they pass through ion channels. Up to 12 water molecules may coat an ion as it traverses a channel. But there is an even faster way for water to cross membranes. Plants and some animal cells (such as red blood and kidney cells) have membrane channels called **aquaporins**. These specific channels allow large amounts of water to move along its concentration gradient, as you will see when we discuss water relations in plants (see Chapter 25) and animals (see Chapter 40).

Aquaporins were first identified by Peter Agre at Duke University, who noticed a membrane protein that was present in red blood cells, kidney cells, and plant cells but did not know its function. A colleague suggested that it might be a water channel, because these cell types show rapid diffusion of water across their membranes. Agre tested this idea by creating egg cells (oocytes) with the protein in their membranes. An oocyte membrane does not normally permit much diffusion of water. Agre injected the oocytes with the mRNA for aquaporin; the protein was produced by the cells and inserted into their membranes. Remarkably, the oocytes began swelling immediately after being

FIGURE 5.4 A Ligand-Gated Channel Protein Opens in Response to a Stimulus The channel protein is anchored in the lipid bilayer by its outer coating of nonpolar (hydrophobic) amino acids. The protein changes its three-dimensional shape when a stimulus molecule (ligand) binds to it, opening a pore lined with polar amino acids. This allows hydrophilic, polar substances to pass through.

transferred to a hypotonic solution, indicating the rapid diffusion of water into the cells (FIGURE 5.5).

Carrier proteins aid diffusion by binding substances

Another kind of facilitated diffusion involves the actual binding of the transported substance to a membrane protein called a carrier protein. Carrier proteins transport polar molecules such as sugars and amino acids.

Glucose is the major energy source for most mammalian cells, and they require a great deal of it. Their membranes contain a carrier protein—the glucose transporter—that facilitates glucose uptake into the cell. Binding of glucose to a specific three-dimensional site on one side of the transport protein causes the protein to change its shape and release glucose on the other side of the membrane (FIGURE 5.6A). Since glucose is usually broken down as soon as it enters the cell, there is almost always a strong concentration gradient favoring glucose entry (that is, a higher concentration outside the cell than inside). The transporter allows glucose molecules to cross the membrane and enter the cell much faster than they would by simple diffusion through the bilayer. This rapid entry is necessary to ensure that the cell receives enough glucose for its energy needs.

Transport by carrier proteins is different from simple diffusion. In both processes, the rate of movement depends on the concentration gradient across the membrane. However, in carrier-mediated transport, a point is reached at which increases

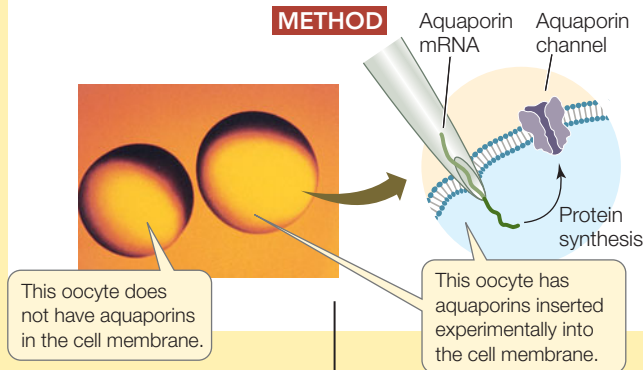

INVESTIGATION

FIGURE 5.5 Aquaporins Increase Membrane Permeability to Water A protein was isolated from the membranes of cells in which water diffuses rapidly across the membranes. When the protein was inserted into oocytes, which do not normally have it, the water permeability of the oocytes was greatly increased.

HYPOTHESIS

Aquaporin increases membrane permeability to water.

METHOD

RESULTS

CONCLUSION

Aquaporin **increases** the rate of water diffusion across the cell membrane.

ANALYZE THE DATA

Oocytes were injected with aquaporin mRNA (red circles) or a solution without mRNA (blue circles). Water permeability was tested by incubating the oocytes in hypotonic solution and measuring cell volume. After time X in the upper curve, intact oocytes were not visible:

- Why did the cells with aquaporin mRNA increase in volume?
- What happened at time X?
- Calculate the relative rates (volume increase per minute) of swelling in the control and experimental curves. What does this show about the effectiveness of mRNA injection?

in the concentration gradient are not accompanied by an increased rate of diffusion. At this point, the facilitated diffusion system is said to be *saturated* (FIGURE 5.6B). Because there are only a limited number of carrier protein molecules per unit of membrane area, the rate of diffusion reaches a maximum when all the carrier molecules are fully loaded with solute molecules. This situation is similar to that of enzyme saturation (see Figure 3.15).

Passive Transport

Do You Understand Concept 5.2?

- What properties of a substance determine whether, and how fast, it will diffuse across a membrane?
- Compare the process of facilitated diffusion through a channel and by a carrier protein. Which might be faster, and why?
- After celery is stored in an open refrigerator for two days, it is wilted. However, immersing the cut stalk in water for a few hours restores the integrity of the celery. How?

Diffusion tends to equalize the concentrations of substances between the outsides and insides of cells or organelles. However, one hallmark of a living thing is that it can have an internal composition quite different from that of its environment. To achieve this, a cell must sometimes move substances *against their concentration gradients*. This process requires work—the input of energy—and is known as active transport.

concept 5.3 Some Substances Require Energy to Cross the Membrane

In many biological situations, there is a different concentration of a particular ion or small molecule inside compared with outside a cell. In these cases, the concentration imbalance is maintained by a protein in the plasma membrane that moves the substance against its concentration gradient. This is called *active transport*, and because it is acting “against the normal flow,” it requires the expenditure of energy. Often the energy source is the nucleotide adenosine triphosphate (ATP). In eukaryotes, ATP is produced in the mitochondria and plastids, and it has chemical energy stored in its terminal phosphate bond. This energy is released when ATP is converted to adenosine diphosphate (ADP) in a hydrolysis reaction that breaks this terminal bond. We will give more details of how ATP provides energy to cells in Concept 6.1.

The differences between diffusion and active transport are summarized in TABLE 5.1.

FIGURE 5.6 A Carrier Protein Facilitates Diffusion The glucose transporter is a carrier protein that allows glucose to enter the cell at a faster rate than would be possible by simple diffusion. (A) The transporter binds to glucose, and as it does so, it changes shape, releasing the glucose into the cell cytoplasm. (B) The graph shows

the rate of glucose entry via a carrier versus the concentration of glucose outside the cell. As the glucose concentration increases, the rate of diffusion increases until the point at which all the available transporters are being used (the system is saturated).

Active transport is directional

Simple and facilitated diffusion follow concentration gradients and can occur in either direction across a membrane. In contrast, active transport is *directional*, and moves a substance either into or out of a cell or organelle against its concentration gradient. In other words, the substance is transported from a lower to a higher concentration. The direction in which a particular substance is transported usually depends on the cell's needs. As in facilitated diffusion, there is usually a specific carrier protein for each substance that is transported.

Different energy sources distinguish different active transport systems

There are two basic types of active transport:

- **Primary active transport** involves the direct hydrolysis of ATP, which provides the energy required for transport.
- **Secondary active transport** does not use ATP directly. Instead, its energy is supplied by an ion concentration gradient or an electrical gradient, established by primary active transport. This transport system uses the energy of ATP indirectly to set up the gradient.

In primary active transport, energy released by the hydrolysis of ATP drives the movement of specific ions against their concentration gradients. For example, the concentration of potassium ions (K^+) inside a cell

is often much higher than the concentration in the fluid bathing the cell. However, the concentration of sodium ions (Na^+) is often much higher outside the cell. A protein in the plasma membrane pumps Na^+ out of the cell and K^+ into the cell against these concentration gradients, ensuring that the gradients are maintained. This **sodium-potassium (Na^+-K^+) pump** is an integral membrane glycoprotein that is found in all animal cells. It breaks down a molecule of ATP to ADP and a free phosphate ion (P_i) and uses the released energy to bring two K^+ ions into the cell, and export three Na^+ ions (FIGURE 5.7).

FRONTIERS Cancer therapy often fails when the targeted cells become resistant to the drugs used to kill them. The drugs may work initially, only to have the cancer return—this time with a membrane protein that actively transports the drugs out of the cancer cells. Designing ways to block this active transport is a major challenge for effective cancer therapy.

TABLE 5.1 Membrane Transport Mechanisms

	SIMPLE DIFFUSION	FACILITATED DIFFUSION (CHANNEL OR CARRIER PROTEIN)	ACTIVE TRANSPORT
Cellular energy required?	No	No	Yes
Driving force	Concentration gradient	Concentration gradient	ATP hydrolysis (against concentration gradient)
Membrane protein required?	No	Yes	Yes
Specificity	No	Yes	Yes

In secondary active transport, the movement of a substance against its concentration gradient is accomplished using energy “regained” by letting ions move across the membrane *with* their concentration gradients. For example, once the $\text{Na}^+\text{-K}^+$ pump establishes a concentration gradient of sodium ions, the passive diffusion of some Na^+ back into a cell can provide energy for the secondary active transport of glucose into the cell. This occurs when glucose is absorbed into the bloodstream from the digestive tract. Secondary active transport is usually accomplished by a single protein that moves both the ion and the actively transported molecule across the membrane. In some cases, the ion and the transported molecule move in opposite directions, whereas in others they move in the same direction (as for glucose and Na^+ in the digestive tract). Secondary active transport aids in the uptake of amino acids and sugars, which are essential raw materials for cell maintenance and growth.

Do You Understand Concept 5.3?

- Why is energy required for active transport?
- The drug ouabain inhibits the activity of the $\text{Na}^+\text{-K}^+$ pump. A nerve cell is incubated in ouabain. Make a table in which you predict what would happen to the concentrations of Na^+ and K^+ inside the cell, as a result of the action of ouabain.
- How would you use experiments to distinguish between the following two ways for glucose to enter a cell: facilitated diffusion via a carrier protein and secondary active transport?

FIGURE 5.7 Primary Active Transport: The Sodium–Potassium Pump In active transport, energy is used to move a solute against its concentration gradient. Here, energy from ATP is used to move Na^+ and K^+ against their concentration gradients.

yourBioPortal.com

Go to ANIMATED TUTORIAL 5.2
Active Transport

We have examined a number of passive and active ways by which ions and small molecules can enter and leave cells. But what about large molecules such as proteins? Many proteins are so large that they diffuse very slowly, and their bulk makes it difficult for them to pass through the phospholipid bilayer. It takes a completely different mechanism to move intact large molecules across membranes.

concept 5.4 Large Molecules Cross the Membrane via Vesicles

Macromolecules such as proteins, polysaccharides, and nucleic acids are simply too large and too charged or polar to pass through biological membranes. This is a fortunate property—cellular integrity depends on containing these macromolecules in specific locations. However, cells must sometimes take up or *secrete* (release to the external environment) intact large molecules. This is done via vesicles, and the general terms for the mechanisms by which cells take up and secrete large molecules or particles are *endocytosis* and *exocytosis* (FIGURE 5.8).

Macromolecules and particles enter the cell by endocytosis

Endocytosis is a general term for a group of processes that bring small molecules, macromolecules, large particles, and

even small cells into the eukaryotic cell (see Figure 5.8A). There are three types of endocytosis: phagocytosis, pinocytosis, and receptor-mediated endocytosis. In all three, the plasma membrane invaginates (folds inward), forming a small pocket around materials from the environment. The pocket deepens, forming a vesicle. This vesicle separates from the plasma membrane and migrates with its contents to the cell's interior.

- In **phagocytosis** (“cellular eating”), part of the plasma membrane engulfs a large particle or even an entire cell. Unicellular protists use phagocytosis for feeding, and some white blood cells use phagocytosis to engulf foreign cells and substances. The food vacuole (phagosome) that forms usually fuses with a lysosome, where its contents are digested.

LINK Review the discussion of phagocytosis in Concept 4.3

- Vesicles also form in **pinocytosis** (“cellular drinking”). However, in this case the vesicles are smaller and they bring fluids and dissolved substances, including proteins, into the cell. Phagocytosis and pinocytosis are relatively nonspecific regarding what they bring into the cell. For example, pinocytosis goes on constantly in the endothelium—the single layer of cells that separates a blood vessel from the surrounding tissue. Pinocytosis allows cells of the endothelium to rapidly acquire fluids and dissolved solutes from the blood.
- In **receptor-mediated endocytosis**, molecules at the cell surface recognize and trigger the uptake of specific materials.

Let's take a closer look at this last process.

Receptor-mediated endocytosis is specific

Receptor-mediated endocytosis is used by animal cells to capture specific macromolecules from the cell's environment. This process depends on **receptors**, which are proteins that bind to specific molecules (their *ligands*) and then set off specific cellular responses. In receptor-mediated endocytosis, the receptors

(A) Endocytosis

The plasma membrane surrounds a part of the exterior environment and buds off as a vesicle.

A vesicle fuses with the plasma membrane. The contents of the vesicle are released, and its membrane becomes part of the plasma membrane.

(B) Exocytosis

FIGURE 5.8 Endocytosis and Exocytosis Eukaryotic cells use endocytosis (A) and exocytosis (B) to take up and release large molecules and particles. Even small cells can be engulfed via endocytosis.

are integral membrane proteins located at particular regions on the extracellular surface of the plasma membrane. These membrane regions are called *coated pits* because they form slight depressions in the plasma membrane, and their cytoplasmic surfaces are coated by another protein (often *clathrin*). The uptake process is similar to that in phagocytosis.

APPLY THE CONCEPT

Some substances require energy to cross the membrane

The liver plays several vital metabolic roles, including protein synthesis, detoxification, and the production of substances necessary for digestion. Liver cells are in contact with the blood and exchange a variety of substances with the blood plasma (the noncellular part of blood). Below and at right is a list of observations about the relative concentrations of various molecules in a liver cell cytoplasm and in the blood plasma. Explain each observation in terms of membrane permeability and transport mechanisms.

1. The concentration of serum albumin, a blood protein, is much higher in the plasma.
2. The concentration of RNA is much higher in the cytoplasm.
3. The concentration of Na^+ is lower in the cytoplasm.
4. The concentration of water is equal in the plasma and the cytoplasm.
5. The concentration of low-density lipoproteins is higher in the cytoplasm.
6. The concentration of glucose is equal in the plasma and the cytoplasm.
7. If K^+ enters the plasma, its concentration rapidly equalizes between the plasma and the cytoplasm.

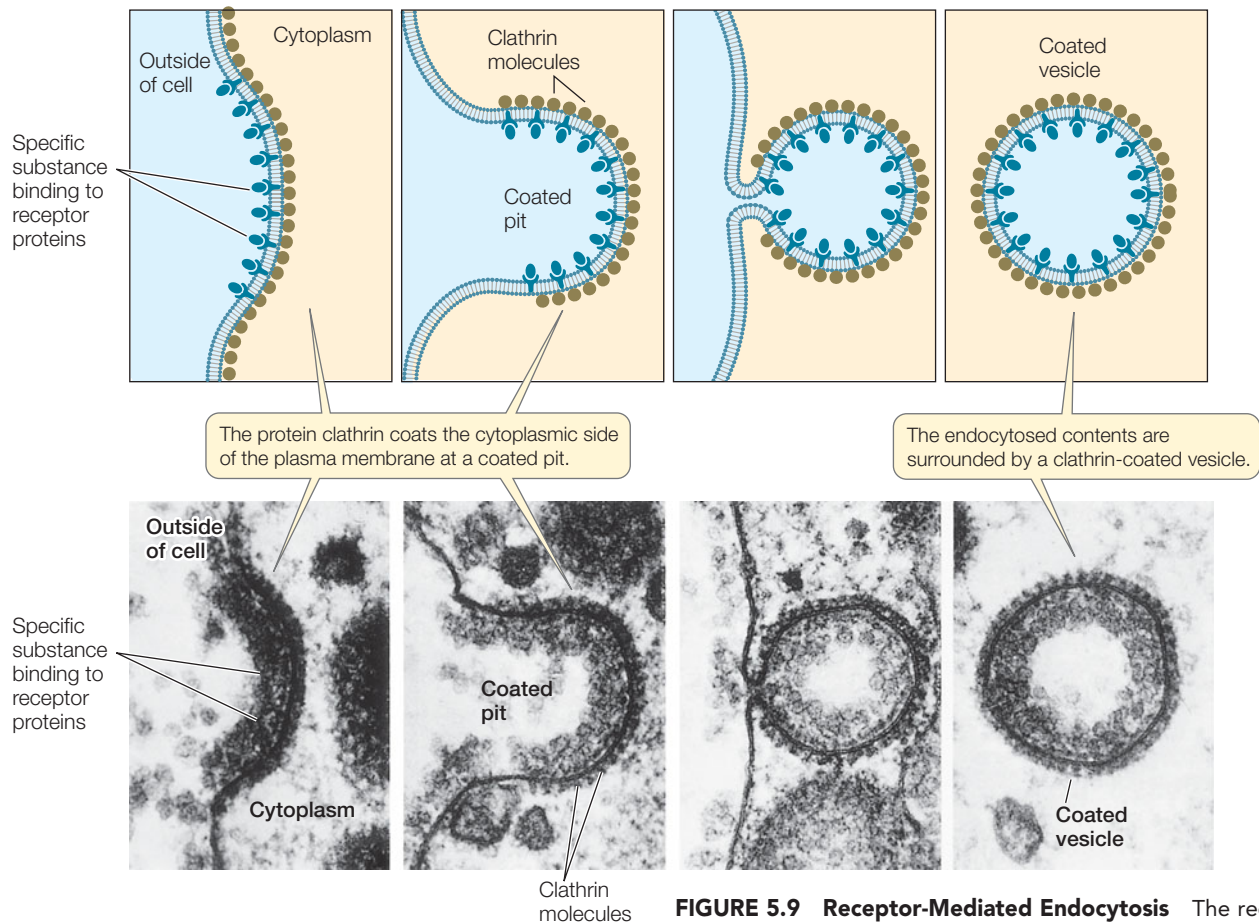

FIGURE 5.9 Receptor-Mediated Endocytosis The receptor proteins in a coated pit bind specific macromolecules, which are then carried into the cell by a coated vesicle.

When the receptors in a coated pit bind to their specific ligands (the macromolecules to be taken into the cell), the coated pit invaginates (folds in) and forms a coated vesicle around the bound macromolecules. The clathrin molecules strengthen and stabilize the vesicle, which carries the macromolecules away from the plasma membrane and into the cytoplasm (**FIGURE 5.9**). Once inside, the vesicle loses its clathrin coat and may fuse with a lysosome, where the engulfed material is digested. Because of its specificity for particular macromolecules, receptor-mediated endocytosis is an efficient method for taking up substances that may exist at low concentrations in the cell's environment.

Receptor-mediated endocytosis is the method by which cholesterol is taken up by most mammalian cells. Water-insoluble cholesterol and triglycerides are packaged by liver cells into lipoprotein particles. Most of the cholesterol is packaged into *low-density lipoproteins* (LDLs) and circulated via the bloodstream. When a particular cell requires cholesterol, it produces specific LDL receptors, which are inserted into the plasma membrane in clathrin-coated pits. LDLs bind to the receptors and are taken into the cell via receptor-mediated endocytosis. Within the resulting vesicle, the LDL particles are freed from the receptors. The receptors segregate to a region that buds off and forms a new vesicle, which is recycled to the plasma membrane. The freed LDL particles remain in the original vesicle,

which fuses with a lysosome. There, the LDLs are digested and the cholesterol made available for use by the cell.

In healthy individuals, the liver takes up unused LDLs for recycling. People with the inherited disease *familial hypercholesterolemia* have a deficient LDL receptor in their livers. This prevents receptor-mediated endocytosis of LDLs in the liver, resulting in dangerously high levels of cholesterol in the blood. The cholesterol builds up in the arteries that nourish the heart and causes heart attacks. In extreme cases where only the deficient receptor is present, children and teenagers can have severe cardiovascular disease.

Exocytosis moves materials out of the cell

Exocytosis is the process by which materials packaged in vesicles are secreted from the cell (see Figure 5.8B). When the vesicle membrane fuses with the plasma membrane, an opening is made to the outside of the cell. The contents of the vesicle are released into the environment, and the vesicle membrane is smoothly incorporated into the plasma membrane.

In Chapter 4 we encounter exocytosis as the last step in the processing of material engulfed by phagocytosis—the release of undigested materials back to the extracellular environment (see Figure 4.9). Secreted proteins are transported out of the cell via exocytosis. The proteins are folded and modified in

the endoplasmic reticulum, transported in vesicles to the Golgi where they may be further modified, then packaged in new vesicles for secretion (see Figure 4.8).

Exocytosis is important in the secretion of many types of substances, including digestive enzymes from the pancreas, neurotransmitters from neurons, and materials for the construction of the plant cell wall. You will encounter these processes in later chapters.

Endocytosis and Exocytosis

Do You Understand Concept 5.4?

- What is the difference between phagocytosis and pinocytosis?
- Would a small molecule such as an amino acid enter a cell by receptor-mediated endocytosis?
- Exocytosis involves the fusion of the membranes of a vesicle and the plasma membrane. Explain how this might occur.

We have just introduced the concept of a membrane-bound receptor, which is a key factor in a cell's interaction with its environment. Let's look more closely at receptors and how they respond to signals.

concept 5.5

The Membrane Plays a Key Role in a Cell's Response to Environmental Signals

A hallmark of living things is their ability to process information from their environment. This information can be thought of in terms of *signals*. The signal may be a physical stimulus such as light or heat, or a chemical such as a hormone. The mere presence of a signal does not mean a particular cell will respond to it. In order to respond, the cell must have a specific receptor that can detect it. Once the receptor is activated by the signal, it sets off a series of events within the cell. A **signal transduction pathway** is a sequence of molecular events and chemical reactions that lead to a cell's response to a signal. The ability of cells to sense and respond to their environment is key to the maintenance of cellular and organismal *homeostasis*, a theme that recurs throughout our discussion of gene regulation and plant and animal physiology in later chapters of this book.

Cells are exposed to many signals and may have different responses

Inside a large multicellular animal, chemical signals made by the body itself reach a target cell by local diffusion or by circulation within the blood. These signals are usually in tiny concentrations (as low as 10^{-10} M) and differ in their sources and mode of delivery (FIGURE 5.10):

FIGURE 5.10 Chemical Signaling Concepts A signal molecule can act on the cell that produces it, a nearby cell, or be transported by the organism's circulatory system to a distant target cell.

- **Autocrine** signals affect the same cells that release them. For example, many tumor cells reproduce uncontrollably because they self-stimulate cell division by making their own division signals.
- **Paracrine** signals diffuse to and affect nearby cells. An example is a neurotransmitter made by one nerve cell that diffuses to an adjacent cell and stimulates it.
- Signals to distant cells travel through the circulatory system and are called **hormones**.

Chemical signals do not always come from within the multicellular organism—some come from the external environment. For example, specific molecules produced by pathogenic organisms trigger signal transduction pathways in plants, leading to defense responses.

For the information from a signal to be transmitted to a cell, the target cell must be able to *sense* the signal and *respond* to it. In a multicellular animal, all the cells may receive chemical signals that are circulated in the blood, but most body cells are not capable of responding to the signals. *Only the cells with the necessary receptors can respond.*

Typically, a signal transduction pathway involves a signal, a receptor, and a response (FIGURE 5.11). These pathways vary

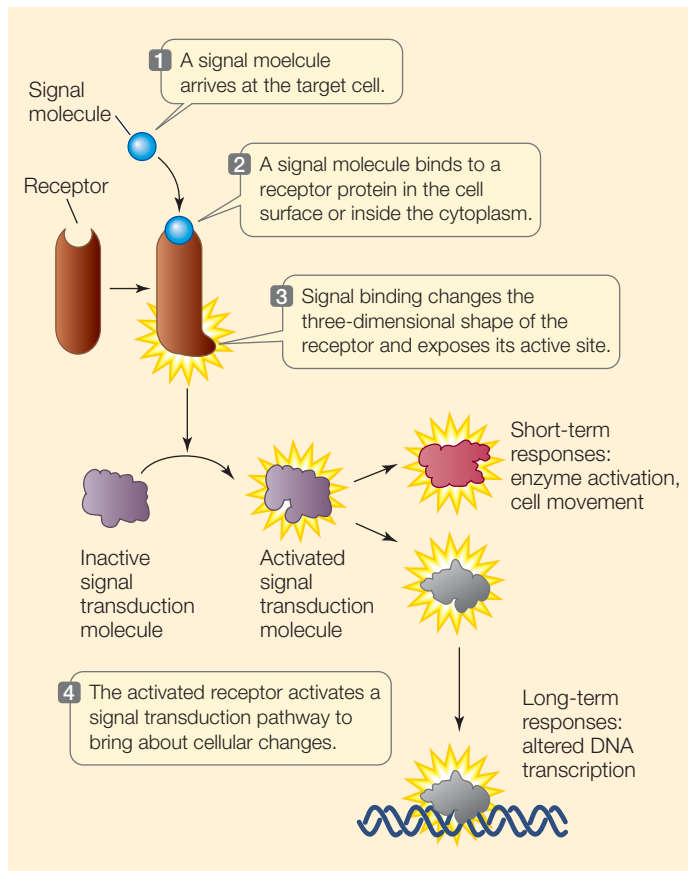

FIGURE 5.11 Signal Transduction Concepts This general pathway is common to many cells and situations. The ultimate cellular responses are either short-term or long-term.

in their details, but a common mechanism is allosteric regulation. Recall that **allosteric regulation** involves an alteration in the three-dimensional shape of a protein as a result of the binding of another molecule at a site other than the protein's active site (see Figure 3.18). You have already seen an example of allosteric regulation in this chapter when we considered a gated channel, which opens (changes shape) after binding to another molecule (see Figure 5.6).

A signal transduction pathway may end in a response that is short term, such as the activation of an enzyme, or long term, such as an alteration in gene expression.

Membrane proteins act as receptors

A cell must have the appropriate receptor in order to respond to a signal. The signal may be a specific molecule or physical stimulus. In the following discussion, we will focus on chemical signals, such as those described in the previous section.

The signal molecule fits into a three-dimensional site on its corresponding receptor protein (**FIGURE 5.12**). As noted earlier in the chapter, a molecule that binds to a receptor in this way is called a *ligand*. Binding of the ligand causes the receptor to change its three-dimensional shape, and that conformational change initiates a cellular response. In many cases, the receptor has an enzyme function (a catalytic domain), with its active site on the cytoplasmic side of the membrane. When the ligand

FIGURE 5.12 A Signal Binds to Its Receptor Human growth factor fits into its membrane-bound receptor (a protein with two subunits) and binds to it noncovalently. There is an equilibrium between bound and unbound receptor.

binds to the receptor (for example, on the outside of the cell), the ligand acts as an allosteric regulator, exposing the active site of the catalytic domain. Generally, the ligand does not contribute further to the cellular response. In fact, the ligand is usually not metabolized (or changed) at all; its role is purely to “knock on the door.” (This is in sharp contrast to enzyme–substrate interactions, which we describe in Concept 3.3. The whole purpose of those interactions is to change substrates into useful products.)

Receptors (R) bind to their ligands (L) noncovalently, according to chemistry's *law of mass action*:

This means the binding is *reversible*, although for most ligand–receptor complexes, the equilibrium point is far to the right of the above reaction—that is, binding is favored. Reversibility is important, however, because if the ligand were never released, the receptor would be continuously stimulated.

An inhibitor (or *antagonist*) can also bind to a receptor protein, preventing the binding of the normal ligand. This is analogous to the competitive inhibition of enzymes (see Concept 3.4). There are both natural and artificial antagonists of receptor binding. For example, many substances that alter human behavior bind to specific receptors in the brain and prevent the binding of the receptors' specific ligands.

Receptors can be classified by location and function

The chemistry of signal ligands is quite variable, but they can be divided into two groups based on whether or not they can diffuse through membranes. Correspondingly, a receptor can be classified by its location in the cell, which largely depends on the nature of its ligand:

- **Cytoplasmic receptors.** Small or nonpolar ligands can diffuse across the phospholipid bilayer of the plasma membrane and enter the cell. Estrogen, for example, is a lipid-soluble steroid hormone that can easily diffuse across the plasma membrane; it binds to a receptor in the cytoplasm. Many cytoplasmic receptors function as regulators of gene expression; they alter (upregulate or downregulate) the expression of specific genes as a result of ligand binding.
- **Membrane receptors.** Large or polar ligands cannot cross the lipid bilayer. Insulin, for example, is a protein hormone that cannot diffuse through the plasma membrane. Instead, it binds to a transmembrane receptor with an extracellular binding domain.

FRONTIERS Some receptor proteins are concentrated in a particular area of the membrane, trapped in a *lipid raft*—a semisolid region with lipids enriched in cholesterol and long-chain fatty acids. How do these rafts get placed where they are, and how do they trap only certain proteins? Scientists are investigating membrane assembly in the endoplasmic reticulum and Golgi apparatus to find out. This information will be important for understanding how cells optimize functions such as cellular signaling.

In complex eukaryotes such as mammals and higher plants, there are three well-studied categories of plasma membrane receptors, which are grouped according to their activities: ion channels, protein kinase receptors, and G protein-linked receptors. Because you will see these receptors several times later in the text, we describe them in some detail here.

ION CHANNEL RECEPTORS As described in Concept 5.2, the plasma membranes of many cells contain *gated ion channels* for ions such as Na^+ , K^+ , Ca^{2+} , or Cl^- (see Figure 5.4). The gate-opening mechanism is an alteration in the three-dimensional shape of the channel protein upon ligand binding; thus these proteins function as receptors. An example is the *acetylcholine receptor*, a ligand-gated sodium channel located in the plasma membranes of skeletal muscle cells. The ligand acetylcholine is a neurotransmitter—a chemical signal released from neurons. Opening of the channel allows Na^+ , which is more concentrated outside the cell than inside, to diffuse into the cell. This initiates a series of events that result in muscle contraction (see Figure 34.9).

LINK Nerve cells communicate with muscle cells at neuromuscular junctions, which are described in Concept 36.1

PROTEIN KINASE RECEPTORS Like gated channel receptors, protein kinase receptors change shape upon ligand binding. But in

FIGURE 5.13 A Protein Kinase Receptor The mammalian hormone insulin binds to a protein kinase receptor on the outside surface of the cell and initiates a response.

this case, the new conformation exposes or activates a domain on the cytoplasmic side of the transmembrane protein that has catalytic (protein kinase) activity (FIGURE 5.13).

In general, **protein kinases** catalyze the following reaction:

Each protein kinase has specific target(s) in the cell. The reaction results in the covalent modification (phosphorylation) of a target protein, thereby changing its activity. Protein kinases are extraordinarily important in biological signaling: about 1 human gene in 50 is a protein kinase, and there is an even higher proportion of such genes in some plants.

An example of a protein kinase receptor is that for the hormone insulin. The activation of this receptor results in the phosphorylation of target proteins in the cytoplasm. The targeted proteins mediate the cell's response, which includes the insertion of glucose transport proteins into the cell membrane.

It should be noted that not all protein kinases are receptors—many function in later steps of signal transduction pathways. In these cases, the protein kinase is activated by a receptor or other protein, and then phosphorylates the next protein in the pathway (as you will see in Concept 5.6).

G PROTEIN-LINKED RECEPTORS A third category of eukaryotic plasma membrane receptors is the family of **G protein-linked receptors**. In this case, ligand binding on the extracellular domain of the receptor changes the shape of its cytoplasmic region, exposing a site that can bind to a mobile membrane protein called a **G protein**. The G protein is partially inserted in the lipid bilayer and partially exposed on the cytoplasmic surface of the membrane.

FIGURE 5.14 A G Protein-Linked Receptor The G protein is an intermediary between the receptor and an effector.

Many G proteins have three polypeptide subunits and can bind three different molecules:

- The receptor
- GDP and GTP (guanosine diphosphate and triphosphate, nucleotides used for energy transfer, like ADP and ATP)
- An effector protein (a protein that causes an effect in the cell)

The activated G protein-linked receptor functions as a *guanine nucleotide exchange factor*, which exchanges a GDP nucleotide bound to the G protein for a more energy-rich GTP. The activated G protein in turn activates the effector protein, leading to downstream signal amplification (**FIGURE 5.14**). G protein-linked receptors are especially important in the sensory systems of animals (see Chapter 35).

G Protein-Linked Signal Transduction and Cancer

Do You Understand Concept 5.5?

- What are the three major steps in cell signaling?
- What are the differences and similarities between ion channel receptors and G protein-linked receptors?
- If an intact cell is treated with an enzyme that hydrolyzes proteins, will the cell be able to receive any environmental signals? Explain.

Regardless of the type of receptor, when a signal activates it, a *signal transduction pathway* ensues. This often involves a series of multiple steps, and it leads to a particular cellular response. This could be the expression of a set of genes that were previously silent. The proteins encoded by these genes change the cell in some way so it can respond to the signal.

concept 5.6 Signal Transduction Allows the Cell to Respond to Its Environment

As we mentioned in Concept 5.5, a signal may be a chemical ligand or a physical stimulus such as light or heat. Its effect is to activate a specific receptor—leading to a cellular response, which is mediated by a signal transduction pathway. Typically, signaling at the plasma membrane initiates a *cascade* (series) of events in the cell, in which proteins interact with other proteins until the final responses are achieved. Through such a cascade, an initial signal can be both *amplified* and *distributed* to cause several different responses in the target cell.

Second messengers can stimulate signal transduction

Often there is a small molecule intermediary between the activated receptor and the cascade of events that ensues. In a series of clever experiments, Earl Sutherland and his colleagues at Case Western Reserve University discovered that a small water-soluble chemical messenger can mediate the cytoplasmic events initiated by a plasma membrane receptor. These researchers were investigating the activation of the liver enzyme glycogen phosphorylase by the hormone epinephrine (also called adrenaline)—the “fight-or-flight” hormone. The enzyme is activated when an animal faces life-threatening conditions and needs energy fast for the fight-or-flight response. Glycogen phosphorylase catalyzes the breakdown of glycogen stored in the liver so that the resulting glucose molecules can be released to the blood (see Figure 39.13). The enzyme is present in the liver cell cytoplasm but is inactive in the absence of epinephrine.

The researchers found that epinephrine could activate glycogen phosphorylase in liver cells that had been broken open, but only if the entire cell contents, including plasma membrane fragments, were present. Under these conditions epinephrine was bound to the plasma membrane fragments, but the active phosphorylase was present in the solution. The researchers hypothesized that there must be a second “messenger” that transmits

INVESTIGATION

FIGURE 5.15 The Discovery of a Second Messenger Glycogen phosphorylase is activated in liver cells after epinephrine binds to a membrane receptor. Sutherland and his colleagues observed that this activation could occur in vivo only if fragments

of the plasma membrane were present. They designed experiments to show that a second messenger caused the activation of glycogen phosphorylase.

HYPOTHESIS

A second messenger mediates between receptor activation at the plasma membrane and enzyme activation in the cytoplasm.

METHOD

RESULTS

Active glycogen phosphorylase is present in the cytoplasm.

CONCLUSION

A soluble second messenger, produced by hormone-activated membranes, is present in the solution and activates enzymes in the cytoplasm.

ANALYZE THE DATA

The activity of previously inactive liver glycogen phosphorylase was measured with and without epinephrine incubation, with these results:

Condition	Enzyme activity (units)
Homogenate	0.4
Homogenate + epinephrine	2.5
Cytoplasm fraction	0.2
Cytoplasm + epinephrine	0.4
Membranes + epinephrine	0.4
Cytoplasm + membranes + epinephrine	2.0

- What do these data show?
- Propose an experiment to show that the factor that activates the enzyme is stable on heating and give predicted data.
- Propose an experiment to show that cAMP can replace the particulate fraction and hormone treatment and give predicted data.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

the epinephrine signal (the “first messenger”) from the plasma membrane to the phosphorylase in the cytoplasm. They investigated this by separating plasma membrane fragments from the cytoplasmic fractions of broken liver cells and following the sequence of steps described in **FIGURE 5.15**. This experiment confirmed the existence of a second messenger, later identified as **cyclic AMP (cAMP; FIGURE 5.16)**. Second messengers do not have enzymatic activity themselves; rather, they act to regulate target enzymes by binding to them noncovalently.

LINK The different types of enzyme regulation are discussed in Concept 3.4

A second messenger is a small molecule that mediates later steps in a signal transduction pathway. While receptor binding is highly specific, second messengers allow a cell to respond to

FIGURE 5.16 The Formation of Cyclic AMP The formation of cAMP from ATP is catalyzed by adenylyl cyclase, an enzyme that is activated by G proteins.

a single event at the plasma membrane with *many events inside the cell*—in other words, the second messenger *distributes* the initial signal. Second messengers also serve to *amplify the signal*—for example, the binding of a single epinephrine molecule leads to the production of many molecules of cAMP. In turn, cAMP activates many enzyme targets by binding to them noncovalently. In the case of epinephrine and the liver cell, glycogen phosphorylase is just one of several enzymes that are activated.

A signaling cascade involves enzyme regulation and signal amplification

Signal transduction pathways often involve multiple sequential steps, in which particular enzymes are either activated or inhibited by other enzymes in the pathway. For example, a protein kinase adds a phosphate group to a target protein, and this covalent change alters the protein's conformation and activates or inhibits its function. Cyclic AMP binds noncovalently to a target protein, and this changes the protein's shape, activating or inhibiting its function. In the case of activation, a previously inaccessible active site is exposed, and the target protein goes on to perform a new cellular role.

A good example of a signaling cascade is the G protein-mediated protein kinase pathway stimulated by epinephrine in liver cells (FIGURE 5.17). Binding of epinephrine to the membrane receptor results in the activation of a G protein, followed by the production of cAMP, which activates a key signaling molecule, protein kinase A. In turn, protein kinase A phosphorylates two other enzymes, with opposite effects:

- **Inhibition.** Glycogen synthase, which catalyzes the joining of glucose molecules to form the energy-storing molecule glycogen, is inactivated when a phosphate group is added to it by protein kinase A. Thus the epinephrine signal *prevents glucose from being stored* in glycogen (Figure 5.17, step 1).
- **Activation.** Phosphorylase kinase is activated when a phosphate group is added to it. It is part of a cascade of reactions that ultimately leads to the activation of glycogen phosphorylase, another key enzyme in glucose metabolism. This enzyme results in the *liberation of glucose molecules* from glycogen (Figure 5.17, steps 2 and 3).

An important consequence of having multiple steps in a signal transduction cascade is that the signal is *amplified* with each step. The amplification of the signal in the pathway illustrated in Figure 5.17 is impressive. Each molecule of epinephrine that arrives at the plasma membrane ultimately results in 10,000 molecules of blood glucose:

- | | |
|--------|---|
| 1 | molecule of epinephrine bound to the membrane activates |
| 20 | molecules of cAMP, which activate |
| 20 | molecules of protein kinase A, which activate |
| 100 | molecules of phosphorylase kinase, which activate |
| 1,000 | molecules of glycogen phosphorylase, which produce |
| 10,000 | molecules of glucose 1-phosphate, which produce |
| 10,000 | molecules of blood glucose |

FIGURE 5.17 A Cascade of Reactions Leads to Altered Enzyme Activity Liver cells respond to epinephrine by activating G proteins, which in turn activate the synthesis of the second messenger cAMP. Cyclic AMP initiates a protein kinase cascade, greatly amplifying the epinephrine signal, as indicated by the blue numbers. The cascade both inhibits the conversion of glucose to glycogen and stimulates the release of previously stored glucose.

Signal Transduction Pathway

Signal transduction is highly regulated

Signal transduction is a temporary event in the cell, and gets “turned off” once the cell has responded. To regulate protein kinases, G proteins, and cAMP, there are enzymes that convert each activated transducer back to its inactive precursor (FIGURE 5.18). The balance between the activities of these regulating enzymes and the signaling enzymes themselves is what determines the ultimate cellular response to a signal. Cells can alter this balance in several ways:

FIGURE 5.18 Signal Transduction Regulatory Mechanisms Some signals lead to the production of active transducers such as (A) protein kinases, (B) G proteins, and (C) cAMP. Other enzymes (red type) inactivate or remove these transducers.

- *Synthesis or breakdown of the enzymes involved.* For example, synthesis of adenylyl cyclase and breakdown of phosphodiesterase (which breaks down cAMP) would tilt the balance in favor of more cAMP in the cell.
- *Activation or inhibition of the enzymes by other molecules.* Examples include the activation of a G protein–linked receptor by ligand binding, and inhibition of phosphodiesterase (which also breaks down cGMP) by sildenafil citrate (Viagra), a drug used to treat erectile dysfunction.

Cell functions change in response to environmental signals

The activation of a receptor by a signal, and the subsequent transduction and amplification of the signal, ultimately leads to changes in cell function. There are many ways in which a cell might respond. Three important types of responses have already been discussed in this chapter:

- *Opening of ion channels* changes the balance of ion concentrations between the outside of the cell and its interior (see Figure 5.4). As you will see in Chapter 34, this results in a change in the electrical potential across the membrane, with important consequences in nerve and muscle cells.
- Many signal transduction pathways lead to *alterations in gene expression*. The expression of some genes may be switched on (upregulated), whereas others are switched off (downregulated). This alters the abundance of the proteins (often enzymes) encoded by the genes, thus changing cell function. You will see many examples that highlight the importance of gene regulation throughout this book.
- A third kind of response involves the *alteration of enzyme activities*. An example is the activation of phosphorylase kinase

and the inhibition of glycogen synthase in liver cells exposed to epinephrine (see Figure 5.17). In this case, the signal transduction pathway does not lead to alterations in the expression of the genes that encode these enzymes. Their *activities* are regulated so that the liver cell can rapidly supply energy-rich glucose for the fight-or-flight response.

Different signal transduction pathways can produce different cellular responses to the same signal-receptor binding event. An example is the responses to epinephrine in heart muscle and in the smooth muscles that line blood vessels. When epinephrine binds to its receptor in heart muscle cells, a G protein is activated that in turn *activates* the signal transduction cascade that results in glucose mobilization for energy and muscle contraction (see Figure 5.17). In smooth muscle cells that line the digestive tract, however, a different G protein gets activated by epinephrine receptor binding, and in this case the G protein *inhibits* a target enzyme, allowing the muscle cells to relax. This increases the diameter of the blood vessels, allowing more nutrients to be carried from the digestive system to the rest of the body. (For more on the flight-or-flight response, see Concept 30.2.) So the same signaling mechanism can lead to different responses in different types of cells.

A great deal has been learned about signal transduction pathways and cellular responses in the past two decades, and there is still much to learn. As biologists tease apart specific pathways, they find that many of them are interconnected: one pathway may be switched on by a particular signal or molecule, and another may be switched off. In this chapter we have concentrated on signaling pathways that occur in animal cells. However, signal transduction pathways are important in the functioning of all living organisms.

Do You Understand Concept 5.6?

- Compare “first messengers” (e.g., hormones) with “second messengers” (e.g., cAMP) with regard to their chemical nature, where and when they are made, and locations of synthesis and activity.
- Outline the steps in the amplification of signaling by epinephrine, resulting in the release of glucose to the bloodstream. At each step, is the amplification due to a covalent or noncovalent interaction?
- What would happen to a liver cell exposed to epinephrine and at the same time to a drug that inhibits protein kinase A? To epinephrine and to a drug that inhibits the hydrolysis of GTP?
- Biochemist Robert Furchgott studied how acetylcholine, released from nerve cells, causes smooth muscles surrounding arteries to relax, dilating the arteries. He found that the smooth muscles in an intact artery section would relax, but if the endothelial cells lining the blood vessel were removed, the addition of acetylcholine would not cause dilation. A second messenger was proposed. How would you investigate this hypothesis? (Hint: see Figure 5.15.)

What role does the cell membrane play in the body's response to caffeine?

ANSWER Caffeine has many effects on the body, but the most noticeable is that it keeps us awake. The caffeine molecule is somewhat large and polar, and it is unlikely to diffuse through the nonpolar lipids of the cell membrane (Concept 5.2). Instead, it binds to receptors on the surfaces of nerve cells in the brain (Concept 5.5).

The nucleoside adenosine (adenine attached to a five-carbon sugar) accumulates in the brain when a person is under stress or has prolonged mental activity. When it binds to a specific receptor in the brain, adenosine sets in motion a signal transduction pathway (Concept 5.6) that results in reduced brain activity, which usually means drowsiness. This membrane-associated signaling by adenosine has evolved as a protective mechanism against the adverse effects of stress.

FIGURE 5.19 Caffeine and the Cell Membrane (A) The adenosine 2A receptor is present in the human brain, where it is involved in inhibiting arousal. (B) Adenosine is the normal ligand for the receptor. Caffeine has a structure similar to that of adenosine and can act as an antagonist that binds the receptor and prevents its normal functioning.

Caffeine has a three-dimensional structure similar to that of adenosine, and is able to bind to the adenosine receptor (**FIGURE 5.19**). Because its binding does not activate the receptor, caffeine functions as an *antagonist* of adenosine signaling, with the result that the brain stays active and the person remains alert.

When we discussed the interaction between a ligand and its receptor, we noted that this is a reversible, noncovalent interaction. In time, after drinking coffee or tea, the caffeine molecules come off the adenosine receptors in the brain, allowing adenosine to bind once again. Otherwise, coffee drinkers might never get to sleep!

In addition to competing with adenosine for a membrane receptor, caffeine blocks the enzyme cAMP phosphodiesterase. This enzyme acts in signal transduction (Concept 5.6) to break down the second messenger cAMP. Looking at the signal transduction pathway in Figure 5.17, can you explain how caffeine augments the fight-or-flight response, which includes an increase in blood sugar and increased heartbeat?

5

SUMMARY

concept 5.1 Biological Membranes Have a Common Structure and Are Fluid

- Biological membranes consist of lipids, proteins, and carbohydrates. The **fluid mosaic model** of membrane structure describes a phospholipid bilayer in which proteins can move about within the plane of the membrane.
- The two layers of a membrane may have different properties because of their different phospholipid compositions, exposed domains of **integral membrane proteins**, and **peripheral membrane proteins**. **Transmembrane proteins** span the membrane. **Review Figure 5.1, WEB ACTIVITY 5.1, and INTERACTIVE TUTORIAL 5.1**

concept 5.2 Some Substances Can Cross the Membrane by Diffusion

- Membranes exhibit **selective permeability**, regulating which substances pass through them.
- A substance can diffuse passively across a membrane by one of two processes: **simple diffusion** through the phospholipid bilayer or **facilitated diffusion**, either through a channel created by a **channel protein** or by means of a **carrier protein**. In both cases, molecules diffuse down their concentration gradients.
- In **osmosis**, water diffuses from a region of higher water concentration to a region of lower water concentration through membrane channels called aquaporins. Ions diffuse across membranes through ion channels. **Review Figures 5.3 and 5.4, ANIMATED TUTORIAL 5.1, and WORKING WITH DATA 5.1**
- **Carrier proteins** bind to polar molecules such as sugars and amino acids and transport them across the membrane. **Review Figure 5.6**

concept 5.3 Some Substances Require Energy to Cross the Membrane

- **Active transport** requires the use of chemical energy to move substances across membranes against their concentration gradients. The **sodium-potassium ($\text{Na}^+\text{-K}^+$) pump** uses energy released from the hydrolysis of ATP to move ions against their concentration gradients. **Review Figure 5.7 and ANIMATED TUTORIAL 5.2**

concept 5.4 Large Molecules Cross the Membrane via Vesicles

- **Endocytosis** is the transport of small molecules, macromolecules, large particles, and small cells into eukaryotic cells via the invagination of the plasma membrane and the formation of vesicles. **Review Figure 5.8A**

- In **receptor-mediated endocytosis**, a specific **receptor** on the plasma membrane binds to a particular macromolecule. **Review Figure 5.9 and ANIMATED TUTORIAL 5.3**
- In **exocytosis**, materials in vesicles are secreted from the cell when the vesicles fuse with the plasma membrane. **Review Figure 5.8B**

concept 5.5 The Membrane Plays a Key Role in a Cell's Response to Environmental Signals

- Cells receive many signals from the physical environment and from other cells. Chemical signals are often at very low concentrations. **Review Figure 5.10**
- A **signal transduction pathway** involves the interaction of a signal (often a chemical **ligand**) with a receptor; the transduction and amplification of the signal via a series of steps within the cell; and a cellular response. The response may be short-term or long-term. **Review Figure 5.11**
- Cells respond to signals only if they have specific receptor proteins that can be activated by those signals. Most receptors are located at the plasma membrane. They include **ion channels**, **protein kinases**, and **G protein-linked receptors**. **Review Figures 5.13 and 5.14 and ANIMATED TUTORIAL 5.4**

concept 5.6 Signal Transduction Allows the Cell to Respond to Its Environment

- A cascade of events, one following another, occurs after a receptor is activated by a signal.
- Often, a soluble second messenger conveys signaling information from the primary messenger (ligand) at the membrane to downstream signaling molecules in the cytoplasm. **Cyclic AMP (cAMP)** is an important second messenger. **Review Figure 5.16 and WORKING WITH DATA 5.2**
- Activated enzymes may in turn activate other enzymes in a signal transduction pathway, leading to impressive amplification of a signal. **Review Figure 5.17 and ANIMATED TUTORIAL 5.5**
- Protein kinases covalently add phosphate groups to target proteins; cAMP binds target proteins noncovalently. Both kinds of binding change the target protein's conformation to expose or hide its active site.
- Signal transduction can be regulated in several ways. The balance between the activation and inactivation of the molecules involved determines the ultimate cellular response to a signal. **Review Figure 5.18**
- The cellular responses to signals may include the opening of ion channels, changes in gene expression, or the alteration of enzyme activities.

See **WEB ACTIVITY 5.2** for a concept review of this chapter.

Pathways that Harvest and Store Chemical Energy

6

Agriculture was a key invention in the development of human civilizations. The planting and harvesting of seeds began about 10,000 years ago. One of the first plants to be turned into a reliable crop was barley, and one of the first uses of barley was to brew beer. Living in what is now Iraq, ancient Sumerians learned that partly germinated and then mashed-up barley seeds, stored under the right conditions, could produce a potent and pleasant drink. An ancient king, Hammurabi, laid down the oldest known law regard-

ing an alcoholic beverage: the daily beer ration was 2 liters for a normal worker, 3 liters for a civil servant, and 5 liters for a high priest. Alcoholic beverages were not just a diversion to these people, because drinking water from rivers and ponds caused diseases, and whatever caused these diseases was not present in liquids containing alcohol.

Early chemists and biologists were interested in how mashed barley seeds (or grapes, in the case of wine) were transformed into alcoholic beverages. By the nineteenth century there were two theories. Chemists claimed that these transformations were simply chemical reactions, not some special property of the plant material. Biologists, armed with their microscopes and cell theory (see Chapter 4), said that the barley and grape extracts were converted to beer and wine by living cells.

The great French scientist Louis Pasteur tackled the question in the 1860s, responding to a challenge posed by a group of distillers who wanted to use sugar beets to produce alcohol. Pasteur

found that (1) nothing happened to beet mash unless microscopic yeast cells were present; (2) in the presence of fresh air, yeast cells grew vigorously on the mash, and bubbles of CO_2 were formed; and (3) without fresh air, the yeast grew slowly, less CO_2 was produced, and alcohol was formed. So the biologists were right: living cells produced alcohol from ground-up, sugary extracts. Later, biochemists broke open yeast cells and unraveled the sequence of chemical transformations from sugar to alcohol. It turned out that the chemists were right too: the production of alcohol was just a series of chemical reactions. These reactions require energy transfers, and the flow of energy in living systems (such as yeast cells) involves the same chemical principles as energy flow in the inanimate world.

These tanks at a winery in California provide conditions without air that are suitable for the production of alcohol by yeast cells.

KEY CONCEPTS

- 6.1 ATP, Reduced Coenzymes, and Chemiosmosis Play Important Roles in Biological Energy Metabolism
- 6.2 Carbohydrate Catabolism in the Presence of Oxygen Releases a Large Amount of Energy
- 6.3 Carbohydrate Catabolism in the Absence of Oxygen Releases a Small Amount of Energy
- 6.4 Catabolic and Anabolic Pathways Are Integrated
- 6.5 During Photosynthesis, Light Energy Is Converted to Chemical Energy

Why does fresh air inhibit the formation of alcohol by yeast cells?

concept
6.1

ATP, Reduced Coenzymes, and Chemiosmosis Play Important Roles in Biological Energy Metabolism

In Chapters 2 and 3 we introduce the general concepts of energy, enzymes, and metabolism. Energy is stored in the chemical bonds of molecules, and it can be released and transformed by the metabolic pathways of living cells. There are five *general principles governing metabolic pathways*:

- A complex chemical transformation occurs in a series of separate, intermediate reactions that form a metabolic pathway.
- Each reaction is catalyzed by a specific enzyme.
- Most metabolic pathways are similar in all organisms, from bacteria to plants to humans.
- In eukaryotes, many metabolic pathways are compartmentalized, with certain reactions occurring inside specific organelles.
- Each metabolic pathway is controlled by key enzymes that can be inhibited or activated, thereby determining how fast the reactions will go.

Chemical energy available to do work is termed *free energy* (G). According to the laws of thermodynamics, a biochemical reaction may change the *form* of energy but not the net *amount*. A biochemical reaction is exergonic if it releases energy from the reactants, or endergonic if energy must be added to the reactants.

LINK You can review the principles of energy transformations in Concept 2.5

In the chemistry lab, energy can be released or added in the form of heat. But in cells, energy-transforming reactions are often coupled; that is, an energy-releasing (exergonic) reaction is coupled in time and location to an energy-requiring (endergonic) reaction. Two widely used coupling molecules are the coenzymes ATP and NADH.

ATP hydrolysis releases energy

Cells use adenosine triphosphate (ATP) as a kind of “energy currency.” Just as it is more effective, efficient, and convenient for you to trade money for a lunch than to trade your actual labor, it is useful for cells to have a single currency for transferring energy between different reactions and cell processes. Some of the energy that is released in exergonic reactions is captured in chemical bonds when ATP is formed from adenosine diphosphate (ADP) and inorganic phosphate (hydrogen phosphate; commonly abbreviated to P_i). The ATP can then be hydrolyzed at other sites in the cell, releasing free energy to drive endergonic reactions (FIGURE 6.1). For example, in Chapter 5 we describe the use of ATP hydrolysis to drive the energy-requiring process of active transport. Later in this chapter you will see how ATP hydrolysis is used in an anabolic (endergonic) pathway—the synthesis of carbohydrates from CO_2 during photosynthesis.

An ATP molecule consists of the nitrogenous base adenine bonded to ribose (a sugar), which is attached to a sequence

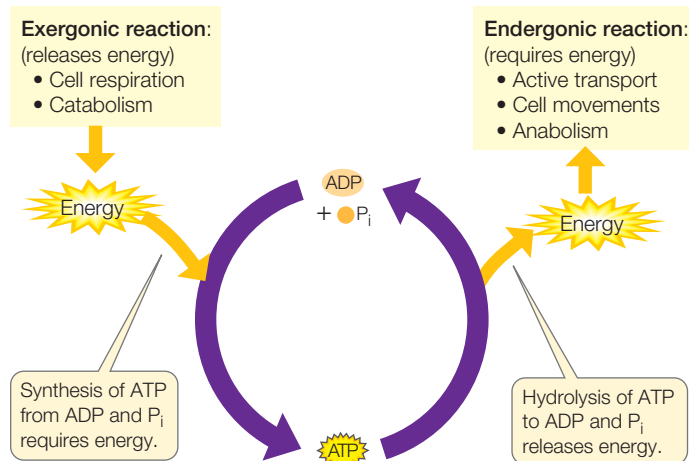

FIGURE 6.1 The Concept of Coupling Reactions Exergonic cellular reactions release the energy needed to make ATP from ADP. The energy released from the conversion of ATP to ADP can be used to drive endergonic reactions.

yourBioPortal.com

Go to WEB ACTIVITY 6.1
ATP and Coupled Reactions

of three phosphate groups (FIGURE 6.2). The hydrolysis of a molecule of ATP yields free energy, ADP, and the inorganic phosphate ion (P_i):

The important property of this reaction is that it is exergonic, releasing free energy. Under standard laboratory conditions,

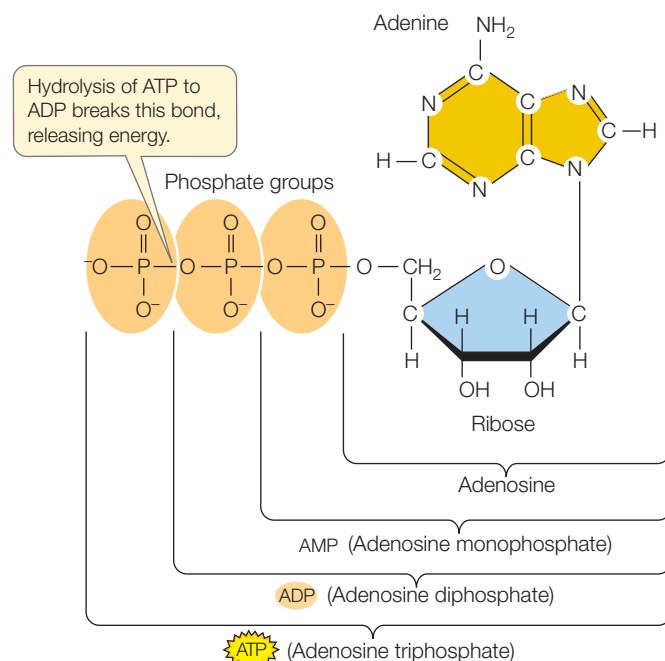

FIGURE 6.2 ATP The nucleotide ATP is built by the addition of terminal phosphate groups onto the nucleoside adenosine.

the *change in free energy* for this reaction (ΔG) is about -7.3 kcal/mol (-30 kJ/mol). Recall that a negative change in free energy means that the product molecules (in this case, ADP and P_i) have less free energy than the reactant (ATP), so the change is negative. A molecule of ATP can also be hydrolyzed to adenosine monophosphate (AMP) and a pyrophosphate ion ($P_2O_7^{4-}$; commonly abbreviated as PP_i). In this case, additional energy may be released by the subsequent conversion of PP_i to two molecules of P_i .

Two characteristics of ATP account for the free energy released by the loss of one or two of its phosphate groups:

- The free energy of the P—O bond between phosphate groups (called a phosphoanhydride bond and often denoted by wavy lines in chemical structures—see below) is much higher than the energy of the O—H bond that forms after hydrolysis. So some usable energy is released by the following hydrolysis:

- Because phosphate groups are negatively charged and so repel each other, it takes energy to get phosphates near enough to each other to make the covalent bond that links them together in the ATP molecule.

In some reactions, ATP is formed by *substrate-level phosphorylation* because it involves the direct transfer of phosphate to ADP. This is the case for some reactions of glycolysis (see Concept 6.2). But most of the ATP in living cells is formed by *oxidative phosphorylation*, which we will discuss shortly.

Redox reactions transfer electrons and energy

Another way of transferring energy in chemical reactions is to *transfer electrons*. A reaction in which one substance trans-

FIGURE 6.3 Oxidation, Reduction, and Energy The more oxidized a carbon atom is, the less its free energy.

fers one or more electrons to another substance is called an oxidation–reduction reaction, or **redox** reaction.

- **Reduction** is the gain of one or more electrons by an atom, ion, or molecule.
- **Oxidation** is the loss of one or more electrons.

Oxidation and reduction *always occur together*: as one chemical is oxidized, the electrons it loses are transferred to another chemical, reducing it. Thus, some molecules are called *oxidizing agents* and others are *reducing agents*:

Although oxidation and reduction are defined in terms of traffic in electrons, it is often helpful to think in terms of the *gain or loss of hydrogen atoms*. Transfers of hydrogen atoms involve transfers of electrons ($\text{H} = \text{H}^+ + e^-$). So *when a molecule loses a hydrogen atom, it becomes oxidized*.

In general, the more reduced a molecule is, the more energy is stored in its covalent bonds (**FIGURE 6.3**). In a redox reaction, some energy is transferred from the reducing agent to the reduced product. Some energy remains in the reducing agent (now oxidized), and some is lost to entropy.

Cells use the coenzyme nicotinamide adenine dinucleotide as an electron carrier in redox reactions (**FIGURE 6.4**). This coenzyme exists in two chemically distinct forms, one oxidized (NAD^+) and the other reduced (NADH). The reduction reaction:

involves the transfer of a proton (the hydrogen ion, H^+) and two electrons, which are released by the accompanying oxidation reaction. This reaction is *highly endergonic*, with a positive ΔG about four times greater than the positive ΔG (free energy change) for ATP formation.

Within the cell, the electrons do not remain with NADH . Oxygen is highly electronegative and readily accepts electrons from the reduced NADH molecule. The oxidation of NADH by O_2 (which occurs in several steps):

is *highly exergonic*, releasing energy with a ΔG of -52.4 kcal/mol (-219 kJ/mol). Note that the oxidizing agent appears here as “ $\frac{1}{2} \text{O}_2$ ” instead of “ O .” This notation emphasizes that it is molecular oxygen, O_2 , that acts as the oxidizing agent.

Because the oxidation of NADH releases more energy than the hydrolysis of ATP, NADH can be thought of as a larger package of free energy than ATP (approximately 50 kcal/mol, or 200 kJ/mol). NAD^+ is a common electron carrier in cells, but not

FIGURE 6.4 NAD⁺/NADH Is an Electron Carrier in Redox Reactions (A) NAD^+ is an important electron acceptor in redox reactions, and its reduced form, NADH , is an important energy intermediary in cells. The unshaded portion of the molecule (left) remains unchanged by the redox reaction. (B) Coupling of redox reactions using NAD^+ / NADH .

In other words, most of the energy-releasing reactions in the cell produce NADH (or similar reduced coenzymes), but most of the energy-consuming reactions require ATP . Cells need a way to connect the two coenzymes; that is, to transfer energy from NADH to the phosphoanhydride bond of ATP . This transfer is accomplished in a process called **oxidative phosphorylation**—the coupling of the *oxidation* of NADH :

to the *production* of ATP :

This coupling is achieved via a mechanism called **chemiosmosis**—the diffusion of protons across a membrane, driving the synthesis of ATP (**FIGURE 6.5A**). Chemiosmosis relies on concepts covered in earlier chapters:

- If the concentration of a substance is greater on one side of a membrane than the other, the substance will tend to diffuse across the membrane to its region of lower concentration (see Concept 5.2).
- If a membrane blocks this diffusion, the substance at the higher concentration has potential energy, which can be converted to other forms of energy (see Concept 2.5).

the only one. Others include flavin adenine dinucleotide (FAD), which also transfers electrons during glucose metabolism (see Concept 6.2), and nicotinamide adenine dinucleotide phosphate (NADP^+), which is used in photosynthesis (see Concept 6.5).

Oxidative phosphorylation couples the oxidation of NADH to the production of ATP

We can summarize the two energy-coupling coenzymes as follows:

- ADP traps chemical energy to make ATP .
- NAD^+ traps the energy released in redox reactions to make NADH .

How do these coenzymes participate in the flow of energy within cells? As you will see below, most chemical energy in cells is stored in the C—H bonds of carbohydrates and lipids (see Chapter 2). The release and reuse of this energy can be summarized as follows:

- Energy is released in *catabolism* by oxidation; this energy can be trapped by the reduction of coenzymes such as NADH .
- Energy for many *anabolic* and other energy-requiring processes is supplied by ATP . For example, as we note in Chapter 5, *active transport* requires ATP .

Because the interior of a membrane is nonpolar, protons (H^+) cannot readily diffuse across the membrane. Chemiosmosis converts the potential energy of a proton gradient across a membrane into the chemical energy in ATP . This has been called the proton motive force. In prokaryotes, the gradient is set up across the plasma membrane, using energy from various sources. In eukaryotes, chemiosmosis occurs in the mitochondria and chloroplasts. In mitochondria, the H^+ gradient is set up across the inner membrane, using energy released by the oxidation of NADH (see Concept 6.2). In chloroplasts, the H^+ gradient is set up across the thylakoid membrane using energy from light (see Concept 6.5). Despite these differences in detail, the mechanism of chemiosmosis is the same, and this mechanism is a key to biological energetics in almost all organisms.

A membrane protein called *ATP synthase* uses the potential energy of the H^+ gradient to drive ATP synthesis. *ATP synthase* is a molecular motor composed of two parts: the F_0 unit, which is a transmembrane domain that functions as the H^+ channel; and the F_1 unit, which contains the active sites for ATP synthesis (**FIGURE 6.5B**). The F_1 unit consists of six subunits (three each of two polypeptide chains), arranged like the segments of an orange around a central polypeptide. The potential energy set up by the proton gradient drives the passage of protons through the ring of polypeptides that make up

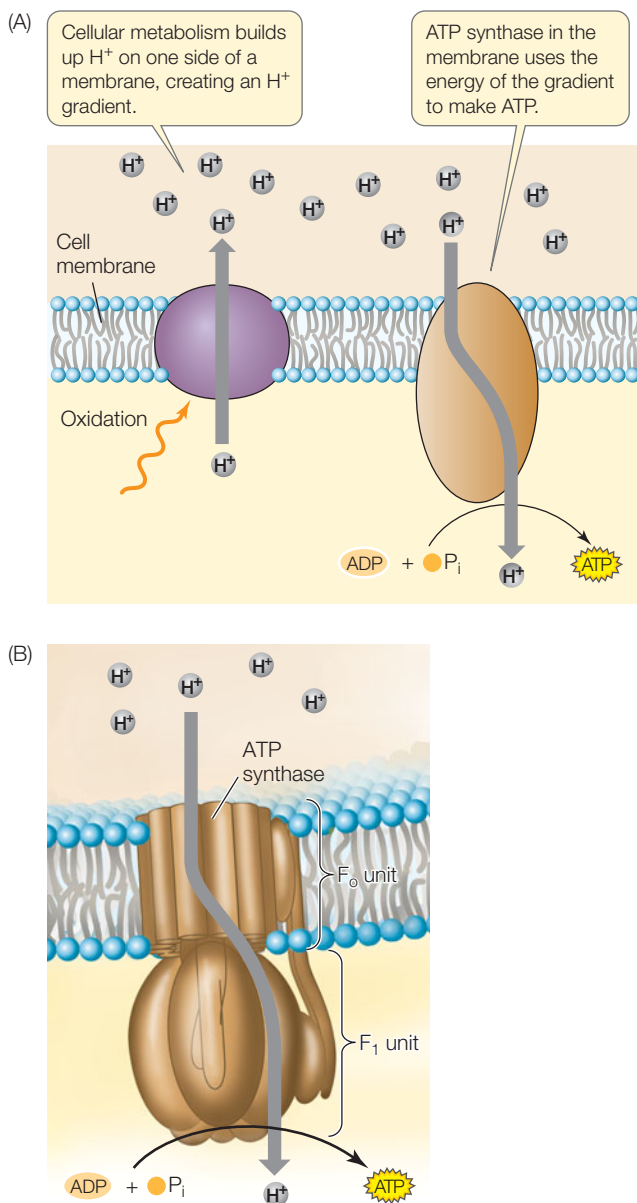

FIGURE 6.5 Chemiosmosis (A) If a cell can generate a proton (H^+) gradient across a membrane, the potential energy resulting from the concentration gradient can be used by a membrane-spanning enzyme to make ATP. (B) ATP synthase has a membrane-embedded channel for H^+ diffusion and a motor that turns, releasing some energy to produce ATP.

An oxidation reaction is always coupled with a reduction. When NADH is oxidized to NAD^+ in the mitochondria, the corresponding reduction reaction (as noted above) is the formation of water:

So the key role of O_2 in cells—the reason we breathe and have a blood system to deliver O_2 to tissues—is to act as an electron acceptor and become reduced. In chloroplasts, the molecule ultimately reduced is $NADP^+$, a relative of NAD^+ .

Chemiosmosis can be demonstrated experimentally. If chloroplasts or mitochondria are isolated from cells and put in a test tube, a proton gradient can be introduced artificially. This artificial gradient drives ATP synthesis (**FIGURE 6.6**), but only if ATP synthase, ADP, inorganic phosphate, and the membrane are present.

What happens if the H^+ gradient is destroyed by the presence of a membrane channel that is always open to protons? Obviously, ATP cannot be made, but the oxidation of NADH still occurs and O_2 is reduced, releasing considerable energy. The released energy forms heat instead of being used to make ATP. In newborn human infants, the membrane protein *thermogenin* disrupts the H^+ gradient in fat cell mitochondria, and this results in the release of heat. Because infants lack body hair, this process helps keep them warm.

A popular weight loss drug in the 1930s was the uncoupler molecule dinitrophenol. There were claims of dramatic weight loss when the drug was administered to obese patients. Unfortunately, the heat that was released caused fatally high fevers, and the effective dose and fatal dose were quite close. The use of this drug was discontinued in 1938, but the general strategy of using an uncoupler for weight loss remains a subject of research.

the F_o component. This ring rotates as the protons pass through the membrane, causing the F_1 unit to rotate as well. ADP and P_i bind to active sites that become exposed on the F_1 unit as it rotates, and ATP is made. The structure and function of ATP synthase are shared by living organisms as diverse as bacteria and humans. These molecular motors make ATP at rates of up to 100 molecules per second.

FRONTIERS Scientists have long thought that life originated in a “primordial soup,” with the first biochemical reactions driven by energy from space. Recently, however, microscopic geochemical H^+ gradients have been discovered in deep-sea vents. These gradients could have provided chemiosmotic energy for the formation of molecules such as carbohydrates, lipids, proteins, and nucleic acids. Scientists are attempting to create such vent systems in the lab to determine if this model is plausible.

ATP and reduced coenzymes link catabolism and anabolism: An overview

We have separately described the cycles of biochemical energy storage and release for ATP (see Figure 6.1) and for reduced coenzymes (see Figure 6.4), as well as the role of chemiosmosis in linking the two (see Figure 6.5). Furthermore, we have mentioned how, in living organisms, catabolism releases chemical energy that can be used to fuel anabolism.

LINK See Concept 2.5 to review the principles of catabolism and anabolism

The next two concepts of this chapter deal with a major catabolic pathway called *cellular respiration*, in which a reduced molecule, the carbohydrate glucose, is oxidized, often all the way to CO_2 :

INVESTIGATION

FIGURE 6.6 An Experiment Demonstrates the Chemiosmotic Mechanism The chemiosmosis hypothesis was a bold departure from the conventional scientific thinking of the time. It required an

intact compartment separated by a membrane. Could a proton gradient drive the synthesis of ATP?

CONCLUSION

In the absence of electron transport, an artificial H^+ gradient is sufficient for ATP synthesis by organelles.

ANALYZE THE DATA

In another experiment, thylakoids were isolated at pH 7 and then incubated with ADP, phosphate (P_i), and magnesium ions (Mg^{2+}) at either pH 7 or pH 3.8. ATP formation was measured using luciferase, which catalyzes the formation of a luminescent (light-emitting) molecule if ATP is present. Here are the data from the paper:

Reaction mixture	Luciferase activity (light emission)	
	Raw data	Corrected data
Complete, pH 3.8	141	
Complete, pH 7.0	12	
Complete, pH 3.8 – P_i	12	
" " – ADP	4	
" " – Mg^{2+}	60	
" " – chloroplasts	7	

- Which reaction mixture is the control? Use the control data to correct the raw data for the other, experimental reaction mixtures and fill in the table.
- Why did ATP production go down in the absence of P_i ?
- What is the role of Mg^{2+} in ATP formation?

This pathway occurs in some form in most cells. Plant cells and some prokaryotes also carry out *photosynthesis*, a major anabolic pathway. You will see in Concepts 6.5 and 6.6 that photosynthesis converts light energy into chemical energy in the form of carbohydrate:

How do these pathways fit together? Cellular respiration and photosynthesis are linked not only by their reactants and products (O_2 , CO_2 , and carbohydrate), but also by the energy "currency" of ATP and reduced coenzymes (FIGURE 6.7). The two pathways can occur in the same cell. For example, a cell in the leaf of a green plant carries out both photosynthesis and cellular respiration, often simultaneously. In these cases, the cell must coordinate the activities of the two processes, using the same mechanisms that integrate anabolism and catabolism in all cells (see Concept 6.4).

More often, however, cells do not carry out photosynthesis for themselves. Even in a green plant, a root cell is not photosynthetic and relies on carbohydrates transported from the leaf to carry out cellular respiration. Humans do not carry out photosynthesis anywhere in their bodies; they rely on carbohydrates obtained in their diet (ultimately derived from photosynthesis) to carry out cellular respiration, which provides

the chemical energy for their bodies' activities, such as active transport and anabolism.

Do You Understand Concept 6.1?

- Sketch the coupling of exergonic and endergonic reactions with ATP and NADH as coenzymes.
- What kind of coenzyme would receive energy released from the following reactions? Explain your answer.
 - Glucose 6-phosphate \rightarrow glucose
 - Fatty acid $\rightarrow \text{CO}_2 + \text{H}_2\text{O}$
- Hibernating animals have low rates of metabolism. They can keep warm by synthesizing a membrane protein not normally present in their cells. What might that protein do?

**FIGURE 6.7 ATP, Reduced Coenzymes, and Metabolism**

The major pathways of energy metabolism, cellular respiration and photosynthesis, are related by their use of energy-transferring substrates, ATP and reduced coenzymes. Note that the net result of these pathways is to convert light energy into chemical energy to fuel the processes of life.

with the best motors that humans have devised. The cell can achieve this through the general principles that govern metabolism listed in Concept 6.1. Most notably, the oxidation occurs in a series of small steps (**FIGURE 6.8**).

In the catabolism of glucose under **aerobic** conditions (in the presence of O₂), the small steps can be grouped into three linked biochemical pathways (**FIGURE 6.9**):

- In **glycolysis**, the six-carbon monosaccharide glucose is converted into two three-carbon molecules of pyruvate.
- In **pyruvate oxidation**, two three-carbon molecules of pyruvate are oxidized to two two-carbon molecules of acetyl CoA and two molecules of CO₂.
- In the **citric acid cycle**, two two-carbon molecules of acetyl CoA are oxidized to four molecules of CO₂.

In glycolysis, glucose is partially oxidized and some energy is released

Glycolysis takes place in the cytosol and involves ten enzyme-catalyzed reactions. During glycolysis, some of the covalent bonds between carbon and hydrogen atoms in the glucose molecule are oxidized, releasing some of the

In this concept we saw that in chemiosmosis, a proton gradient across a membrane drives the production of ATP. This oxidative phosphorylation of ADP to produce ATP is linked to NADH oxidation. We will now turn to the biochemical pathway that results in the production of NADH.

concept 6.2 Carbohydrate Catabolism in the Presence of Oxygen Releases a Large Amount of Energy

Cellular respiration is the catabolism of organic molecules within cells, and it is one of the key ways in which cells obtain energy. Considerable energy is released when reduced molecules with many C—C and C—H bonds are fully oxidized to CO₂. We will consider in detail only the catabolism of carbohydrates, but bear in mind that cells also obtain energy from the catabolism of other molecules, such as lipids.

The chemical energy released from the complete oxidation of glucose to CO₂ is considerable, and the cell traps the energy by forming ATP:

In a chemistry lab this energy is all lost as heat (686 kcal/mol). In the cell, much of the released energy is trapped as ATP (234 kcal/mol). The efficiency of this energy-trapping process is impressive, even when compared

FIGURE 6.8 Energy Metabolism Occurs in Small Steps

(A) In living systems, glucose is oxidized via a series of steps, releasing small amounts of energy that can be efficiently trapped by coenzymes. (B) Glucose that is burned releases its energy as heat in one big step.

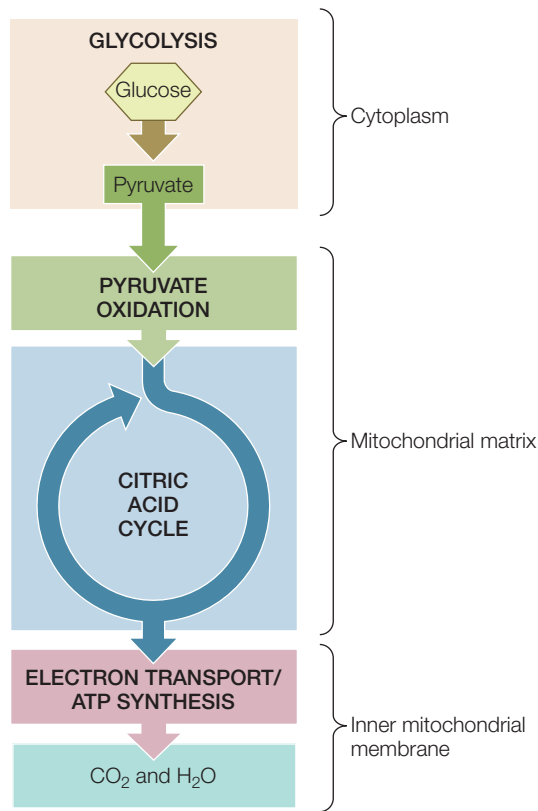

FIGURE 6.9 Energy-Releasing Metabolic Pathways The catabolism of glucose under aerobic conditions occurs in three sequential metabolic pathways: glycolysis, pyruvate oxidation, and the citric acid cycle. The reduced coenzymes are then oxidized by the respiratory chain, and ATP is made.

stored energy. The final products are two molecules of pyruvate (pyruvic acid), two molecules of ATP, and two molecules of NADH. Glycolysis can be divided into two stages: the initial energy-investing reactions that consume chemical energy stored in ATP, and the energy-harvesting reactions that produce ATP and NADH (FIGURE 6.10).

To help you understand the process without getting into extensive detail, we will focus on two consecutive reactions in this pathway (steps 6 and 7 in Figure 6.10).

These are examples of two types of reactions that occur repeatedly in glycolysis and in many other metabolic pathways:

1. **Oxidation–reduction:** In this exergonic reaction, more than 50 kcal/mol of energy are released in the oxidation of glyceraldehyde 3-phosphate. (Look at the first carbon atom, where an H is replaced by an O.) The energy is trapped via the reduction of NAD^+ to NADH.

FIGURE 6.10 Glycolysis Converts Glucose into Pyruvate Glucose is converted to pyruvate in ten enzyme-catalyzed steps. Along the way, energy is released to form ATP and NADH.

2. *Substrate-level phosphorylation*: The second reaction in this series is also exergonic, but in this case less energy is released. It is enough to transfer a phosphate from the substrate to ADP, forming ATP.

The end product of glycolysis, pyruvate, is somewhat more oxidized than glucose. In the presence of O_2 , further oxidation can occur. In prokaryotes these subsequent reactions take place in the cytosol, but in eukaryotes they take place in the mitochondrial matrix.

Pyruvate oxidation links glycolysis and the citric acid cycle

The next step in the aerobic catabolism of glucose involves the oxidation of pyruvate to a two-carbon acetate molecule and CO_2 . The acetate is then bound to **coenzyme A (CoA)**, which is used in various biochemical reactions as a carrier of acyl groups:

This is the link between glycolysis and further oxidative reactions (see Figure 6.9).

The formation of acetyl CoA is a multistep reaction catalyzed by the *pyruvate dehydrogenase complex*, containing 60 individual proteins and 5 different coenzymes. The overall reaction is exergonic, and one molecule of NAD^+ is reduced. But the main role of acetyl CoA is to donate its acetyl group to the four-carbon compound oxaloacetate, forming the six-carbon molecule citrate. This initiates the citric acid cycle, one of life's most important energy-harvesting pathways.

The citric acid cycle completes the oxidation of glucose to CO_2

Acetyl CoA is the starting point for the citric acid cycle. This pathway of eight reactions completely oxidizes the two-carbon acetyl group to two molecules of CO_2 . The free energy released from these reactions is captured by ADP and the electron carriers NAD^+ and FAD (FIGURE 6.11). This is a cycle because the starting material, oxaloacetate, is regenerated in the last step and is ready to accept another acetate group from acetyl CoA. The citric acid cycle operates twice for each glucose molecule that enters glycolysis (once for each pyruvate that enters the mitochondrion).

Let's focus on the final reaction of the cycle (step 8 in Figure 6.11), as an example of the kind of reaction that occurs:

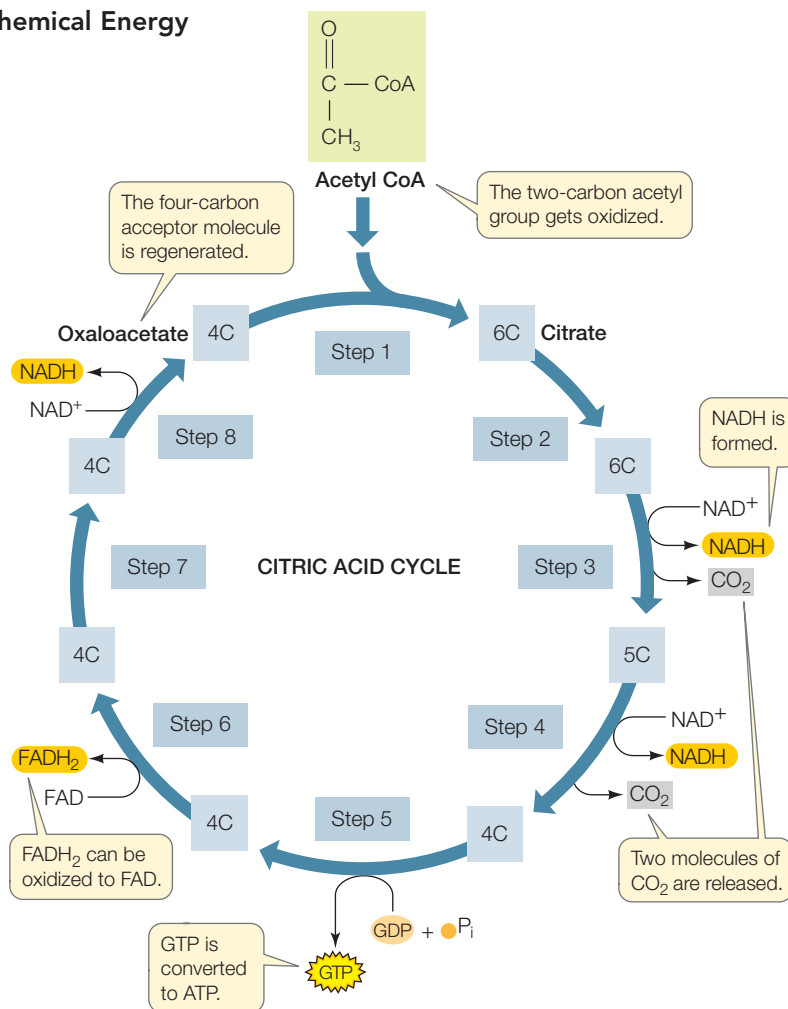

FIGURE 6.11 The Citric Acid Cycle Also called the Krebs cycle for its discoverer, Hans Krebs, the citric acid cycle involves eight steps and fully oxidizes acetyl CoA to CO_2 .

yourBioPortal.com

Go to WEB ACTIVITY 6.2
The Citric Acid Cycle

This oxidation reaction (see the second carbon atom) is exergonic, and the released energy is trapped by NAD^+ , forming $NADH$. With four such reactions ($FADH_2$ is a reduced coenzyme similar to $NADH$), the citric acid cycle harvests a great deal of chemical energy from the oxidation of acetyl CoA.

$NADH$ is oxidized by the respiratory chain, and ATP is formed by chemiosmosis

As we discussed in Concept 6.1, the $NADH$ is reoxidized to NAD^+ . In the process, O_2 is reduced to H_2O :

This does not happen in a single step. Rather, there is a series of redox carrier proteins called the *respiratory chain* embedded in the inner membrane of the mitochondrion (FIGURE 6.12). The electrons from the oxidation of $NADH$ and $FADH_2$ pass from one carrier to the next in the chain, in a process called **electron transport**. The oxidation reactions are exergonic, and they

FIGURE 6.12 Electron Transport and ATP Synthesis in Mitochondria As electrons pass through the protein complexes of the respiratory chain, protons are pumped from the mitochondrial matrix into the intermembrane space. As the protons return to the matrix through ATP synthase, ATP is formed.

release energy that is used to actively transport H⁺ ions out of the mitochondrial matrix. Thus, a proton gradient is set up across the inner membrane. In addition to the electron transport carriers, the inner membrane contains an ATP synthase that uses the H⁺ gradient to synthesize ATP by chemiosmosis. The basic principles of chemiosmosis are shown in Figure 6.5. Note that in mitochondria, the inner membrane provides the

compartments needed for separation of H⁺ and formation of the H⁺ gradient.

Oxidative phosphorylation yields a lot of ATP. For each NADH (or FADH₂) that begins the chain, two to three ATP molecules are formed under the conditions in the cell. Taking 2.5 as an average number, the 4 molecules of reduced coenzyme produced by each turn of the citric acid cycle yield 10 molecules (4 × 2.5) of ATP. Two molecules of acetyl CoA are produced from each glucose, so the total is about 20 ATPs per

APPLY THE CONCEPT

Carbohydrate catabolism in the presence of oxygen releases a large amount of energy

The following reaction occurs in the citric acid cycle:

Answer each of the following questions, and explain your answers:

1. Is this reaction an oxidation or reduction?
2. Is the reaction exergonic or endergonic?
3. This reaction requires a coenzyme. What kind of coenzyme?
4. What happens to the fumarate after the reaction is completed?
5. What happens to the coenzyme after the reaction is completed?

molecule of glucose. Add to this the NADH produced by glycolysis and pyruvate oxidation, and the ATP formed by substrate-level phosphorylation during glycolysis and the citric acid cycle, and the total is about 32 molecules of ATP produced per fully oxidized glucose.

The vital role of O_2 is now clear: most of the ATP produced in cellular respiration is formed by oxidative phosphorylation, which is due to the reoxidation of NADH. The accumulation of atmospheric O_2 caused by photosynthesis by ancient anaerobes provided an evolutionary selective advantage to those organisms—the aerobes—that could exploit the O_2 .

Do You Understand Concept 6.2?

- Draw the molecules of glucose and pyruvate and compare them with respect to their oxidation/reduction states. What does this mean in terms of available chemical energy?
- Compare the energy yields (in terms of ATP per glucose) from glycolysis and the combination of pyruvate oxidation and the citric acid cycle.
- High levels of ammonia (NH_3) are toxic to mammals. One reason is that ammonia bonds with α -ketoglutarate (the substrate for step 4 in Figure 6.11), forming the amino acid glutamate. This removes α -ketoglutarate from the citric acid cycle. Explain the consequence of this for the cell.

We have seen that a large amount of energy is released when carbohydrates are catabolized in the presence of O_2 . If O_2 is absent—that is, when conditions are **anaerobic**—the yield of ATP is much lower. We will now turn to this situation.

concept 6.3

Carbohydrate Catabolism in the Absence of Oxygen Releases a Small Amount of Energy

Under anaerobic conditions the respiratory chain cannot operate. Without an alternative, the NADH produced by glycolysis would not be reoxidized and glycolysis would stop, because there would be no NAD^+ for step 6 of glycolysis (see Figure 6.10). To solve this problem, organisms use **fermentation** to reoxidize the NADH, thus allowing glycolysis to continue (FIGURE 6.13).

Like glycolysis, fermentation pathways occur in the cytoplasm. There are many different types of fermentation used by different organisms in nature, but all operate to regenerate NAD^+ . The consequence of this is that the NADH made during

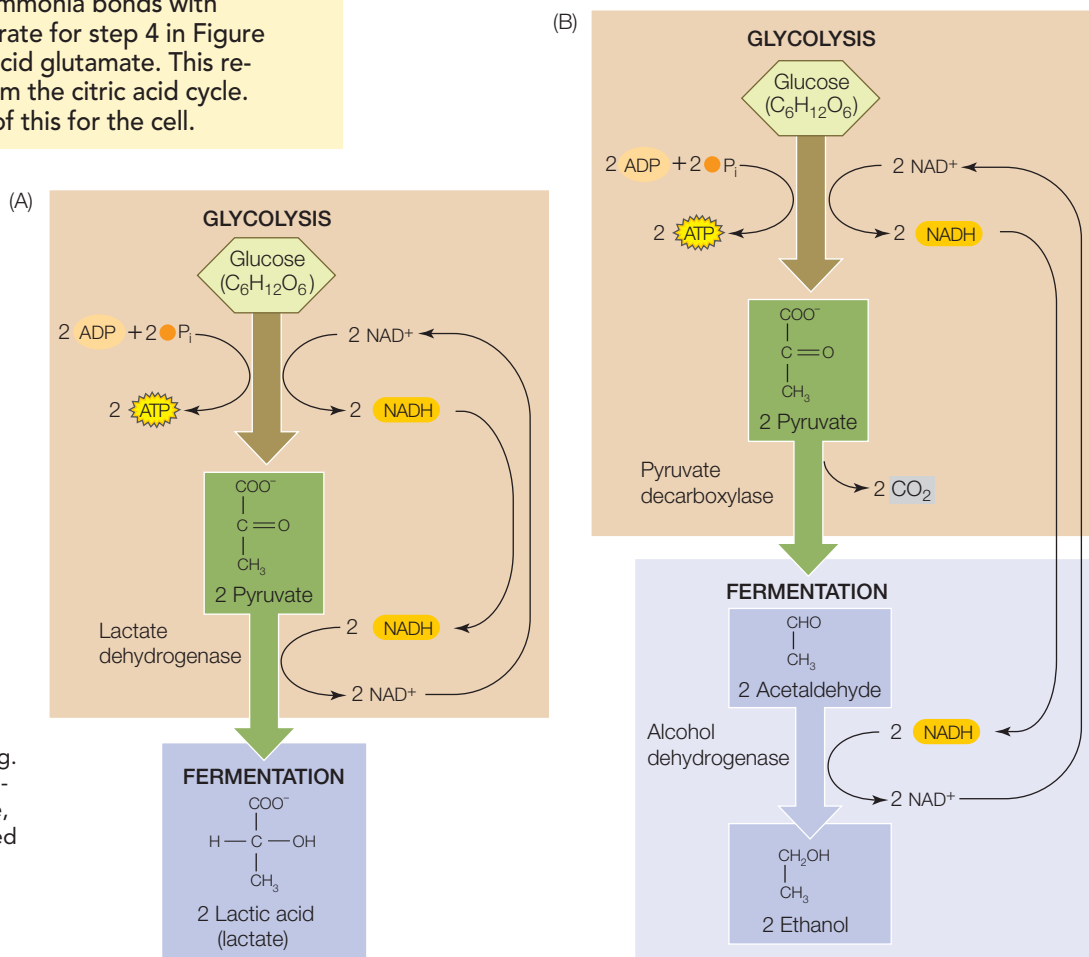

FIGURE 6.13 Fermentation
 (A) In lactic acid fermentation, NADH is used to reduce pyruvate to lactic acid, thus regenerating NAD^+ to keep glycolysis operating. (B) In alcoholic fermentation, pyruvate is converted to acetaldehyde, and CO_2 is released. NADH is used to reduce acetaldehyde to ethanol, again regenerating NAD^+ for glycolysis.

yourBioPortal.com

Glycolysis and Fermentation

Summary of reactants and products:
 $C_6H_{12}O_6 + 2 ADP + 2 P_i \rightarrow 2 \text{ lactic acid} + 2 \text{ ATP}$

Summary of reactants and products:
 $C_6H_{12}O_6 + 2 ADP + 2 P_i \rightarrow 2 \text{ ethanol} + 2 CO_2 + 2 \text{ ATP}$

glycolysis is not available for reoxidation by the respiratory chain to form ATP. Therefore, the overall yield of ATP from fermentation is reduced to only the ATP made in glycolysis (two ATP per glucose).

Two fermentation pathways are found in a wide variety of organisms:

- Lactic acid fermentation, whose end product is lactic acid (lactate)
- Alcoholic fermentation, whose end product is ethyl alcohol (ethanol)

In *lactic acid fermentation*, pyruvate serves as the electron acceptor and lactate is the product (see Figure 6.13A). This process takes place in many microorganisms and complex organisms, including more complex plants and vertebrates. A notable example of lactic acid fermentation occurs in vertebrate muscle tissue. Usually, vertebrates get their energy for muscle contractions aerobically, with the circulatory system supplying O_2 to muscles. This is almost always adequate for small vertebrates, which explains why birds can fly long distances without resting. But in larger vertebrates such as humans, the circulatory system is not up to the task of delivering enough O_2 when the need is great, such as during a long sprint. At this point, the muscle cells break down glycogen (a stored polysaccharide) and undergo lactic acid fermentation. The process is reversible; lactate is converted back to pyruvate once O_2 is available again.

Alcoholic fermentation takes place in certain yeasts (eukaryotic microbes) and some plant cells under anaerobic conditions. In this process, pyruvate is converted to ethanol (see Figure 6.13B). We saw these reactions (as did Pasteur) in the opening story of this chapter. As with lactic acid fermentation, the reactions are essentially reversible.

FRONTIERS Industrial chemicals such as acetone and butyric acid were once made using microbial fermentation. In the twentieth century, fermentation was supplanted by the synthesis of these substances from petroleum. With the higher prices and reduced supply of oil, there is renewed interest in microbial fermentation. The efficiency of the microbes is being improved with biotechnology.

By recycling NAD^+ , fermentation allows glycolysis to continue, thus producing small amounts of ATP through substrate-level phosphorylation. The net yield of two ATPs per glucose molecule is much lower than the energy yield from oxidative phosphorylation. For this reason, most organisms existing in anaerobic environments are small microbes that grow relatively slowly.

Energy Levels

Do You Understand Concept 6.3?

- Why is replenishing NAD^+ crucial to cellular metabolism?
- Compare the sources and total energy yield in terms of ATP per glucose in human cells in the presence versus the absence of O_2 .
- Conditions can become anaerobic in a heart muscle cell during a heart attack, because of the inadequate supply of blood. If O_2 is restored, what will happen to the lactate produced by the heart muscle?

You have seen how cells harvest chemical energy in cellular respiration. Now we will see how that energy moves through other metabolic pathways in the cell.

concept 6.4 Catabolic and Anabolic Pathways Are Integrated

Metabolic transformations are a hallmark of life. The pathways we have seen thus far in the chapter, including glycolysis and the citric acid cycle, do not operate in isolation. Rather, there is an interchange of molecules into and out of these pathways, to and from the metabolic pathways for the synthesis and breakdown of amino acids, nucleotides, fatty acids, and other building blocks of life. *Carbon skeletons* (a term describing molecules with covalently linked carbon atoms) can enter catabolic pathways and be oxidized to release their energy, or they can enter anabolic pathways to be used in the formation of the macromolecules that are the major constituents of the cell. These relationships are summarized in **FIGURE 6.14**.

Catabolism and anabolism are linked

A hamburger or veggie burger on a bun contains three major sources of carbon skeletons: carbohydrates, mostly in the form of starch (a polysaccharide); lipids, mostly as triglycerides (three fatty acids attached to glycerol); and proteins (polymers of amino acids). Look at Figure 6.14 to see how each of these three types of macromolecules can be hydrolyzed and used in catabolism or anabolism.

CATABOLIC INTERCONVERSIONS Polysaccharides, lipids, and proteins can all be broken down to provide energy:

- *Polysaccharides* are hydrolyzed to glucose. Glucose then passes through glycolysis, pyruvate oxidation, and the respiratory chain, where its energy is captured in ATP.
- *Lipids* are broken down into their constituents—glycerol and fatty acids. Glycerol is converted into dihydroxyacetone phosphate, an intermediate in glycolysis. Fatty acids are highly reduced molecules that are converted to acetyl CoA in a process called *β -oxidation*. This is carried out by a series of oxidation enzymes inside the mitochondrion. For

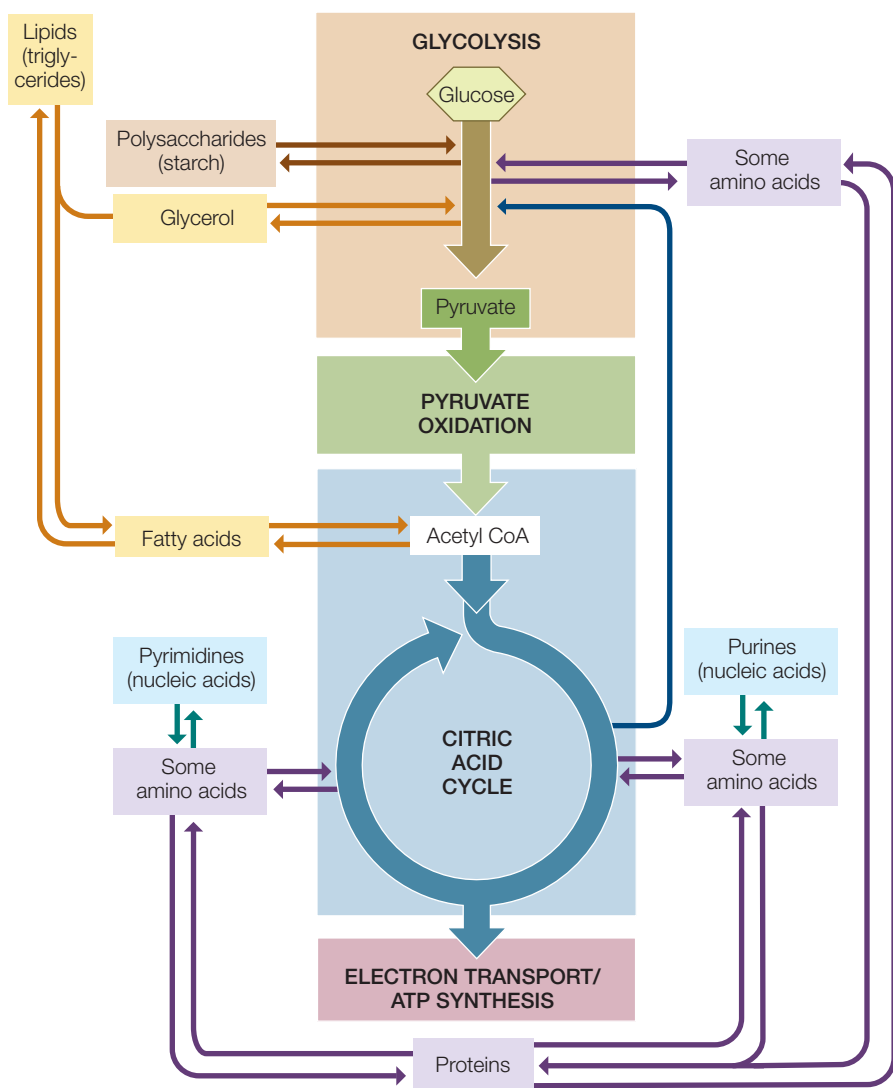

FIGURE 6.14 Relationships among the Major Metabolic Pathways of the Cell Note the central positions of glycolysis and the citric acid cycle in this network of metabolic pathways. Also note that many of the pathways can operate essentially in reverse.

in a process called **gluconeogenesis** (which means “new formation of glucose”). Likewise, acetyl CoA can be used to form fatty acids. The most common fatty acids have even numbers of carbons: 14, 16, or 18. These are formed by the addition of two-carbon acetyl CoA “units” one at a time until the appropriate chain length is reached.

Some intermediates in the citric acid cycle are reactants in pathways that synthesize important components of nucleic acids. For example, α -ketoglutarate and oxaloacetate are starting points for purines and pyrimidines, respectively.

Catabolism and anabolism are integrated

A carbon atom from a protein in your burger can end up in DNA, fat, or CO_2 , among other fates. How does the organism “decide” which metabolic pathways to follow, in which cells? With hundreds of enzymes and all the possible interconversions, you might expect that the cellular concentrations of various biochemical molecules would vary widely. Remarkably, the levels of these substances in what is called the *metabolic pool*—the sum total of all the biochemical molecules in a cell—are quite constant. Metabolic changes in the cell are a bit like the changes in traffic patterns in a city: if an accident blocks traffic on a major road, drivers take alternate routes, where the traffic volume consequently changes.

Consider what happens to the starch in your burger bun. In the digestive system, starch is hydrolyzed to glucose, which enters the blood. If it is needed, the glucose is distributed to the rest of the body. But if there is already enough glucose in the blood to supply the body’s needs, the excess glucose is converted into glycogen and stored in the liver. If not enough glucose is supplied by food, glycogen is broken down, or other molecules are used to make glucose by gluconeogenesis. The end result is that the level of glucose in the blood is remarkably constant. How does the body accomplish this?

Metabolic enzymes (including those of glycolysis, the citric acid cycle, and the respiratory chain) are subject to regulation, and often the regulatory mechanisms involve allosteric effects. An example is feedback inhibition, illustrated in Figure 3.19. In a metabolic pathway, a high concentration of the final product can inhibit the enzyme that catalyzes the commitment step (see Concept 3.4). By contrast, there can be positive feedback when an excess of the product of one pathway speeds up reactions in another pathway.

example, the β -oxidation of a C_{16} (16-carbon) fatty acid occurs in several steps:

The acetyl CoA can then enter the citric acid cycle and be catabolized to CO_2 .

- **Proteins** are hydrolyzed to their amino acid building blocks. The 20 different amino acids feed into glycolysis or the citric acid cycle at different points. For example, the amino acid glutamate is converted into α -ketoglutarate, an intermediate in the citric acid cycle.

ANABOLIC INTERCONVERSIONS Many catabolic pathways can operate essentially in reverse, with some modifications. Glycolytic and citric acid cycle intermediates, instead of being oxidized to form CO_2 , can be reduced and used to form glucose

LINK Review the discussion of enzyme regulation in Concept 3.4

Metabolic enzymes can also be regulated by altering the transcription of the genes that encode them. Excess levels of glucose and other dietary factors can lead to increased transcription of the gene for *fatty acid synthase*, a key enzyme in the synthesis of fatty acids. Excess citrate produced by the citric acid cycle is broken down to acetyl CoA, which in turn is used in fatty acid synthesis. This is one reason why people accumulate fat after eating too much. The fatty acids may be metabolized later to produce more acetyl CoA.

Regulation of Energy Pathways

Do You Understand Concept 6.4?

- Give examples of the catabolic conversion of a lipid and the anabolic conversion of a protein.
- Trace the biochemical pathway by which a carbon atom from a starch molecule in rice eaten today can end up in a muscle protein tomorrow.
- Describe what might happen if there were no mechanisms for modulating the level of acetyl CoA.

We have seen how cellular respiration allows organisms to harvest chemical energy from organic molecules. For the rest of the chapter, we'll look at how plants and other photosynthetic organisms produce these organic molecules using energy from light.

concept 6.5 During Photosynthesis, Light Energy Is Converted to Chemical Energy

The energy released by catabolic pathways in all organisms, including animals, plants, and prokaryotes, ultimately comes from the sun. **Photosynthesis** (literally, "synthesis from light") is an anabolic process by which the energy of sunlight is captured and used to convert carbon dioxide (CO₂) and water (H₂O) into carbohydrates (which we represent as a six-carbon sugar, C₆H₁₂O₆) and oxygen gas (O₂):

This equation shows a highly endergonic reaction. The net outcome is the reverse of the general equation for glucose catabolism that we discussed in Concept 6.2. Many of the molecular processes of photosynthesis are similar to those for glucose catabolism. For example, both processes involve redox reactions, electron transport, and chemiosmosis. However, the details of photosynthesis are quite different.

Photosynthesis involves two pathways (FIGURE 6.15):

- The **light reactions** convert light energy into chemical energy in the form of ATP and the reduced electron carrier NADPH. This molecule is similar to NADH (see Figure 6.4A) but with an additional phosphate group attached to the sugar of its adenosine.
- The **carbon-fixation reactions** do not use light directly, but instead use the ATP and NADPH made by the light reactions, along with CO₂, to produce carbohydrates.

Both the light reactions and the carbon-fixation reactions stop in the dark because ATP synthesis and NADP⁺ reduction require light. In photosynthetic prokaryotes (e.g., cyanobacteria) the light reactions take place on internal membranes and the carbon-fixation reactions occur in the cytosol. In plants, which will be our focus here, both pathways proceed within the chloroplast, but they occur in different parts of that organelle (see Figure 6.15).

Light energy is absorbed by chlorophyll and other pigments

Light is a form of energy that can be converted to other forms, such as heat or chemical energy. It is helpful here to discuss light in terms of its *photochemistry* and *photobiology*.

FIGURE 6.15 An Overview of Photosynthesis Photosynthesis consists of two pathways: the light reactions and the carbon-fixation reactions. In eukaryotes, these occur in the chloroplast.

PHOTOCHEMISTRY Light is a form of **electromagnetic radiation**. Electromagnetic radiation is propagated in waves, and the amount of energy in the radiation is inversely proportional to its **wavelength**—the shorter the wavelength, the greater the energy. The visible portion of the electromagnetic spectrum (**FIGURE 6.16**) encompasses a wide range of wavelengths and energy levels. In addition to traveling in waves, light also behaves as particles, called **photons**, which have no mass. In plants and other photosynthetic organisms, receptive molecules absorb photons in order to harvest their energy for biological processes. These receptive molecules absorb only specific wavelengths of light—photons with specific amounts of energy.

When a photon meets a molecule, one of three things can happen:

- The photon may bounce off the molecule—it may be *scattered* or *reflected*.

- The photon may pass through the molecule—it may be *transmitted*.
- The photon may be *absorbed* by the molecule, adding energy to the molecule.

Neither of the first two outcomes causes any change in the molecule. However, in the case of absorption, the photon disappears and its energy is absorbed by the molecule. The photon's *energy* cannot disappear, because according to the first law of thermodynamics, energy is neither created nor destroyed. When the molecule acquires the energy of the photon it is raised from a ground state (with lower energy) to an excited state (with higher energy):

The difference in free energy between the molecule's excited state and its ground state is approximately equal to the free energy of the absorbed photon (a small amount of energy is lost to entropy). The increase in energy boosts one of the electrons within the molecule into a shell farther from its nucleus; this electron is now held less firmly, making the molecule *unstable and more chemically reactive*.

PHOTOBIOLOGY Each type of molecule absorbs light at specific, characteristic wavelengths. Molecules that absorb wavelengths in the visible spectrum are called **pigments**.

When a beam of white light (containing all the wavelengths of visible light) falls on a pigment, certain wavelengths are absorbed. The remaining wavelengths are scattered or transmitted and make the pigment appear to us as colored. For example, the pigment *chlorophyll* absorbs both blue and red light, and we see the remaining light, which is primarily green. If we plot light absorbed by a purified pigment against wavelength, the result is an **absorption spectrum** for that pigment.

In contrast to the absorption spectrum, an **action spectrum** is a plot of the *biological activity* of an organism against the wavelengths of light to which it is exposed. An action spectrum can be determined as follows:

1. Place the organism (for example, a water plant with thin leaves) in a closed container.
2. Expose it to light of a certain wavelength for a period of time.
3. Measure the rate of photosynthesis by the amount of O_2 released.
4. Repeat with light of other wavelengths.

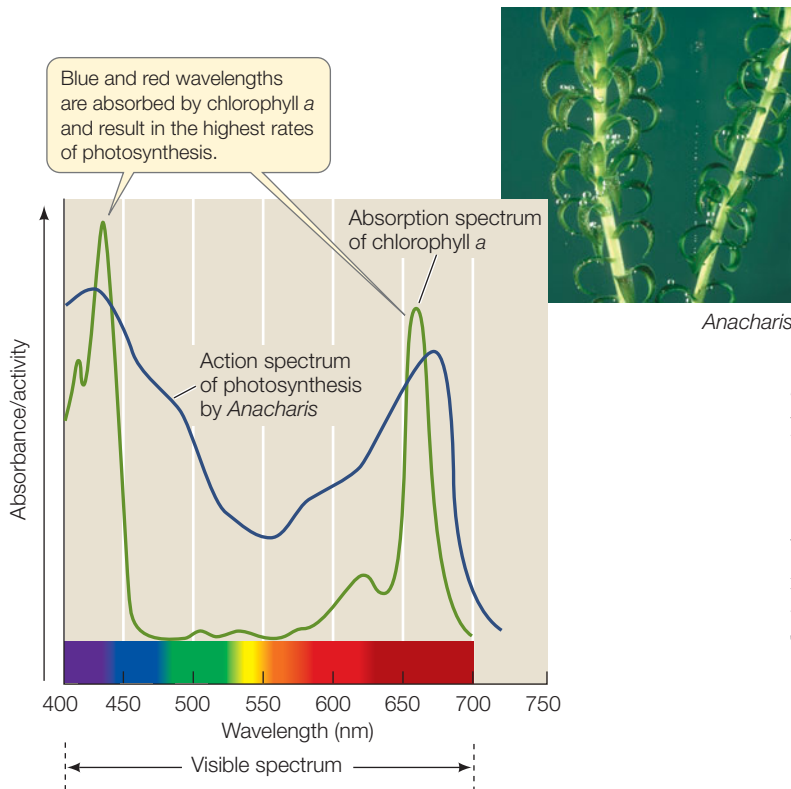

FIGURE 6.17 Absorption and Action Spectra The absorption spectrum of the purified pigment chlorophyll *a* from the aquatic plant *Anacharis* is similar to the action spectrum, obtained when different wavelengths of light are shone on the intact plant and the rate of photosynthesis is measured. In the thicker leaves of land plants, the action spectra show less of a dip in the green region (500–650 nm).

are found in red algae and in cyanobacteria, absorb various yellow-green, yellow, and orange wavelengths.

Light absorption results in photochemical change

When chlorophyll absorbs light it enters an excited state. This is an unstable situation, and the chlorophyll rapidly returns to its ground state, releasing most of the absorbed energy. This is an extremely rapid process—measured in picoseconds

FIGURE 6.17 shows the absorption spectrum of the pigment chlorophyll *a*, which was isolated from the leaves of *Anacharis*, a common aquarium plant. Also shown is the action spectrum for photosynthetic activity by the same plant. A comparison of the two spectra shows that the wavelengths at which photosynthesis is highest are the same wavelengths at which chlorophyll *a* absorbs light.

In plants, two chlorophylls absorb light energy to drive the light reactions: **chlorophyll a** and **chlorophyll b**. These two molecules differ only slightly in their molecular structures. Both have a complex ring structure, similar to that of the heme group of hemoglobin, with a magnesium ion at the center (**FIGURE 6.18**). A long hydrocarbon “tail” anchors the chlorophyll molecule to integral proteins in the thylakoid membrane of the chloroplast.

As mentioned above, the chlorophylls absorb blue and red light, which are near the two ends of the visible spectrum (see Figure 6.17). In addition, plants possess accessory pigments that absorb photons intermediate in energy between the red and the blue wavelengths, and then transfer a portion of that energy to the chlorophylls. Among these accessory pigments are *carotenoids* such as β -carotene, which absorb photons in the blue and blue-green wavelengths and appear deep yellow. The *phycobilins*, which

FIGURE 6.18 The Molecular Structure of Chlorophyll

Chlorophyll consists of a complex ring structure (green) with a magnesium ion at its center, plus a hydrocarbon “tail.” The tail anchors chlorophyll molecules to integral membrane proteins in the thylakoid membrane. Chlorophyll *a* and chlorophyll *b* are identical except for the replacement of a methyl group ($-\text{CH}_3$) with an aldehyde group ($-\text{CHO}$), shown on the upper right side of the ring structure. Most chlorophylls absorb light and pass the energy on to a chlorophyll in the reaction center of a photosystem.

(trillionths of a second)! For most chlorophyll molecules embedded in the thylakoid membrane, the released energy is absorbed by other, adjacent chlorophyll molecules. The pigments in photosynthetic organisms are arranged into energy-absorbing *antenna systems*, also called **light-harvesting complexes**. These form part of a large multi-protein complex called a **photosystem**. The photosystem spans the thylakoid membrane and consists of multiple antenna systems with their associated pigment molecules, all surrounding a **reaction center** (see Figure 6.18).

A ground-state chlorophyll molecule at the reaction center (symbolized by Chl) absorbs the energy from the adjacent chlorophylls and becomes excited (Chl*), but when this chlorophyll returns to the ground state, something very different occurs. *The reaction center converts the absorbed light energy into chemical energy.* The chlorophyll molecule in the reaction center absorbs sufficient energy that it actually *gives up its excited electron to a chemical acceptor*:

This, then, is the first consequence of light absorption by chlorophyll: *the reaction center chlorophyll (Chl*) loses its excited electron in a redox reaction and becomes Chl*. As a result of this transfer of an electron, the chlorophyll gets oxidized, while the acceptor molecule is reduced.

Reduction leads to ATP and NADPH formation

The electron acceptor that is reduced by Chl* is the first of a chain of electron carriers in the thylakoid membrane. Electrons are passed from one carrier to another in an energetically “downhill” series of reductions and oxidations. Thus, the thylakoid membrane has an *electron transport* system similar to

the respiratory chain of mitochondria (see Concept 6.2). The final electron acceptor is NADP⁺, which gets reduced:

As in mitochondria, ATP is produced chemiosmotically during the process of electron transport (a process called *photophosphorylation*). **FIGURE 6.19** shows the series of noncyclic electron transport reactions that use the energy from light to generate NADPH and ATP. There are two photosystems, each with its own reaction center:

- **Photosystem I** (containing the “P₇₀₀” chlorophylls at its reaction center) absorbs light energy at 700 nm and passes an excited electron to NADP⁺, reducing it to NADPH.
- **Photosystem II** (with “P₆₈₀” chlorophylls at its reaction center) absorbs light energy at 680 nm and produces ATP and oxidizes water molecules.

Let’s look in more detail at these photosystems, beginning with photosystem II.

Photophosphorylation

FIGURE 6.19 Noncyclic Electron Transport Uses Two Photosystems As chlorophyll molecules in the reaction centers of photosystems I and II absorb light energy, they pass electrons into a series of redox reactions, ultimately producing NADPH and ATP. The term “Z scheme” describes the path (blue arrows) of electrons as they travel through the two photosystems. In this scheme the vertical positions represent the energy levels of the molecules in the electron transport system.

APPLY THE CONCEPT

During photosynthesis, light energy is converted to chemical energy

The key role of water in supplying electrons for reduction of light-activated chlorophyll in the light reactions and in the release of O₂ to the atmosphere in the process of energy conversion has been investigated using isotopes of oxygen. The ¹⁸O isotope is heavier than normal oxygen (¹⁶O), and a mass spectrometer can be used to detect the difference. Green plant cells were exposed to light, water, and CO₂. (The CO₂ was supplied as the bicarbonate ion HCO₃⁻, which forms CO₂ when dissolved in water.) In the first experiment, some of the oxygen atoms in the water molecules were ¹⁸O (H₂¹⁸O), while CO₂ had the normal form of oxygen (C¹⁶O₂). In the second experiment, the situation was reversed, with H₂¹⁶O and C¹⁸O₂ being supplied to the plants. After 2 hours of photosynthesis,

the ratio of ¹⁸O to ¹⁶O was measured in the O₂ produced by the cells.

EXPERIMENT	ISOTOPE RATIO		
	H ₂ O	CO ₂	O ₂
1	0.85	0.31	0.84
2	0.20	0.50	0.20

- In experiment 1, was the isotopic ratio of O₂ more similar to that of H₂O or CO₂?
- What about experiment 2? What can you conclude from these data?

PHOTOSYSTEM II After an excited chlorophyll in the reaction center (Chl*) gives up its energetic electron to reduce a chemical acceptor molecule, the chlorophyll lacks an electron and is very unstable. It has a strong tendency to “grab” an electron from another molecule to replace the one it lost—in chemical terms, it is a strong oxidizing agent. The replenishing electrons come from water, splitting the H—O—H bonds:

Notice that *the source of O₂ in photosynthesis is H₂O.*

Go to **ANIMATED TUTORIAL 6.4**
The Source of the Oxygen Produced by Photosynthesis

Back to the electron acceptor in the electron transport system: the energetic electrons are passed through a series of membrane-bound carriers to a final acceptor at a lower energy level. As in the mitochondrion, a proton gradient is generated and is used by ATP synthase to store energy in the bonds of ATP.

PHOTOSYSTEM I In photosystem I, an excited electron from the Chl* at the reaction center reduces an acceptor. The oxidized chlorophyll (Chl⁺) now “grabs” an electron, but in this case the electron comes from the last carrier in the electron transport system of photosystem II. This links the two photosystems chemically. They are also linked spatially, with the two photosystems adjacent to one another in the thylakoid membrane. The energetic electrons from photosystem I pass through several molecules and end up reducing NADP⁺ to NADPH.

Next in the process of harvesting light energy to produce carbohydrates is the series of *carbon-fixation* reactions. These reactions require more ATP than NADPH. If the pathway we just described—the *linear* or *noncyclic* pathway—were the only set of light reactions operating, there might not be sufficient ATP for carbon fixation. **Cyclic electron transport** makes up for this imbalance. This pathway uses only photosystem I and produces ATP but not NADPH; it is cyclic because an electron is passed from an excited chlorophyll and recycles back to the same chlorophyll (**FIGURE 6.20**).

FIGURE 6.20 Cyclic Electron Transport Traps Light Energy as ATP Cyclic electron transport produces ATP but no NADPH.

Do You Understand Concept 6.5?

- What are the reactants and products of the light reactions of photosynthesis?
- What happens when electromagnetic radiation at the following wavelengths arrives at a leaf: 180 nm; 400 nm; 550 nm; 600 nm; 680 nm; 700 nm; 900 nm?
- Trace the flow of electrons in noncyclic electron transport in the chloroplast and compare it with that of cyclic electron transport.
- Write equations for the production of the following, and indicate whether they are oxidations, reductions, or neither: Chl^* ; O_2 ; ATP; NADPH.

We have seen how photosystems I and II absorb light energy, which ultimately ends up as chemical energy in ATP and NADPH. Let's look now at how these two energy-rich mol-

ecules are used in the carbon-fixation reactions to reduce CO_2 and thereby form carbohydrates.

concept 6.6

Photosynthetic Organisms Use Chemical Energy to Convert CO_2 to Carbohydrates

The energy in ATP and NADPH is used in the carbon-fixation reactions to “fix” CO_2 into a reduced form and convert it to carbohydrates. Most CO_2 fixation occurs only in the light, when ATP and NADPH are being generated. The metabolic pathway occurs in the stroma, or central region, of the chloroplast (see Figure 6.15) and is called the **Calvin cycle** after one of its discoverers, Melvin Calvin.

Like all biochemical pathways, each reaction in the Calvin cycle is catalyzed by a specific enzyme. The cycle is composed of three distinct processes (FIGURE 6.21):

yourBioPortal.com

Go to WEB ACTIVITY 6.7
The Calvin Cycle

FIGURE 6.21 The Calvin Cycle The Calvin cycle uses the ATP and NADPH generated in the light reactions to produce G3P from CO_2 . The G3P is used as a starting material for the production of glucose and other carbohydrates. Six turns of the cycle are needed to produce one molecule of the hexose glucose.

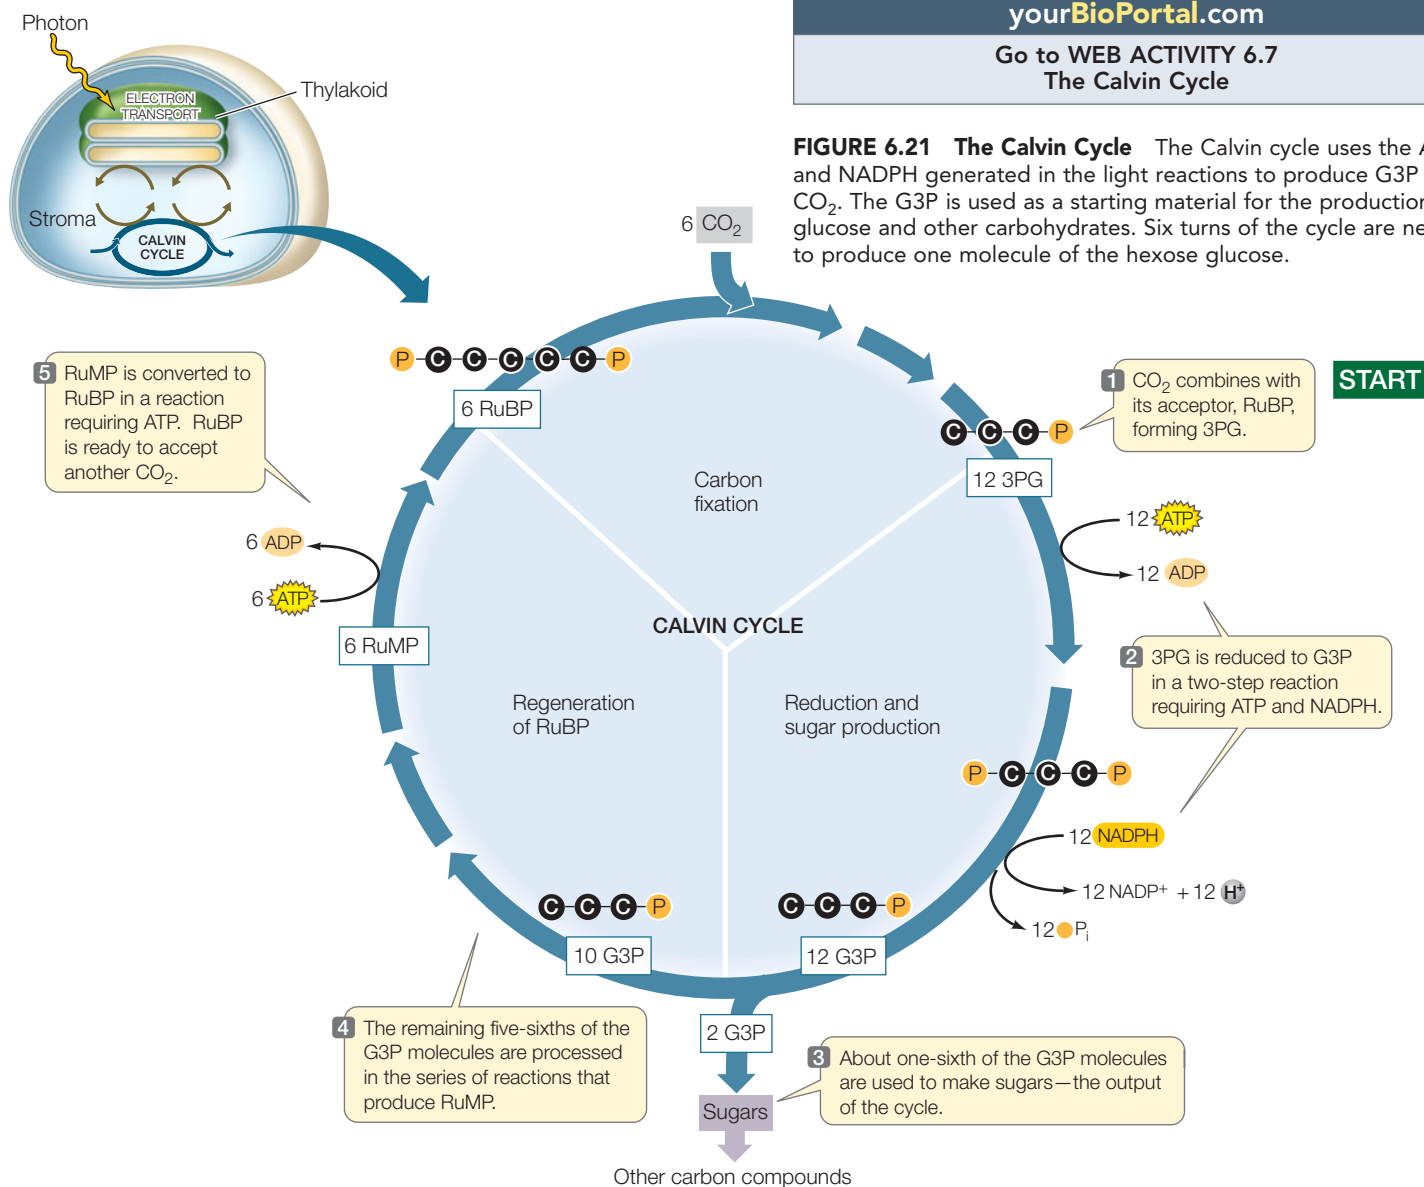

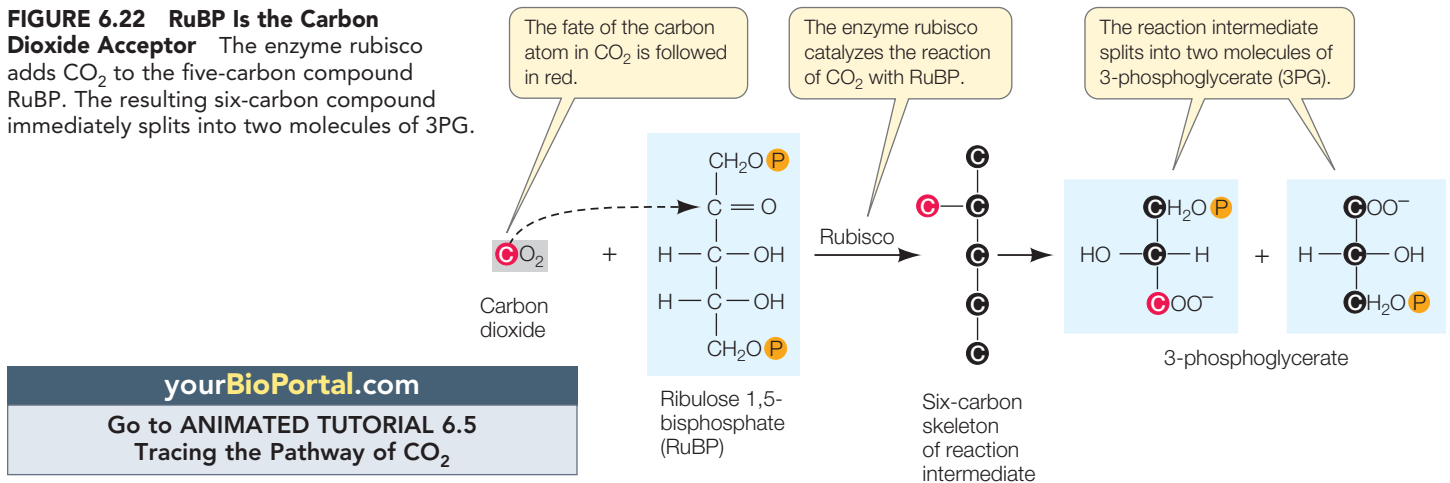

FIGURE 6.22 RuBP Is the Carbon Dioxide Acceptor The enzyme rubisco adds CO₂ to the five-carbon compound RuBP. The resulting six-carbon compound immediately splits into two molecules of 3PG.

- **Fixation of CO₂.** The initial reaction of the Calvin cycle adds the one-carbon CO₂ to an acceptor molecule, the five-carbon ribulose 1,5-bisphosphate (RuBP). The immediate product is a six-carbon molecule, which quickly breaks down into two three-carbon molecules called 3-phosphoglycerate (3PG; **FIGURE 6.22**). The enzyme that catalyzes this reaction, **ribulose bisphosphate carboxylase/oxygenase (rubisco)**, is rather sluggish as enzymes go. It typically catalyzes two to three fixation reactions per second. Because of this, plants need a lot of rubisco to perform enough photosynthesis to satisfy the needs of growth and metabolism. Rubisco constitutes about half of all the protein in a leaf, and it is probably the most abundant protein in the world!
- **Reduction of 3PG to form glyceraldehyde 3-phosphate.** This series of reactions involves a phosphorylation (using the high-energy phosphate from an ATP made in the light reactions) and a reduction (using an NADPH made in the light reactions). The product is **glyceraldehyde 3-phosphate (G3P)**, which is a three-carbon sugar phosphate, also called triose phosphate:

Glyceraldehyde 3-phosphate (G3P)

- **Regeneration of the CO₂ acceptor, RuBP.** Most of the G3P ends up as ribulose monophosphate (RuMP), and ATP is used to convert this compound into RuBP. So for every “turn” of the Calvin cycle, one CO₂ is fixed and the CO₂ acceptor is regenerated.

What happens to the extra G3P made by the Calvin cycle (see Figure 6.21)? It has two fates, depending on the time of day and the needs of different parts of the plant:

- Some of the extra G3P is exported out of the chloroplast to the cytosol, where it is converted to *hexoses* (glucose and fructose). This is the familiar C₆H₁₂O₆ from the general equation

for photosynthesis. These molecules may be catabolized for energy; used as carbon skeletons for the synthesis of amino acids and other molecules (see Figure 6.14); or converted to sucrose, which is transported out of the leaf to other organs in the plant.

- Late in the day when glucose has accumulated inside the chloroplast, the glucose units are linked to form the starch polysaccharide. This storage carbohydrate can then be drawn upon during the night so that the photosynthetic tissues can continue to export sucrose to the rest of the plant, even when photosynthesis is not taking place. In addition, starch is abundant in nonphotosynthetic organs such as roots, underground stems, and seeds, where it provides a ready supply of glucose to fuel cellular activities, including plant growth.

FRONTIERS Laboratory and field studies show that increases in CO₂ result in more photosynthesis. With the global increases in atmospheric CO₂, scientists are interested in what the effects will be on plant growth, especially of plants important to humans. By exposing plants in the field to pipes emitting CO₂, biologists are making actual measurements of these possible effects.

The products of the Calvin cycle are of crucial importance to Earth’s entire biosphere. The C—H covalent bonds generated by this cycle provide almost all of the energy for life on Earth. Photosynthetic organisms, which are also called **autotrophs** (“self-feeders”), release most of this energy in cellular respiration, and use it to support their own growth, development, and reproduction. But plants are also the source of energy for other organisms. Much plant matter ends up being consumed by **heterotrophs** (“other-feeders”), including animals, which cannot photosynthesize. Heterotrophs depend on autotrophs for chemical energy, which they harvest via cellular respiration. In addition, many heterotrophs rely on plants to produce molecules that the heterotrophs cannot synthesize for themselves.

LINK The roles of autotrophs and heterotrophs in ecosystems are described in Concept 45.3

Do You Understand Concept 6.6?

- What are the three processes of the Calvin cycle?
- If green plant cells are incubated in the presence of CO_2 molecules containing radioactive carbon atoms, the fate of the carbon atoms can be followed. In an experiment, radioactive CO_2 was given for 1 minute to plant cells, and then the cells were examined after 1, 5, 10, 20, and 30 minutes. The following molecules were labeled with radioactive carbon at some point(s): glucose, glyceraldehyde 3-phosphate, glycine (an amino acid), 3-phosphoglycerate, ribulose 1,5-bisphosphate, and sucrose. List these molecules in the order in which they first become labeled.

Why does fresh air inhibit the formation of alcohol by yeast cells?

ANSWER Armed with our knowledge of metabolism, we can now explain Pasteur's observations of beet sugar and alcohol:

1. *Nothing happened to beet mash unless microscopic yeast cells were present.* Beet sugar is a product of photosynthetic CO_2 fixation (Concept 6.6). Catabolism of carbohydrates is a cellular activity, characteristic of virtually all living things (Concepts 6.2 and 6.3).
2. *In the presence of fresh air, yeast cells grew vigorously on the mash, and bubbles of CO_2 were formed.* Carbohydrate catabolism under aerobic conditions yields a large amount of ATP (Concepts 6.1 and 6.2), which can be used to fuel anabolic pathways for growth (Concept 6.4). Under aerobic conditions, glucose is fully oxidized to CO_2 (Concept 6.2).
3. *Without fresh air, the yeast grew slowly, less CO_2 was produced, and alcohol was formed.* Alcoholic fermentation occurs in anaerobic conditions, and yields far less ATP (for growth) than aerobic metabolism; a small amount of CO_2 is produced (Concept 6.3).

As we note in the opening story, the use by humans of yeasts for fermentation has a long history (FIGURE 6.23).

Beer comes from the fermentation of barley seeds. These are soaked to begin the process of germination, which includes the induction of an enzyme that hydrolyzes the starch stored in the seed. The resulting disaccharide, maltose, is what the yeast cells use for energy—they first break the maltose down to its glucose monomers. At a cool temperature and under anaerobic conditions, yeast produces alcohol. An herb called hops is added to impart a distinctive bitter flavor.

Wine grapes are crushed, and the resulting juice contains sugars that are used by yeast for fermentation. There are yeasts growing on the skins of grapes naturally, so the original winemakers did not add yeast. More recently, special yeast strains have been used to control the fermentation process. The longer this process is allowed to proceed, the less sugar remains (resulting in a less sweet taste) and the higher the alcoholic content. After fermentation the wine is stored in wooden casks, typically at cool temperatures. During this time hundreds of molecular transformations occur, giving different wines distinctive properties.

Bread is made from ground-up plant seeds (flour), which contain abundant starch. Moisture activates enzymes inside the seed that catabolize the starch to monosaccharides, which in turn are used by yeast for growth under aerobic conditions. The resulting CO_2 provides bubbles that cause the complex flour mixture to rise to a familiar texture.

FIGURE 6.23 Products of Glucose Metabolism Beer and wine are made by fermentation, whereas bread rises because of aerobic catabolism of glucose.

6

SUMMARY

concept 6.1 ATP, Reduced Coenzymes, and Chemiosmosis Play Important Roles in Biological Energy Metabolism

- Metabolism is carried out in small steps and involves coenzymes as carriers of chemical energy.
- Adenosine triphosphate (ATP) serves as “energy currency” in the cell. Hydrolysis of ATP releases a large amount of free energy. **Review Figure 6.1 and WEB ACTIVITY 6.1**
- In **oxidation**, a material loses electrons by transfer to another material, which thereby undergoes **reduction**. Such **redox** reactions transfer large amounts of energy.
- The coenzyme nicotinamide adenine dinucleotide is a key electron carrier in biological redox reactions. It exists in two forms, one oxidized (NAD^+) and the other reduced (NADH). **Review Figure 6.4**
- In **oxidative phosphorylation**, ATP is formed with the energy derived from the reoxidation of reduced coenzymes. This depends on the process of **chemiosmosis**, in which a proton gradient across a membrane powers ATP formation. This occurs at the plasma membrane in prokaryotes, and in the mitochondria and chloroplasts in eukaryotes. **Review Figures 6.5 and 6.6, WORKING WITH DATA 6.1, and ANIMATED TUTORIAL 6.1**

concept 6.2 Carbohydrate Catabolism in the Presence of Oxygen Releases a Large Amount of Energy

- The sequential pathways of aerobic glucose catabolism are **glycolysis**, **pyruvate oxidation**, and the **citric acid cycle**. **Review Figure 6.9**
- In glycolysis, a series of ten enzyme-catalyzed reactions in the cell cytoplasm converts glucose to two molecules of pyruvate. Some energy is released and captured as ATP and NADH. **Review Figure 6.10**
- The next pathway, pyruvate oxidation, links glycolysis to the citric acid cycle. Pyruvate oxidation converts pyruvate into the two-carbon molecule acetyl CoA.
- In the citric acid cycle, a series of eight enzyme-catalyzed reactions fully oxidizes acetyl CoA to CO_2 . Much energy is released, and most is used to form NADH. **Review Figure 6.11 and WEB ACTIVITY 6.2**
- The energy in NADH is used to make ATP via a series of **electron transport** carriers and chemiosmosis. **Review Figure 6.12, ANIMATED TUTORIAL 6.2, and WEB ACTIVITY 6.3**

concept 6.3 Carbohydrate Catabolism in the Absence of Oxygen Releases a Small Amount of Energy

- In the absence of O_2 , glycolysis is followed by **fermentation**. Together, these pathways partially oxidize pyruvate and generate the end products lactic acid or ethanol. In the process, NAD^+ is regenerated from NADH so that glycolysis can continue, thus generating a small amount of ATP. **Review Figure 6.13 and WEB ACTIVITY 6.4**
- For each molecule of glucose used, fermentation yields 2 molecules of ATP. In contrast, glycolysis, pyruvate oxidation, the citric acid cycle, and oxidative phosphorylation yield up to 32 molecules of ATP per molecule of glucose. **Review WEB ACTIVITY 6.5**

concept 6.4 Catabolic and Anabolic Pathways Are Integrated

- The catabolic pathways for the breakdown of carbohydrates, lipids, and proteins feed into the energy-harvesting metabolic pathways. **Review Figure 6.14**
- Anabolic pathways use intermediate components of the energy-harvesting pathways to synthesize fatty acids, amino acids, and other essential building blocks.
- The formation of glucose from intermediates of glycolysis and the citric acid cycle is called **gluconeogenesis**.
- The enzymes of glycolysis and the citric acid cycle are regulated by various mechanisms, including allosteric regulation. Excess acetyl CoA is diverted into fatty acid synthesis. **Review WEB ACTIVITY 6.6**

concept 6.5 During Photosynthesis, Light Energy Is Converted to Chemical Energy

- The **light reactions** of photosynthesis convert light energy into chemical energy. They produce ATP and reduce NADP^+ to NADPH. **Review Figure 6.15**
- Light is a form of **electromagnetic radiation**. It is emitted in particle-like packets called **photons** but has wavelike properties. Molecules that absorb light in the visible spectrum are called **pigments**. Photosynthetic organisms have several pigments, most notably **chlorophylls**. **Review Figures 6.16 and 6.17**
- The absorption of a photon puts a chlorophyll molecule into an excited state that has more energy than its ground state. This energy can be transferred via other chlorophylls to one in the **reaction center** of a photosystem. **Review Figure 6.18**
- An excited chlorophyll can act as a reducing agent, transferring excited electrons to other molecules. Oxidized chlorophyll regains electrons by the splitting of H_2O .
- In the thylakoid membrane of the chloroplast, photosystems I and II and a noncyclic electron transport system produce ATP via oxidative phosphorylation. NADPH and O_2 are also produced. **Review Figure 6.19 and ANIMATED TUTORIALS 6.3 and 6.4**
- **Cyclic electron transport** uses only photosystem I and produces only ATP. **Review Figure 6.20**

concept 6.6 Photosynthetic Organisms Use Chemical Energy to Convert CO_2 to Carbohydrates

- The **Calvin cycle** makes carbohydrates from CO_2 . The cycle consists of three processes: fixation of CO_2 , reduction and sugar production, and regeneration of RuBP. **Review Figure 6.21 and WEB ACTIVITY 6.7**
- RuBP is the initial CO_2 acceptor, and 3PG is the first stable product of CO_2 fixation. The enzyme **rubisco** catalyzes the reaction of CO_2 and RuBP to form 3PG. **Review Figure 6.22 and ANIMATED TUTORIAL 6.5**
- The ATP and NADPH formed by the light reactions are used to fuel the reduction of 3PG to form **glyceraldehyde 3-phosphate (G3P)**.

Genetics

The Cell Cycle and Cell Division

7

Ruth felt healthy and was surprised when she was called back to her physician's office a week after her annual checkup. "Your lab report indicates you have early cervical cancer," said the doctor. "I ordered a follow-up test, and it came back positive—at some point, you were infected with HPV."

Ruth felt numb as soon as she heard the word "cancer." Her mother had died of breast cancer in the previous year. The doctor's statement about HPV—human papillomavirus—did not register in her consciousness. Sensing Ruth's discomfort, the doctor quickly reassured her that the cancer was caught at an early stage and that a simple surgical procedure would remove it. Two weeks later, the cancer was removed and Ruth remains cancer-free. She was fortunate that her annual medical exam included a Papanicolaou (Pap) test, in which the cells lining the cervix are examined for abnormalities. Since they were begun almost 50 years ago in Europe, Pap tests have resulted in the early detection and removal of millions of early cervical cancers, and the death rate from this potentially lethal disease has plummeted.

Only recently was HPV found to be the cause of most cervical cancers. The German physician Harald Zur-Hausen was awarded the Nobel Prize in 2008 for this discovery, and it has led to a vaccine to prevent future infections. There are many different types of HPV, and many of the ones that infect humans cause warts, which are small, rough growths on the skin. The types of HPV that infect tissues at the cervix get there by sexual transmission, and this is a common infection.

When HPV arrives at the tissues lining the cervix, it has one of two fates. Most of the time it enters the cells and turns them into HPV factories, releasing a lot of

HPV particles into the mucus outside the uterus. These viruses can infect another person during a sexual encounter. But in some cases the virus follows a different, more sinister path. The viral DNA becomes incorporated into the DNA of the cervical cells, and the cells are stimulated to reproduce.

Cell reproduction in healthy humans is tightly controlled by a variety of mechanisms, but the virus-infected cells lose these controls. Understanding how cell division is controlled is clearly an important subject for the development of cancer treatments. But cell division is not just important in medicine. It underlies the growth, development, and reproduction of all organisms.

These cervical cancer cells are actively dividing; many of the cells are in various stages of mitosis and cytokinesis.

KEY CONCEPTS

- 7.1 Different Life Cycles Use Different Modes of Cell Reproduction
- 7.2 Both Binary Fission and Mitosis Produce Genetically Identical Cells
- 7.3 Cell Reproduction Is Under Precise Control
- 7.4 Meiosis Halves the Nuclear Chromosome Content and Generates Diversity
- 7.5 Programmed Cell Death Is a Necessary Process in Living Organisms

How does infection with HPV result in uncontrolled cell reproduction?*

*You will find the answer to this question on page 141.

concept 7.1 Different Life Cycles Use Different Modes of Cell Reproduction

In Chapter 4 we describe cells as the basic compartments of life, where biological processes are separated from the external environment. Cells are also essential for biological reproduction.

The lifespan of an organism, from birth to death, is intimately linked to cell reproduction. (Although you will see that it is somewhat of a misnomer, we will follow convention and refer to cell reproduction as cell division.) Cell division plays important roles in the growth and repair of tissues in multicellular organisms, as well as in the reproduction of all organisms (FIGURE 7.1). Although the details vary widely, organisms have two basic strategies for reproducing themselves: asexual reproduction and sexual reproduction. These two strategies make use of different types of cell division.

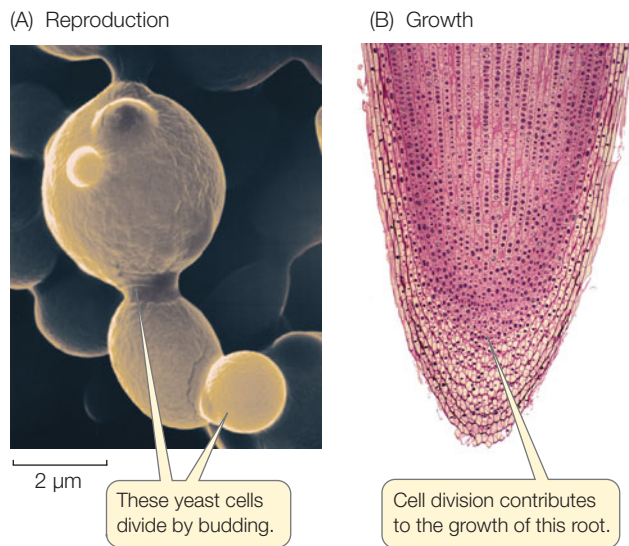

FIGURE 7.1 The Importance of Cell Division Cell division is the basis for (A) reproduction, (B) growth, and (C) repair and regeneration of tissues.

Asexual reproduction by binary fission or mitosis results in genetic constancy

Asexual reproduction is a rapid and effective means of making new individuals, and it is common in nature. The offspring resulting from asexual reproduction are **clones** of the parent organism—they are genetically identical (or virtually identical) to each other and the parent. Any genetic variations among the parent and offspring are due to changes called *mutations*, which are alterations in DNA sequence caused by environmental factors or errors in DNA replication. As you will see, this small amount of variation contrasts with the extensive variation possible in sexually reproducing organisms.

In most cases, single-celled prokaryotes reproduce by *binary fission*, an asexual process that we will discuss in Concept 7.2. A cell of the bacterium *Escherichia coli* is the whole organism, so when it divides to form two new cells, it is reproducing. Similarly, single-celled eukaryotes (such as fission yeast) can reproduce asexually through *mitosis*, a type of cell division that also produces two genetically identical cells.

Many eukaryotes, including fungi and plants, can also reproduce asexually. Perhaps the most dramatic example of this is a forest stand of aspen trees (*Populus tremuloides*) in the Wasatch Mountains of Utah (FIGURE 7.2). DNA analyses have shown that these trees are clones—they are virtually identical genetically. Aspen can reproduce sexually, with male and female plants, but in this case all the trees are males. An extensive root system has spread through the soil, and at intervals stems have formed and grown into trees. These trees look like separate organisms, but they are actually clones derived from asexual reproduction.

Sexual reproduction by meiosis results in genetic diversity

Sexual reproduction involves the fusion of two specialized cells called **gametes**, and can result in offspring with considerable

FIGURE 7.2 Asexual Reproduction on a Large Scale In this forest, the aspen trees arose from asexual reproduction and are virtually identical genetically.

genetic variation. The gametes form by **meiosis**—a process of cell division (described in Concept 7.4) that results in daughter cells with only half the genetic material of the original cell. During meiosis, the genetic material is randomly separated and reorganized so that the daughter cells differ genetically from one another. Because of this genetic variation, some offspring of sexual reproduction may be better adapted than others to survive and reproduce in a particular environment. Meiosis thus generates the genetic diversity that is the raw material for natural selection and evolution.

As we describe in Chapter 4, the DNA in eukaryotic cells is organized into multiple structures called *chromosomes*. Each **chromosome** consists of a single molecule of DNA and associated proteins. In multicellular organisms, the body cells that are *not* specialized for reproduction are called **somatic cells**. Somatic cells each contain *two sets of chromosomes*, and the chromosomes occur in pairs called **homologous pairs**. One chromosome of each pair comes from the organism's female parent, and the other comes from its male parent. For example, in humans with 46 chromosomes, 23 come from the mother and 23 from the father, with, for example, a chromosome 1 from each parent, and so on. The two chromosomes in a homologous pair (called *homologs*) bear corresponding, though not identical, genetic information. For example, a homologous pair of chromosomes in a plant may carry different versions of a gene that controls seed shape. One homolog may carry the version

for wrinkled seeds, while the other may carry the version for smooth seeds.

LINK The inheritance of characteristics such as seed shape is discussed in Chapter 8

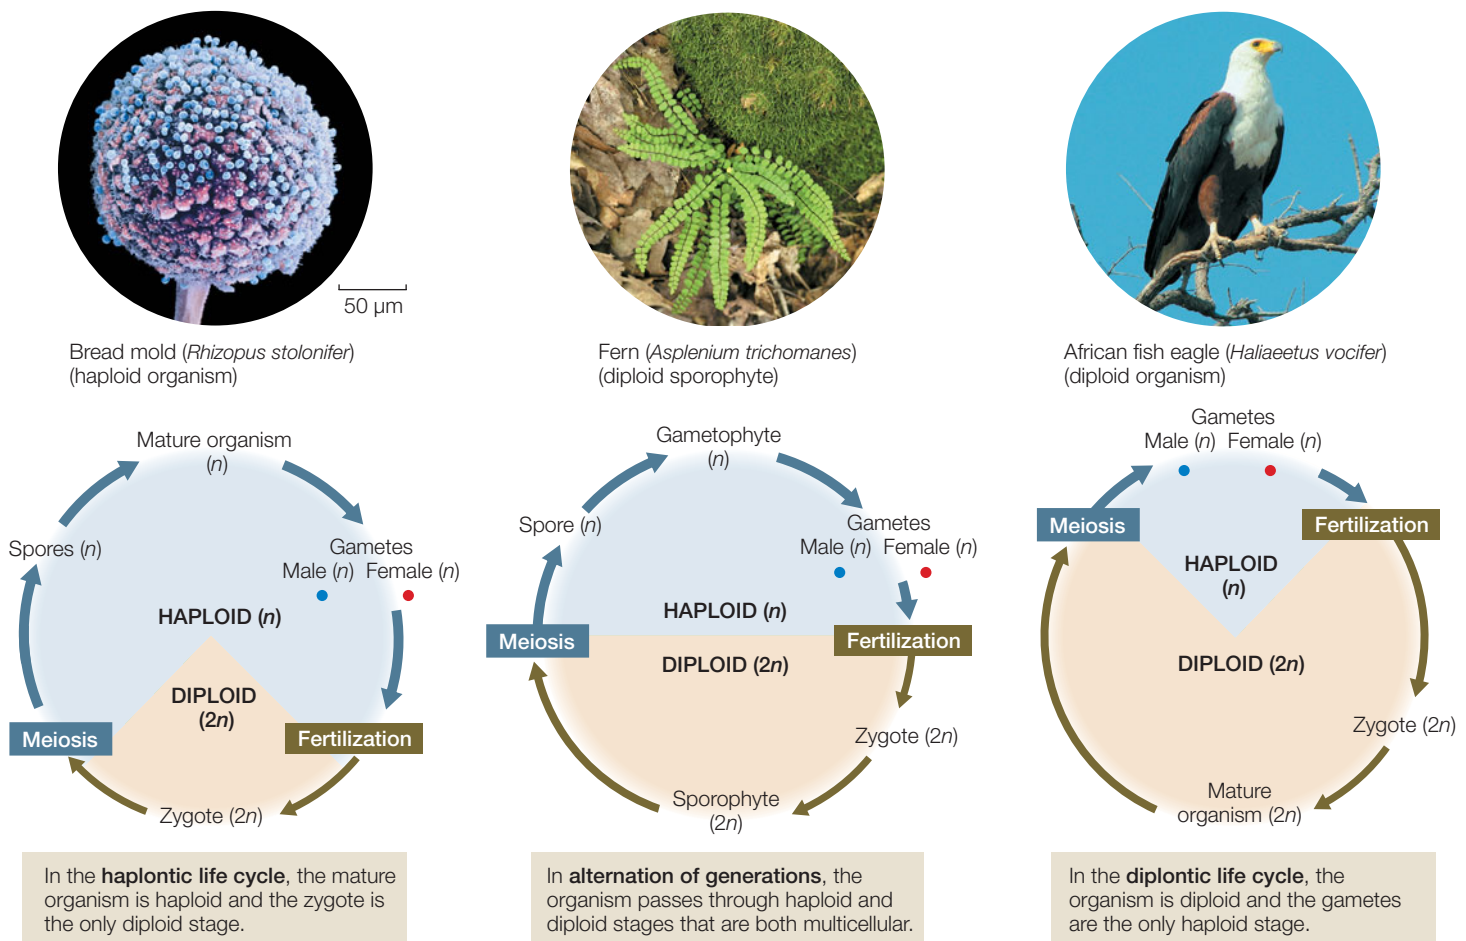

Gametes, by contrast, contain only a single set of chromosomes—that is, one homolog from each pair. The number of chromosomes in a gamete is denoted by n , and the cell is said to be **haploid**. During sexual reproduction, two haploid gametes fuse to form a **zygote** in a process called **fertilization**. The zygote thus has two sets of chromosomes, just as the somatic cells do. The chromosome number in the zygote is denoted by $2n$, and the cells are said to be **diploid**.

In many familiar organisms the zygote divides by mitosis, producing a new, mature organism with diploid somatic cells (as we have just described). But some other organisms have haploid stages in their life cycles.

Sexual Life Cycle

FIGURE 7.3 All Sexual Life Cycles Involve Fertilization and Meiosis In sexual reproduction, haploid (n) cells or organisms alternate with diploid ($2n$) cells or organisms.

All sexual life cycles involve meiosis to produce haploid cells. In some cases, gametes develop immediately after meiosis. In others, each haploid cell divides and develops into a haploid organism—the haploid stage of the life cycle—which eventually produces gametes by mitosis. The fusion of gametes results in a zygote and begins the diploid stage of the life cycle. Since the origin of sexual reproduction, evolution has generated many different versions of the sexual life cycle. **FIGURE 7.3** presents three examples:

- In *haplontic* organisms, including most protists, fungi, and some green algae, the tiny zygote is the only diploid cell in the life cycle. After it is formed it immediately undergoes meiosis to produce more haploid cells. These are usually *spores*, which are the dispersal units for the organism. A spore germinates to form a new haploid organism, which may be single-celled or multicellular. Cells of the mature haploid organism produce gametes that fuse to form the diploid zygote.
- Most plants and some fungi display **alternation of generations**. As in many haplontic organisms, meiosis gives rise to haploid spores, which divide by mitosis to form a haploid life stage called the *gametophyte*. In flowering plants the gametophytes are very small: the male gametophyte is the pollen, and the female gametophyte is the embryo sac—a part of the flower. In mosses and liverworts the gametophytes are larger and multicellular. The gametophyte forms gametes by mitosis, and they fuse to produce the diploid zygote. The zygote divides by mitosis to become the diploid *sporophyte*, which in turn produces haploid spores by meiosis.
- In *diplontic* organisms, which include animals, brown algae, and some fungi, the gametes are the only haploid cells in the life cycle, and the mature organism is diploid.

These life cycles are described in greater detail in Part Four. For now we will focus on the role of sexual reproduction in generating diversity among individual organisms.

The essence of sexual reproduction is the *random selection of half of the diploid chromosome set* to make a haploid gamete, followed by fusion of two haploid gametes from separate parents to produce a diploid cell. As we will see later in this chapter, further diversity is introduced by events that take place during meiosis. All of these steps contribute to a shuffling of genetic information in the population, so that no two individuals have exactly the same genetic constitution. The diversity provided by sexual reproduction opens up enormous opportunities for evolution.

Do You Understand Concept 7.1?

- In terms of the genetic composition of offspring, what is the difference between sexual and asexual reproduction?
- Discuss the advantages and disadvantages of sexual versus asexual reproduction in terms of evolution. Could evolution proceed without sexual reproduction?

We have briefly described the roles that different types of cell division play in the life cycles of organisms. Now let's look in more detail at the processes of cell division, starting with binary fission and mitosis.

concept 7.2 Both Binary Fission and Mitosis Produce Genetically Identical Cells

Cell reproduction by either binary fission or mitosis produces two genetically identical cells. For single-celled organisms, this is the basis of asexual reproduction. For multicellular organisms, mitosis is a way to build tissues and organs during development and to repair damaged tissues once development is complete.

In order for any cell to divide, the following events must occur:

- There must be a *reproductive signal*. This signal initiates cell division and may originate from either inside or outside the cell.
- **Replication** of DNA (the genetic material) must occur so that each of the two new cells will have a full complement of genes to complete cell functions.
- The cell must distribute the replicated DNA to each of the two new cells. This process is called **segregation**.
- Enzymes needed for cell division must be synthesized, new organelles must be formed, and new material must be added to the plasma membrane (and the cell wall in organisms that have one). The division of the cytoplasm to form two daughter cells is called **cytokinesis**.

These events proceed somewhat differently in prokaryotes and eukaryotes. We will discuss replication, segregation, and cytokinesis here, and reproductive signals in Concept 7.3.

Prokaryotes divide by binary fission

In prokaryotes, cell division results in the reproduction of the entire single-celled organism. The cell grows in size, replicates its DNA, and then separates the cytoplasm and DNA into two new cells by a process called **binary fission**.

REPLICATION OF DNA In most prokaryotic cells, almost all of the genetic information is carried on one single chromosome. In many cases the ends of the single DNA molecule are covalently joined, making the chromosome circular. Two regions of the prokaryotic chromosome play functional roles in cell reproduction:

- *ori*: the site where replication of the circular chromosome starts (the *origin* of replication)
- *ter*: the site where replication ends (the *terminus* of replication)

Chromosome replication takes place as the DNA is threaded through a “replication complex” of proteins near the center of the cell. Replication begins at the *ori* site and moves toward the *ter* site. When replication is complete, the two daughter DNA molecules separate and segregate from one another at opposite

FIGURE 7.4 Prokaryotic Cell Division The process of cell division in a bacterium involves DNA replication, segregation, and cytokinesis.

an animal cell (see below). As the membrane pinches in, new cell wall materials are deposited, which finally separate the two cells.

Eukaryotic cells divide by mitosis followed by cytokinesis

As in prokaryotes, cell reproduction in eukaryotes entails DNA replication, segregation, and cytokinesis. Some of the details, however, are quite different:

- **Replication of DNA.** Unlike prokaryotes, eukaryotes have more than one chromosome. But the replication of each eukaryotic DNA molecule is similar to replication in prokaryotes, in that it is achieved by threading the long strands through replication complexes (see Concept 9.2). DNA replication occurs only during a specific stage of the cell cycle.
- **Segregation of DNA.** When a cell divides, one copy of each chromosome must end up in each of the two new cells—for example, each new somatic cell in a human will have all 46 chromosomes (23 pairs). In eukaryotes, the newly replicated chromosomes are closely associated with each other. They become highly condensed, and a mechanism called **mitosis** segregates them into two new nuclei. The cytoskeleton is involved in this process.
- **Cytokinesis.** Cytokinesis follows mitosis. The process in plant cells (which have cell walls) is different than in animal cells (which do not have cell walls).

These events occur within the context of the **cell cycle**, the period from one division to the next. In eukaryotes, the cell cycle can be divided into mitosis and cytokinesis—referred to as the M phase—and a much longer interphase. During **interphase**, the cell nucleus is visible and typical cell functions occur—including DNA replication in cells that are dividing. This phase of the cell cycle begins when cytokinesis is completed and ends when mitosis begins (FIGURE 7.5).

Interphase has three subphases called G1, S, and G2. **G1** (the G stands for gap) is quite variable, and a cell may spend a long time in this phase carrying out its specialized functions. The cell's DNA is replicated during **S phase** (the S stands for synthesis). During **G2**, the cell makes preparations for mitosis—for example, by synthesizing components of the microtubules that will move the segregating chromosomes to opposite ends of the dividing cell.

ends of the cell. In rapidly dividing prokaryotes, DNA replication occupies the entire time between cell divisions.

SEGREGATION OF DNA Replication begins near the center of the cell, and as it proceeds, the *ori* regions move toward opposite ends of the cell (FIGURE 7.4). DNA sequences adjacent to the *ori* region bind proteins that are essential for this segregation. This is an active process, since the binding proteins hydrolyze ATP. Components of the prokaryotic cytoskeleton are involved in the segregation process. In particular, a bacterial protein that is structurally related to actin but functionally related to tubulin provides a filament along which the *ori* regions and their associated proteins move.

LINK Review the description of the cytoskeleton and its components in Concept 4.4

CYTOKINESIS The actual division of a single cell and its contents into two cells begins immediately after chromosome segregation. Initially, there is a pinching in of the plasma membrane caused by the contraction of a ring of fibers on the inside surface of the membrane (similar to a drawstring on shorts being tightened). In this case, the major component of these fibers is structurally similar to eukaryotic tubulin (which makes up microtubules), but its function is analogous to that of actin in the contractile ring of

Mitosis

Prophase sets the stage for DNA segregation

In mitosis (the M phase of the cell cycle), a single nucleus gives rise to two daughter nuclei that each contain the same number of chromosomes as the parent nucleus. While mitosis is a continuous

FIGURE 7.5 The Phases of the Eukaryotic Cell Cycle The eukaryotic cell cycle has several phases. DNA in the interphase nucleus is diffuse and becomes compacted as mitosis begins.

CONDENSED CHROMOSOMES Before the S phase of interphase, each chromosome contains one very long double-stranded DNA molecule. If all of the DNA in a typical human cell were put end to end, it would be nearly 2 meters long. Yet the nucleus is only 5 μm (0.000005 m) in diameter. So even during interphase the eukaryotic DNA is packaged in a highly organized way. The DNA is wound around specific proteins, and other proteins coat the DNA coils (see Concept 11.3). During prophase the chromosomes become much more tightly coiled and condensed.

After DNA replication, each chromosome has *two* DNA molecules, known as **sister chromatids**. The chromatids are held together at a region called the **centromere** until separation during mitosis (see below). During prophase the chromosomes become so compact that they can be seen clearly with a light microscope after staining with special dyes. (The term *chromosomes* means “staining bodies” and was coined in the late nineteenth century before the discovery of DNA and its structure.) Specialized protein structures called **kinetochores** assemble on the centromeres, one on each chromatid. These structures are important for chromosome movement.

For a given organism, the number and sizes of the condensed chromosomes constitute the **karyotype**. Each chromosome has a particular length, and the centromere is located at a particular position along its length. For example, humans have 46 chromosomes that can be distinguished from one another by their sizes and centromere positions. Karyotype analysis used to be a way to identify organisms, and is still used to detect gross chromosomal abnormalities in humans. However, DNA sequence analysis is now used much more commonly to identify and classify organisms.

process in which each event flows smoothly into the next, it is convenient to subdivide it into a series of stages: prophase, prometaphase, metaphase, anaphase, and telophase.

During interphase, only the nuclear envelope and the nucleolus (the region of the nucleus where ribosomes are formed; see Concept 4.3) are visible under the light microscope. The *chromatin* (the DNA with its associated proteins) is not yet condensed, and individual chromosomes cannot be discerned. The appearance of the nucleus changes as the cell enters **prophase**—the beginning of mitosis. Here we describe three structures that appear during prophase and contribute to the orderly segregation of the replicated DNA during mitosis: the condensed chromosomes, the centrosome and the spindle:

CENTROSOME Before the spindle apparatus forms (see below), its orientation is determined. In many cells, this is accomplished by the **centrosome** (“central body”), an organelle in the cytoplasm near the nucleus. The centrosome consists of a pair of **centrioles**, each one a hollow tube formed by nine triplets of microtubules. During S phase the centrosome becomes duplicated, and at the G₂-to-M transition, the two centrosomes separate from one another, moving to opposite sides of the nucleus. Eventually these identify “poles” toward which chromosomes move during segregation.

The positions of the centrosomes determine the plane at which the cell divides; therefore they determine the spatial relationship between the two new cells. This relationship may be of little consequence to single free-living cells such as yeasts, but it is important for development in a multicellular organism. For example, during the development of an embryo, the daughter cells from some divisions must be positioned correctly to receive signals to form new tissues. Plant cells lack centrosomes, but distinct microtubule organizing centers at each end of the cell play the same role.

Interphase

1 During the S phase of interphase, the nucleus replicates its DNA and centrosomes.

Prophase

2 The chromatin coils and supercoils, becoming more and more compact and condensing into visible chromosomes. The chromosomes consist of identical, paired sister chromatids. Centrosomes move to opposite poles.

Prometaphase

3 The nuclear envelope breaks down. Kinetochore microtubules appear and connect the kinetochores to the poles.

SPINDLE Each of the two centrosomes, when positioned on opposite sides of the nucleus, serves as a *pole*, toward which the chromosomes move. Tubulin dimers from around the centrosomes aggregate into microtubules that extend from the poles into the middle region of the cell. Together these microtubules make up a **spindle**. The spindle forms during prophase and prometaphase, when the nuclear envelope breaks down (see below).

There are two types of microtubules in the spindle:

- *Polar microtubules* form the framework of the spindle and run from one pole to the other, keeping the two poles apart.
- *Kinetochore microtubules*, which form later, attach to the kinetochores on the chromosomes. The two sister chromatids in each chromosome become attached to kinetochore microtubules from opposite sides of the cell. This ensures that the two chromatids will be pulled toward opposite poles.

The growing end of a developing microtubule is unstable and will fall apart unless it is attached to a kinetochore.

Separation of the chromatids and movement of the **daughter chromosomes** (which the sister chromatids become after separation) is the central feature of mitosis. It accomplishes the segregation that is needed for cell division and completion of the cell cycle.

Chromosome separation and movement are highly organized

During the next three phases of mitosis—prometaphase, metaphase, and anaphase—dramatic changes take place in the cell and the chromosomes:

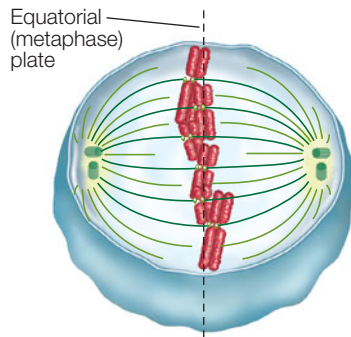

- In **prometaphase** the nuclear envelope breaks down and the compacted chromosomes, each consisting of two chromatids, attach to the kinetochore microtubules.
- In **metaphase** the chromosomes line up at the midline of the cell (the equatorial position).
- In **anaphase** the chromatids separate, and the daughter chromosomes move away from each other toward the poles.

You will find these events depicted and described in **FIGURE 7.6**. The separation of chromatids into daughter chromosomes occurs at the beginning of anaphase. The migration of the daughter chromosomes to the poles of the cell is a highly organized, active process. Two mechanisms operate to move the chromosomes along. First, the kinetochores contain a protein called *cytoplasmic dynein* that acts as a “molecular motor.” It hydrolyzes ATP to ADP and phosphate, thus releasing energy that moves the chromosomes along the microtubules toward the poles. This accounts for about 75 percent of the force of motion. Second, the kinetochore microtubules shorten from the poles, drawing the chromosomes toward them, accounting for about 25 percent of the force of motion.

yourBioPortal.com

Go to WEB ACTIVITY 7.2
The Mitotic Spindle

Metaphase

4 The centromere/kinetochore complexes become aligned in a plane, which is often at the cell's equator.

Anaphase

5 The paired sister chromatids separate, and the new daughter chromosomes begin to move toward the poles.

Telophase

6 The daughter chromosomes reach the poles. As telophase concludes, the nuclear envelopes and nucleoli re-form, the chromatin decondenses, and, after cytokinesis, the daughter cells enter interphase once again.

FIGURE 7.6 The Phases of Mitosis Mitosis results in two new nuclei that are genetically identical to each other and to the nucleus from which they were formed. In the micrographs, the green dye stains microtubules (and thus the spindle); the blue dye stains the chromosomes. The chromosomes in the diagrams are stylized to emphasize the fates of the individual chromatids.

yourBioPortal.com

Go to WEB ACTIVITY 7.3
Images of Mitosis

Telophase occurs after the chromosomes have separated and is the last phase of mitosis. During this period, a nuclear envelope forms around each set of new chromosomes, nucleoli appear, and the chromosomes become less compact. The spindle also disappears at this stage. As a result, there are two new nuclei in a single cell.

Cytokinesis is the division of the cytoplasm

Mitosis refers only to the division of the nucleus. Cytokinesis, the division of the cell's cytoplasm, is the final stage of cell reproduction. This process occurs differently in plants and animals.

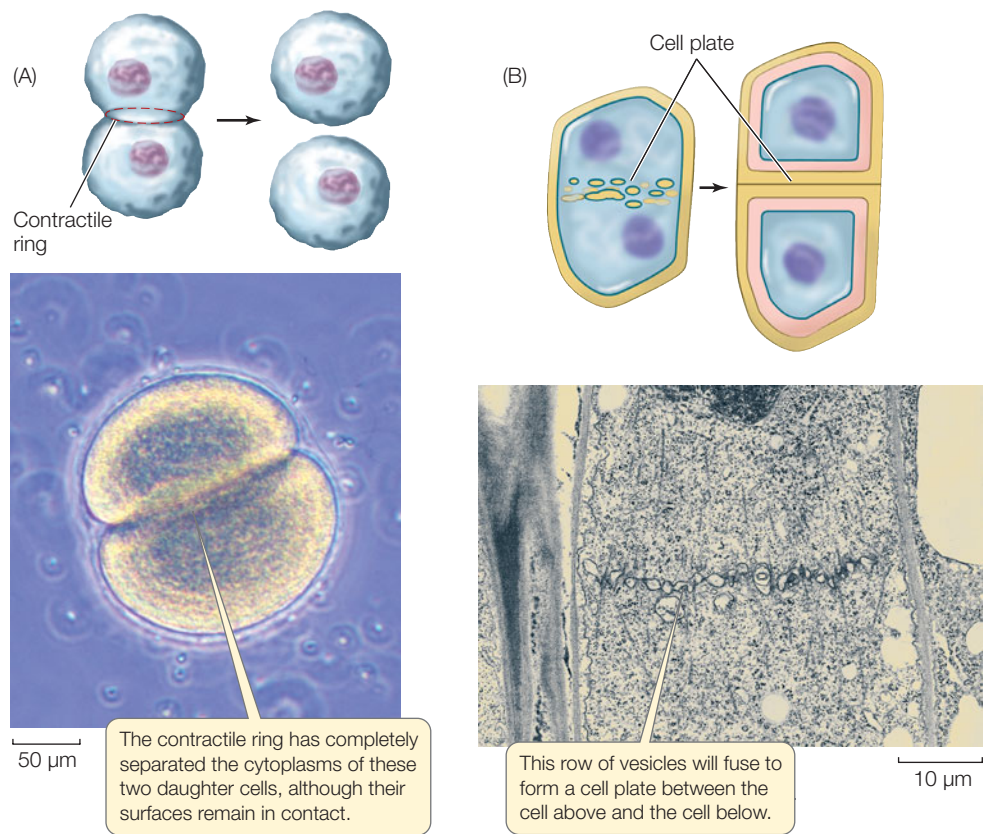

ANIMAL CELLS Cytokinesis usually begins with a furrowing of the plasma membrane, as if an invisible thread were cinching the cytoplasm between the two nuclei (**FIGURE 7.7A**). This *contractile ring* is composed of microfilaments of actin and myosin, which form a ring on the cytoplasmic surface of the plasma membrane. These two proteins interact to produce a

contraction (just as they do in muscles), pinching the cell in two. The microfilaments assemble rapidly from actin monomers that are present in the interphase cytoskeleton. Their assembly is controlled by calcium ions (commonly used in cellular signaling) that are released from storage sites in the center of the cell.

PLANT CELLS In plant cells, the cytoplasm divides differently because plants have cell walls. As the spindle breaks down after mitosis, membranous vesicles derived from the Golgi apparatus appear along the plane of cell division, roughly midway between the two daughter nuclei. The vesicles are propelled along microtubules by the motor protein *kinesin* and fuse to form a new plasma membrane. At the same time they contribute their contents to a *cell plate*, which is the beginning of a new cell wall that will lie between the two new cells (**FIGURE 7.7B**).

FRONTIERS Orientation of the mitotic spindle and cytokinesis in a dividing cell is usually nonrandom. During embryo development, the plane of cell division and whether the daughter cells get equal amounts of cytoplasm have important consequences for the subsequent fates of the daughter cells (see Concept 14.2). Animal and plant biologists are characterizing the genes and protein products involved in spindle orientation, with the aim of describing how it is involved in the formation of organs.

FIGURE 7.7 Cytokinesis Differs in Animal and Plant Cells (A) A sea urchin zygote (fertilized egg) that has just completed cytokinesis at the end of the first cell division of its development into an embryo. (B) An electron micrograph of a plant cell in late telophase. Plant cells divide differently than animal cells because they have cell walls.

Following cytokinesis, *each daughter cell contains all the components of a complete cell*. A precise distribution of chromosomes is ensured by mitosis. In contrast, organelles such as ribosomes, mitochondria, and chloroplasts are not necessarily distributed equally between daughter cells (as long as some of each are present in each cell). Although the *orientation* of cell division is important in development (see above), there does not appear to be a precise mechanism for the distribution of the cytoplasmic contents.

Do You Understand Concept 7.2?

- How does the mitotic spindle ensure that each daughter cell receives a full complement of the genetic material in the cell nucleus?
- Sketch the five stages of mitosis for an organism with four chromosomes (two pairs). Clearly label chromosomes and chromatids and note the number of double-stranded DNA molecules in each structure at each stage.
- The drug cytochalasin B blocks the assembly and function of microfilaments. What would happen if animal cells were treated with this drug after telophase but before cytokinesis?

Light microscopists have studied the dramatic events of mitosis and cell division since the 1880s, and we now have detailed descriptions of these processes. More recently, biologists have focused on the mechanisms controlling cell reproduction, which will be our next topic.

concept 7.3 Cell Reproduction Is Under Precise Control

Cell reproduction cannot go on continuously and indefinitely. If a single-celled species had no control over its reproduction, it

would soon overrun its environment and starve to death. In a multicellular organism, cell reproduction must be controlled to maintain the forms and functions of different parts of the body.

The reproductive rates of many prokaryotes respond to general conditions in the environment. For example, the bacterium *Bacillus subtilis* normally divides every 30 minutes. But when nutrients in its environment are low it stops dividing, and then resumes dividing when conditions improve.

Unlike prokaryotes, eukaryotic cells do not constantly divide whenever environmental conditions are adequate. In fact, the specialized cells of a multicellular eukaryotic organism may seldom or never divide. The signals for eukaryotic cell division are related to the needs of the entire organism. Mammals produce a variety of substances called **growth factors** that stimulate cell division and differentiation. For example, if you cut yourself and bleed, a blood clot eventually forms. Cell fragments called platelets in the blood vessels surrounding the clot secrete various growth factors that stimulate nearby skin cells to divide and heal the wound.

The eukaryotic cell division cycle is regulated internally

As we discussed in Concept 7.2, the eukaryotic cell cycle can be divided into four stages: G₁, S, G₂, and M. Progression through these phases is tightly regulated. For example, at the end of G₁, the **G₁-S transition** marks a key decision point for the cell: passing this point (called *R*, the *restriction point*) usually means

FIGURE 7.8 The Eukaryotic Cell Cycle The cell cycle consists of a mitotic (M) phase, during which mitosis and cytokinesis take place, and a long period of growth known as interphase. Interphase has three subphases (G1, S, and G2) in cells that divide.

the cell will proceed with the rest of the cell cycle and divide (FIGURE 7.8).

What events cause a cell to enter the S or M phases? A first indication that there were substances that control these transitions came from experiments involving *cell fusion*. Polyethylene glycol is a nonpolar solvent that partially dissolves membrane lipids and can be used to make different cells fuse together. Experiments involving the fusion of mammalian cells at different phases of the cell cycle showed that a cell in S phase produces a substance that activates DNA replication (FIGURE 7.9). Similar experiments pointed to a molecular activator for entry into M phase.

The cell cycle is controlled by cyclin-dependent kinases

The molecular activators revealed by the cell fusion experiments turned out to be *protein kinases*. These enzymes, common in cell signal transduction (see Concept 5.5), catalyze the phosphorylation of target proteins that regulate the cell cycle:

The class of protein kinases involved in cell cycle regulation is called **cyclin-dependent kinases (Cdk's)**, and as their name

INVESTIGATION

FIGURE 7.9 Regulation of the Cell Cycle Nuclei in G1 do not undergo DNA replication, but nuclei in S phase do. To determine if there is some signal in the S cells that stimulates G1 cells to replicate their DNA, cells in the G1 and S phases were fused together, creating cells with both G1 and S properties.

HYPOTHESIS

A cell in S phase contains an activator of DNA replication.

METHOD

RESULTS

CONCLUSION

The S phase cell produces a substance that diffuses to the G1 nucleus and activates DNA replication.

ANALYZE THE DATA

The experiment used mammalian cells undergoing the cell cycle synchronously. Radioactive labeling and microscopy were used to determine which nuclei were synthesizing DNA. Here are counts of the cell nuclei that were labeled:

Type of cells	Cells with labeled nuclei/total cells
Unfused G1:	6/300
Unfused S:	435/500
Fused G1 and S cells:	17*/19

*Both nuclei labeled

- What were the percentages of cells in S phase in each of the three experiments?
- What does this mean in terms of control of the cell cycle?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

implies, Cdk's are activated by binding to the protein **cyclin**. This binding changes the shape of a Cdk such that its active site is exposed, and is an example of *allosteric regulation* (see Concept 3.4).

FIGURE 7.10 Cyclins Are Transient in the Cell Cycle Cyclins are made at a particular time and then break down. In this case, the cyclin is present during G1 and activates a Cdk at that time.

There are several Cdk's (which vary in different eukaryotic species) that regulate the cell cycle at specific stages called **cell cycle checkpoints**. Each Cdk has its own cyclin to activate it, and the cyclin is made only at the right time. After the Cdk acts, the cyclin is broken down by a protease (**FIGURE 7.10**). So a key event controlling transition from one cell cycle phase to the next is the synthesis and subsequent breakdown of a cyclin. Cyclins are synthesized in response to various molecular signals, including growth factors. This starts a chain reaction:

To illustrate the concept of cell cycle control by a particular cyclin–Cdk complex, let's take a look at the complex that controls the R point at the G1–S transition (see Figure 7.8).

G1–S cyclin–Cdk catalyzes the phosphorylation of a protein called *retinoblastoma protein* (RB). In many cells, RB or a protein like it acts as an *inhibitor of the cell cycle* at the R point. To begin S phase, a cell must overcome the RB block. Here is where G1–S cyclin–Cdk comes in: it catalyzes the addition of a phosphate to RB. This causes a change in the three-dimensional structure of RB, thereby inactivating it. With RB out of the way, the cell cycle can proceed. To summarize:

Now we can be more specific about the chain of events involved in growth factor stimulation of cell division: the specific cyclin whose synthesis is activated is the one that allosterically activates the Cdk that phosphorylates RB, and this allows the cell cycle to exit G1 and begin DNA replication in S phase. This example illustrates how regulation of the cell cycle involves a

number of cellular processes that we have examined in this and other chapters: signal transduction (see Chapter 5), gene expression and protein synthesis (see Chapter 3), and cell division.

FRONTIERS Regulation of progress through the cell cycle by Cdk's and cyclins is itself regulated by a host of molecules that "regulate the regulators." These in turn may be regulated by signals from outside the cell. Biologists have found that the constant cell cycling seen in cancer cells can be caused by abnormalities in these regulatory proteins. This new knowledge may lead to cancer therapies that target specific regulatory processes.

Do You Understand Concept 7.3?

- Compare the cell cycles of prokaryotes and eukaryotes with regard to signals for initiation, how many chromosomes are present, and how the replicated DNA segregates.
- Draw a diagram and describe the events that occur in the four stages of the eukaryotic cell cycle.
- Cultures of eukaryotic cells can be synchronized, so they are all at the same phase of the cell cycle at the same time. If you examined a culture at the beginning of G1, would the Cdk that acts at the R point be present? Would it be active? Would its cyclin be present? What would your answers be if the cell was in G2?

Binary fission and mitosis result in daughter cells with the same number of chromosomes as their parent cells. But sexual reproduction requires a process of cell division in which the number of chromosomes is halved. We'll look at this process next.

concept 7.4 Meiosis Halves the Nuclear Chromosome Content and Generates Diversity

In Concept 7.1 we described the role and importance of meiosis in sexual reproduction. Now we will see how meiosis accomplishes the orderly and precise generation of haploid cells.

Meiosis consists of *two* nuclear divisions that reduce the number of chromosomes to the haploid number. Although the *nucleus divides twice* during meiosis, the *DNA is replicated only once*. Unlike the products of mitosis, the haploid cells that are the products of meiosis are genetically different from one another and from the parent cell. **FIGURE 7.11** compares the two processes.

To understand the process of meiosis and its specific details, it is useful to keep in mind the overall functions that meiosis has evolved to serve:

- To reduce the chromosome number from diploid to haploid
- To ensure that each of the haploid products has a complete set of chromosomes
- To generate genetic diversity among the products

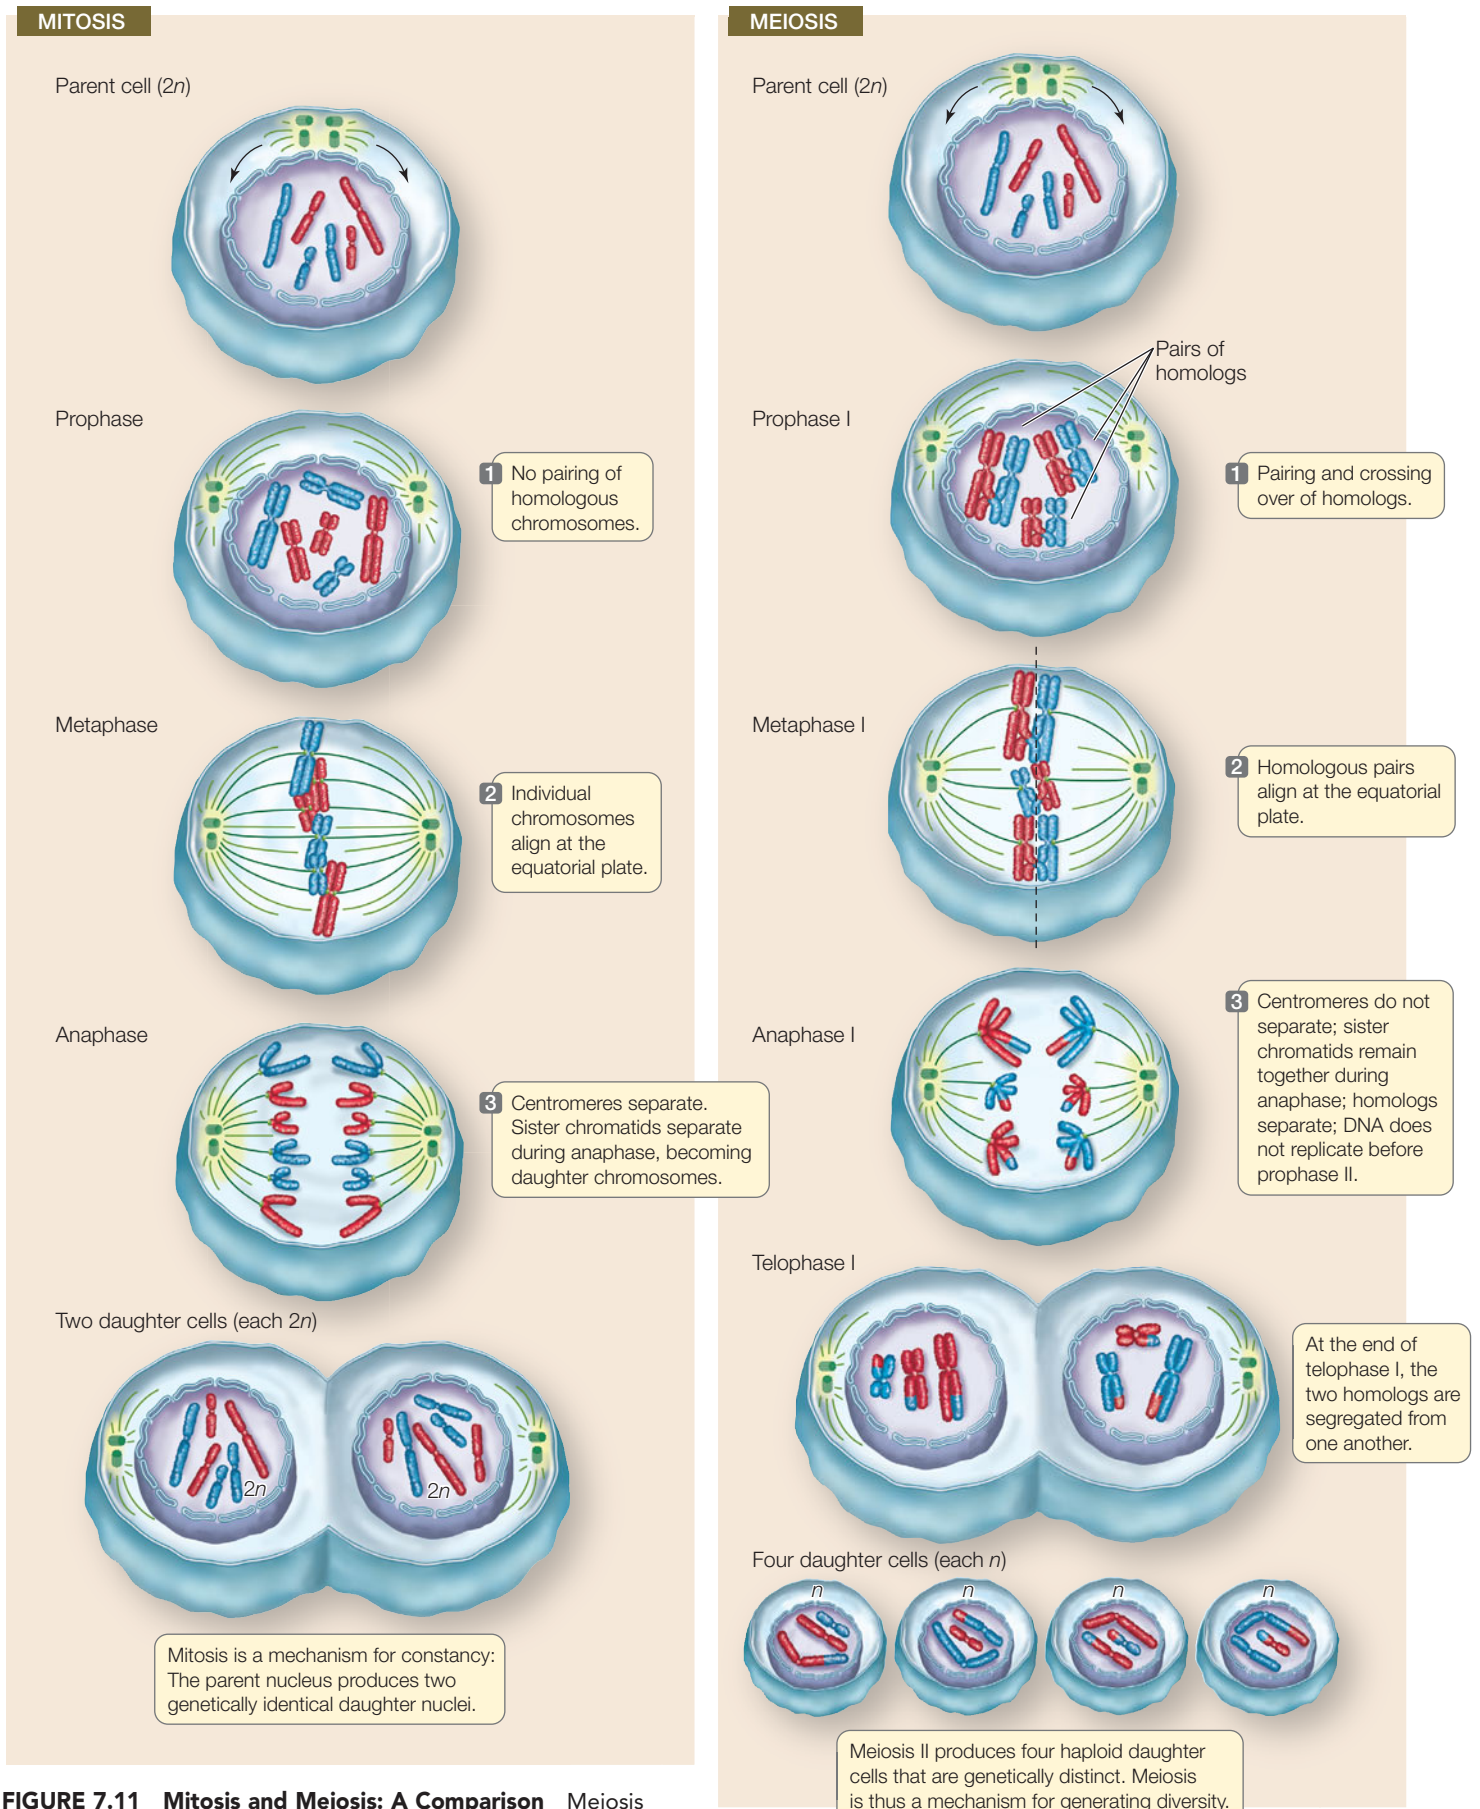

FIGURE 7.11 Mitosis and Meiosis: A Comparison Meiosis differs from mitosis chiefly by the pairing of homologs and by the failure of the centromeres to separate at the end of metaphase I.

MEIOSIS I

Early prophase I

1 The chromatin begins to condense following interphase.

Mid-prophase I

2 Synapsis aligns homologs, and chromosomes condense further.

Late prophase I–Prometaphase

3 The chromosomes continue to coil and shorten. The chiasmata reflect crossing over, the exchange of genetic material between non-sister chromatids in a homologous pair. In prometaphase the nuclear envelope breaks down.

MEIOSIS II

Prophase II

7 The chromosomes condense again, following a brief interphase (interkinesis) in which DNA does not replicate.

Metaphase II

8 The centromeres of the paired chromatids line up across the equatorial plates of each cell.

Anaphase II

9 The chromatids finally separate, becoming chromosomes in their own right, and are pulled to opposite poles. Because of crossing over and independent assortment, each new cell will have a different genetic makeup.

The events of meiosis are illustrated in **FIGURE 7.12**. In this section, we will discuss some of the key features that distinguish meiosis from mitosis.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 7.2**
Meiosis

Meiotic division reduces the chromosome number

As noted above, meiosis consists of two nuclear divisions, *meiosis I* and *meiosis II*. Two unique features characterize **meiosis I**:

- *Homologous chromosomes come together and line up along their entire lengths.* No such pairing occurs in mitosis.

Metaphase I

Equatorial plate

4 The homologous pairs line up on the equatorial (metaphase) plate.

Anaphase I

5 The homologous chromosomes (each with two chromatids) move to opposite poles of the cell.

Telophase I

6 The chromosomes gather into nuclei, and the original cell divides.

Telophase II

10 The chromosomes gather into nuclei, and the cells divide.

Products

11 Each of the four cells has a nucleus with a haploid number of chromosomes.

FIGURE 7.12 Meiosis: Generating Haploid Cells

In meiosis, two sets of chromosomes are divided among four daughter cells, each of which has half as many chromosomes as the original cell. The four haploid cells are the result of two successive nuclear divisions. The micrographs show meiosis in the male reproductive organ of a lily; the diagrams show the corresponding phases in an animal cell. (For instructional purposes, the chromosomes from one parent of the original organism are colored blue and those from the other parent are red.)

yourBioPortal.com

Go to **WEB ACTIVITY 7.4**
Images of Meiosis

- *The homologous chromosome pairs separate, but the individual chromosomes, each consisting of two sister chromatids, remain intact. (The chromatids will separate during meiosis II.)*

Like mitosis, meiosis I is preceded by an interphase with an S phase, during which each chromosome is replicated. As a result, each chromosome consists of two sister chromatids. At the end of meiosis I two nuclei form, each with half of the original

chromosomes (one member of each homologous pair). Since the centromeres did not separate, these chromosomes are still double—composed of two sister chromatids. The sister chromatids are separated during **meiosis II**, which is *not* preceded by DNA replication. As a result, the products of meiosis I and II are four cells, each containing the haploid number of chromosomes. But *these four cells are not genetically identical.*

Crossing over and independent assortment generate diversity

A diploid organism has two sets of chromosomes ($2n$): one set derived from its male parent, the other from its female parent. As the organism grows and develops, its cells undergo mitotic divisions. In mitosis, each chromosome behaves independently of its homolog, and its two chromatids are sent to opposite poles during anaphase. Each daughter nucleus ends up with an identical set of $2n$ chromosomes. In meiosis, things are very different (see Figure 7.11).

An important consequence of meiosis is that the four resulting cells differ from one another genetically. The shuffling of genetic material occurs by two processes: crossing over and independent assortment.

CROSSING OVER Meiosis I begins with a long prophase I (the first three panels of Figure 7.12), during which the chromosomes change markedly. The homologous chromosomes pair by adhering along their lengths in a process called *synapsis*. (This does not happen in mitosis.) This pairing process lasts from prophase I to the end of metaphase I. The four chromatids of each pair of homologous chromosomes form a **tetrad**, or *bivalent*. For example, in a human cell at the end of prophase I there are 23 tetrads, each consisting of four chromatids. The four chromatids come from the two partners in each homologous pair of chromosomes.

Throughout prophase I and metaphase I, the chromatin continues to coil and compact and the chromosomes become more condensed. At a certain point, the homologous chromosome pairs appear to repel each other, especially near the centromeres, but they remain attached. The X-shaped attachment points are called *chiasmata* (singular *chiasma*, “cross”):

A chiasma is a point where *genetic material is exchanged* between nonsister chromatids on homologous chromosomes—a process called **crossing over** (FIGURE 7.13). Any of the four chromatids in the tetrad can participate in this exchange, and a single chromatid can exchange material at more than one point along its length. Crossing over occurs shortly after synapsis begins, but chiasmata do not become visible until later, when the homologs are repelling each other. Crossing over results in **recombinant** chromatids, and it increases genetic variation among the products of meiosis by reshuffling genetic information between homologous chromosome pairs. In Concept 8.3 we explore further the genetic consequences of crossing over.

Mitosis seldom takes more than an hour or two, but meiosis can take *much* longer. In human males, the cells in the testis that undergo meiosis take about a week for prophase I and about a month for the entire meiotic cycle. In females, prophase I begins long before a woman’s birth, during her early fetal development, and ends as much as decades later, during the monthly ovarian cycle.

INDEPENDENT ASSORTMENT In addition to crossing over, meiosis provides a second source of genetic diversity. It is a matter of chance which member of a homologous pair goes to which daughter cell at anaphase I. For example, imagine a diploid organism with two pairs of homologous chromosomes (pairs 1 and 2). One member of each pair came from the male parent of the organism (paternal 1 and 2), and the other member of each pair came from the female parent (maternal 1 and 2). When cells in this organism undergo meiosis, a particular daughter nucleus could receive paternal 1 and maternal 2, paternal 2 and maternal 1, both maternal, or both paternal chromosomes. It all depends on how the homologous pairs line up at metaphase I. This phenomenon is termed **independent assortment**.

Note that of the four possible outcomes just described, only two daughter nuclei receive the full complements of either maternal or paternal chromosomes (apart from the material exchanged by crossing over). *The greater the number of chromosomes, the lower the probability of reestablishing the original parental combinations, and the greater the potential for genetic diversity.* Most species of diploid organisms have more than two pairs of chromosomes. In humans, with 23 chromosome pairs, 2^{23} (8,388,608) different combinations of maternal and paternal

APPLY THE CONCEPT

Meiosis halves the nuclear chromosome content and generates diversity

In the anther (male sex organ) of the lily plant, cells undergo mitosis in synchrony. These cells can be removed and studied in the laboratory. An antibody was developed that would bind specifically to a chromosomal protein called B1. A procedure involving antibody binding and staining of the antibody was used to detect the protein in the anther cells. The protein was detected at the centromeres of mitotic chromosomes, and its presence or absence was monitored at different stages of the cell

cycle. The results were: G1, absent; early S, absent; late S through metaphase, present; anaphase, absent; telophase, absent.

1. Propose a role for this protein in sister chromatid function.
2. What results would you expect if meiotic cells were examined for this protein? At what stages of meiosis would the protein be present or absent?

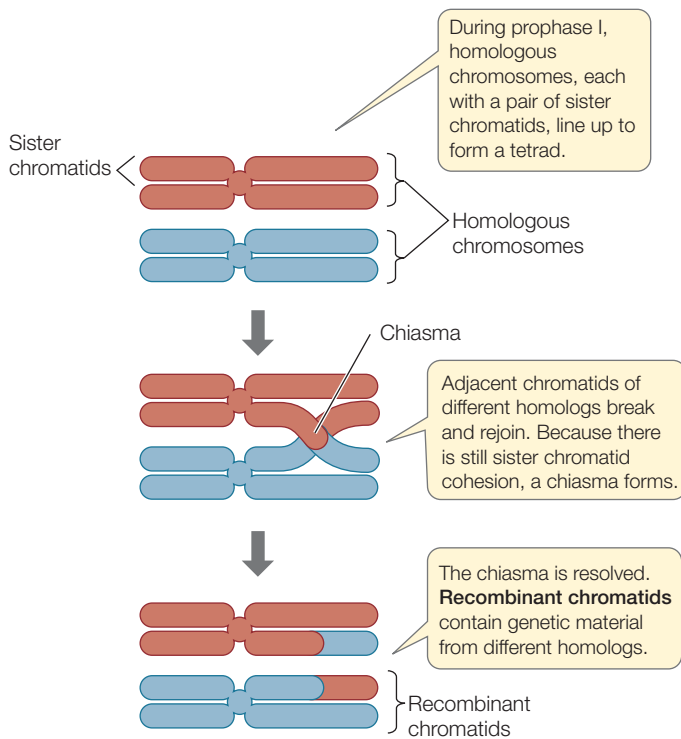

FIGURE 7.13 Crossing Over Forms Genetically Diverse Chromosomes The exchange of genetic material by crossing over results in new combinations of genetic information on the recombinant chromosomes. The two different colors distinguish the chromosomes contributed by the male and female parents of the organism whose cell is undergoing meiosis.

chromosomes can be produced just by the mechanism of independent assortment! Taking the extra genetic shuffling afforded by crossing over into account, the number of possible combinations is virtually infinite. Crossing over and independent assortment, along with the processes that result in mutations, provide the genetic diversity needed for evolution by natural selection.

We have seen how meiosis I is fundamentally different from mitosis. However, meiosis II is similar to mitosis, in that it involves the separation of chromatids into daughter nuclei (see steps 7–11 in Figure 7.12). The final products of meiosis I and meiosis II are four haploid daughter cells, each with one set (n) of chromosomes.

Meiotic errors lead to abnormal chromosome structures and numbers

In the complex process of meiosis, things occasionally go wrong. For example, chromosomes may break or homologs may fail to separate at anaphase I or anaphase II. The gametes formed from meiotic errors have abnormal chromosomes, and when they take part in fertilization, the consequences for offspring can be significant.

NONDISJUNCTION Occasionally, a homologous chromosome pair fails to separate (fails to *disjoin*) at anaphase I, or a pair

of chromatids fail to separate at anaphase II. This failure to separate is referred to as **nondisjunction**. If a chromosome pair fails to separate at anaphase I, two of the four daughter nuclei will each end up with both members of that homologous pair, and the other two will have neither member of the pair. If nondisjunction occurs at anaphase II, only two of the four daughter nuclei will be affected: one will have an extra chromosome and the other will have less than the full complement of chromosomes. Using humans as an example, if during anaphase I the two homologs of chromosome 10 fail to separate, half the gametes will have two copies of chromosome 10, with a total of 24 chromosomes instead of 23. If one of these gametes fuses with a normal gamete during fertilization, the zygote will have 47 ($23 + 24$) chromosomes, with three copies of chromosome 10. The condition of having an extra chromosome (*trisomy*) or missing a chromosome (*monosomy*) is called **aneuploidy**.

For reasons that are unclear, aneuploidy is a common and harmful condition in humans. About 10–30 percent of all conceptions show aneuploidy, but most of the embryos that develop from such zygotes do not survive to birth, and those that do often die before the age of 1 year. At least one-fifth of all recognized human pregnancies are spontaneously terminated (miscarried) during the first 2 months, largely because of trisomies and monosomies. The actual proportion of spontaneously terminated pregnancies is certainly higher, because the earliest ones often go unrecognized. The most common form of aneuploidy in humans is trisomy 16 (three copies of chromosome 16), but almost none of these embryos survive to birth. Among the few aneuploidies that allow survival is Down syndrome—trisomy 21. Such individuals generally have mental retardation, but can lead long and productive lives.

POLYPLOIDY Most organisms are either diploid (for example, most animals) or haploid (for example, most fungi). Under some circumstances, triploid ($3n$), tetraploid ($4n$), or higher-order **polyploid** nuclei may form. This can occur in a variety of ways. For example, there could be an extra round of DNA replication preceding meiosis, or there could be no spindle formed in meiosis II. Polyploidy occurs naturally in some animals and in many plants, and in some cases it has probably led to speciation—the evolution of a new species.

A diploid nucleus can undergo normal meiosis because there are two sets of chromosomes to make up homologous pairs, which separate during anaphase I. Similarly, a tetraploid nucleus has an even number of each kind of chromosome, so each chromosome can pair with its homolog. However, a triploid nucleus cannot undergo normal meiosis because one-third of the chromosomes would lack partners. Polyploidy has implications for agriculture, particularly in the production of hybrid plants. For example, ploidy must be taken into account in wheat breeding because there are diploid, tetraploid, and hexaploid wheat varieties. Polyploidy can be a desirable trait in crops and ornamental plants because it often leads to more robust plants with larger flowers, fruits, and seeds. In addition, triploid fruit varieties are desirable because they are infertile and therefore seedless.

FRONTIERS Polyploid plants, produced either naturally or in the laboratory, often have larger vegetative organs, flowers, or seeds—desirable characteristics for crops and ornamental plants. But for reasons not fully understood, some polyploid plants show no increased vigor. Scientists are analyzing the DNA and proteins of polyploid plants to shed light on the mechanisms of polyploidy vigor.

TRANSLOCATION During crossing over in meiosis I, chromatids from homologous chromosome pairs break and rejoin. Occasionally this can happen between *non-homologous chromosomes*. The result is a **translocation**, and these are quite common, even in mitotic cells. As we point out in our discussion of gene expression and its regulation in Chapters 10 and 11, the location of genes relative to other DNA sequences is important, and translocations can have profound effects on gene expression.

An example of a translocation that is known to occur in humans is the swap of material between chromosomes 9 and 22:

In this case, the DNA sequence *abl* on chromosome 9 comes to lie adjacent to the sequence *bcr* on chromosome 22. If the translocation occurs in a mitotic cell forming white blood cells, the result of this combination is a form of leukemia, a cancer of white blood cells. If a translocation occurs during meiosis, the gametes that result may carry it and pass it on to offspring after fertilization.

Do You Understand Concept 7.4?

- How do crossing over and independent assortment during meiosis result in daughter nuclei that differ genetically?
- What are the differences between meiosis and mitosis?
- An organism has a diploid number of 6. How many chromosomes are present in the following cells: A gamete? A gamete with monosomy of chromosome 2? A liver cell? A sperm cell at meiotic anaphase II?

An essential role of cell division in complex eukaryotes is to replace cells that die. What causes cells to die?

concept 7.5 Programmed Cell Death Is a Necessary Process in Living Organisms

Cells die in one of two ways. The first type of cell death, **nekrosis**, occurs when cells are damaged by mechanical means or toxins, or are starved of oxygen or nutrients. These cells often swell up and burst, releasing their contents into the extracellular environment. This process often results in inflammation (see Concept 31.1).

APPLY THE CONCEPT

Programmed cell death is a necessary process in living organisms

The DNA content of an individual cell can be measured by applying a DNA-specific dye to the cell and then passing it through an instrument that measures the staining intensity. A new drug was tested on a population of rapidly dividing tumor cells and their DNA contents analyzed and compared with those of untreated cells:

DYE INTENSITY	% OF UNTREATED CELLS	% OF TREATED CELLS
<10	0	20
10	10	5
20	55	60
30	5	5
40	30	10
50	0	0

1. Plot percentage of cells versus DNA content for the untreated and treated cells.
2. Explain the data for the untreated cells. Which cells are in G1? What do the data indicate about how much time cells spend in G1 relative to other phases?
3. Explain the data for treated cells and compare them with untreated cells. At what stage of the cell cycle do you think the new drug acts?

More typically, cell death is due to **apoptosis** (Greek, “falling apart”). Apoptosis is a *genetically programmed series of events that result in cell death*. Why would a cell initiate apoptosis, which is essentially cell suicide? In animals, there are two possible reasons:

- *The cell is no longer needed by the organism.* For example, before birth, a human fetus has weblike hands, with connective tissue between the fingers. As development proceeds, this unneeded tissue disappears as its cells undergo apoptosis in response to specific signals.
- *The longer cells live, the more prone they are to genetic damage that could lead to cancer.* This is especially true of epithelial cells on the surface of an organism, which may be exposed to radiation or toxic substances. Such cells normally die after only days or weeks and are replaced by new cells.

The events of apoptosis are similar in many organisms. The cell becomes detached from its neighbors, hydrolyzes its DNA into small fragments, and forms membranous lobes, or “blebs,” that break up into cell fragments (FIGURE 7.14A). In a remarkable example of the economy of nature, the surrounding living cells usually ingest the remains of the dead cell by phagocytosis. The remains are digested in the lysosomes, and the digestion products are recycled.

Apoptosis is also used by plant cells in an important defense mechanism called the *hypersensitive response*. Plants can protect themselves from disease by undergoing apoptosis at the site of infection by a fungus or bacterium. With no living tissue to grow in, the invading organism is not able to spread to other parts of the plant. Because of their rigid cell walls, plant cells do not form blebs the way animal cells do. Instead, they digest their own cell contents in the vacuole and then release the digested components into the vascular system.

Despite these differences between plant and animal cells, they share many of the signal transduction pathways that

lead to apoptosis. Like the cell division cycle, programmed cell death is controlled by signals, which may come from inside or outside the cell (FIGURE 7.14B). Internal signals may be linked to the age of the cell or the recognition of damaged DNA. External signals (or a lack of them) can cause a receptor protein in the plasma membrane to change its shape, and in turn activate a signal transduction pathway. Both internal and external signals can lead to the activation of a class of enzymes called **caspases**. These enzymes are proteases that hydrolyze target molecules in a cascade of events. As a result, the cell dies as the caspases hydrolyze proteins of the nuclear envelope, nucleosomes, and plasma membrane.

Do You Understand Concept 7.5?

- What are some differences between apoptosis and necrosis?
- Give examples of when apoptosis is necessary in animals and in plants.
- In the worm *Caenorhabditis elegans* the fertilized egg divides by mitosis to produce 1,090 somatic cells. But the adult worm has only 959 cells. What happens to the 131 other cells formed during worm embryo development? What might happen if the 131 cells did not undergo this process?

How does infection with HPV result in uncontrolled cell reproduction?

ANSWER Human papillomavirus (HPV) stimulates the cell cycle when it infects tissues lining the cervix. It does this by “hijacking” the regulatory mechanisms that control the

FIGURE 7.14 Apoptosis: Programmed Cell Death (A) Many cells are programmed to “self-destruct” when they are no longer needed, or when they have lived long enough to accumulate a burden of DNA damage that might harm the organism. (B) Both external and internal signals stimulate caspases, the enzymes that break down specific cell constituents, resulting in apoptosis.

cell cycle (Concept 7.3). There are two types of proteins that regulate the cell cycle:

- **Oncogene** proteins are positive regulators of the cell cycle in cancer cells. They are derived from normal positive regulators that have become mutated to be overly active, or that are present in excess, and they stimulate the cancer cells to divide more often. An example of an oncogene protein is the growth factor receptor in a breast cancer cell (**FIGURE 7.15A**). Normal breast cells have relatively low numbers of the growth factor receptor *human epidermal growth factor receptor 2* (HER2). So the growth factor does not normally find many breast cell receptors with which to bind and initiate cell division. In about 25 percent of breast cancers, a DNA change results in the increased production of HER2. This results in positive stimulation of the cell cycle, and a rapid proliferation of cells with the altered DNA.
- **Tumor suppressors** are negative regulators of the cell cycle in normal cells, but in cancer cells they are inactive. An example is the retinoblastoma (RB) protein that acts at R (the restriction point) in G1 (see Figure 7.8). When RB is active the cell cycle does not proceed, but it is inactive in cancer cells, allowing the cell cycle to occur (**FIGURE 7.15B**). This is where *HPV hijacks the system*. When it infects cells lining the cervix, HPV causes the synthesis of a protein called E7, which has a three-dimensional shape that just fits into the protein-binding site of RB, thereby inactivating it. With no active RB to prevent it, cell division proceeds. Uncontrolled cell reproduction is a hallmark of cancer—and so cervical cancer begins.

Most tumors are treated by surgery. But when a tumor has spread from its original site (a common occurrence, unfortunately), surgery does not cure it. Instead, drugs—chemotherapy—are used. Generally, these drugs stop cell division by targeting specific cell cycle events (Concepts 7.2 and 7.3). For example, some drugs block DNA replication (e.g., 5-fluorouracil); others damage DNA, stopping the cells at G2 (e.g., etoposide); and still others prevent the normal functioning of the mitotic spindle (e.g., paclitaxel). Many of these drugs do not kill the cell, but they cause the cell cycle to stop, and the damaged cell is stimulated to undergo apoptosis (Concept 7.5).

A major problem with these treatments is that they target normal cells as well as the tumor cells. They are toxic to tissues with large populations of normal dividing cells such as those in the intestine, skin, and bone marrow (producing blood cells). There is an ongoing search for better and more specific drugs. For example, a drug was designed that affects the protein

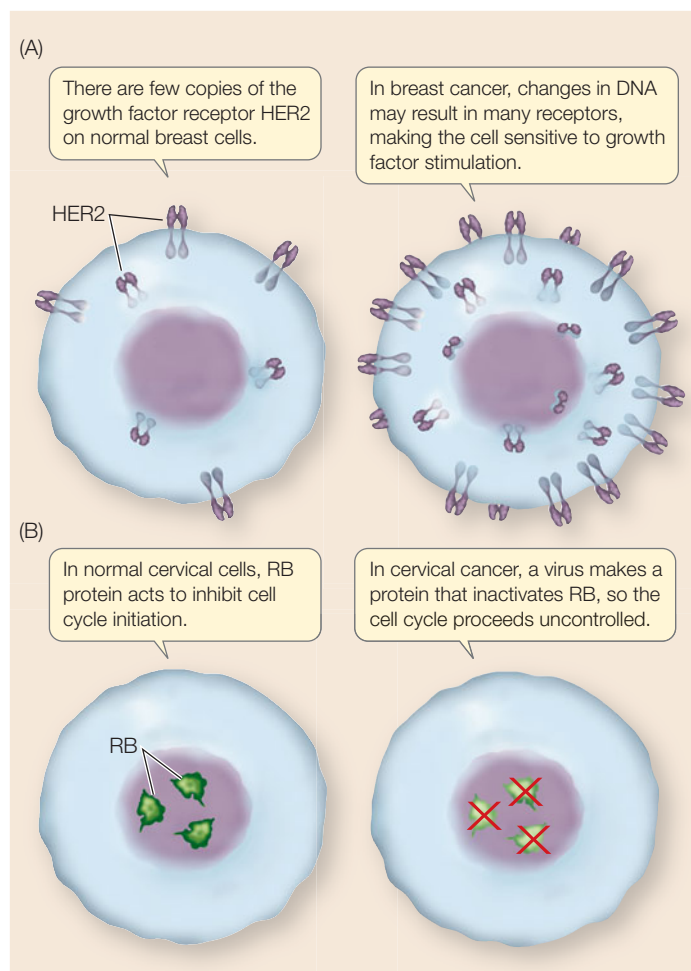

FIGURE 7.15 Molecular Changes Regulate the Cell Cycle in Cancer Cells In cancer cells, oncogene proteins become active (A) and tumor suppressor proteins become inactive (B).

produced from the translocated chromosome (Concept 7.4) that causes leukemia. The drug is rather specific and has been very successful at treating this tumor.

In this chapter we examined the cell cycle and cell division by binary fission and mitosis. We have seen how the normal cell cycle is disrupted in cancer. We also examined meiosis and the production of haploid cells in sexual life cycles. In the coming chapters we examine heredity, genes, and DNA. In Concept 8.1 we discuss Gregor Mendel's studies of heredity, and how the enormous power of his discoveries founded the science of genetics.

7

SUMMARY

concept 7.1 Different Life Cycles Use Different Modes of Cell Reproduction

- Cell division is necessary for the reproduction, growth, and repair of organisms. **Review Figure 7.1**
- **Asexual reproduction** produces clones, new organisms that are virtually identical genetically to the parent. Any genetic variation is the result of mutations.
- In **sexual reproduction**, two **haploid** gametes—one from each parent—unite in **fertilization** to form a genetically unique, **diploid zygote**. There are many different sexual life cycles that can be haplontic, diplontic, or involve **alternation of generations**. **Review Figure 7.3 and WEB ACTIVITY 7.1**
- Diploid cells contain **homologous pairs** of **chromosomes**. In sexually reproducing organisms, certain cells undergo **meiosis**, a process of cell division in which the chromosome number is halved. Each of the haploid daughter cells contains one member of each homologous pair of chromosomes.

concept 7.2 Both Binary Fission and Mitosis Produce Genetically Identical Cells

- Cell division must be initiated by a signal. Before a cell can divide, the genetic material (DNA) must undergo **replication** and **segregation** to separate portions of the cell. **Cytokinesis** then divides the cytoplasm into two cells.
- In prokaryotes, most cellular DNA is a single molecule, usually in the form of a circular chromosome. Prokaryotes reproduce by **binary fission**. **Review Figure 7.4**
- During most of the eukaryotic cell cycle, the cell is in **interphase**, which is divided into three subphases: **S**, **G1**, and **G2**. DNA is replicated during S phase. **Mitosis** (M phase) and cytokinesis follow. **Review Figure 7.5 and ANIMATED TUTORIAL 7.1**
- In mitosis, a single nucleus gives rise to two nuclei that are genetically identical to each other and to the parent nucleus.
- At mitosis, the replicated chromosomes, called **sister chromatids**, are held together at the **centromere**. Each chromatid contains one double-stranded DNA molecule. During mitosis, sister chromatids line up at the equatorial plate and attach to the spindle. **Review WEB ACTIVITY 7.2**
- Mitosis can be divided into several phases called **prophase**, **prometaphase**, **metaphase**, **anaphase**, and **telophase**. **Review Figure 7.6 and WEB ACTIVITY 7.3**

- Nuclear division is usually followed by cytokinesis. Animal cell cytoplasm divide via a contractile ring made up of actin microfilaments. In plant cells, cytokinesis is accomplished by vesicles that fuse to form a cell plate. **Review Figure 7.7**

concept 7.3 Cell Reproduction Is Under Precise Control

- Interactions between **cyclins** and **Cdk's** regulate the passage of cells through checkpoints in the cell cycle. External controls such as **growth factors** can stimulate the cell to begin a division cycle. **Review Figure 7.10**

concept 7.4 Meiosis Halves the Nuclear Chromosome Content and Generates Diversity

- Meiosis consists of two nuclear divisions, **meiosis I** and **meiosis II**, which collectively reduce the chromosome number from diploid to haploid. Meiosis results in four genetically diverse haploid cells, often gametes. **Review ANIMATED TUTORIAL 7.2**
- In meiosis I, entire chromosomes, each with two chromatids, migrate to the poles. In meiosis II, the sister chromatids separate. **Review Figures 7.11 and 7.12 and WEB ACTIVITY 7.4**
- During prophase I, homologous chromosomes undergo synapsis to form pairs in a **tetrad**. Chromatids can form junctions called chiasmata, and genetic material may be exchanged between the two homologs by **crossing over**. **Review Figure 7.13**
- Both crossing over during prophase I and **independent assortment** of the homologs as they separate during anaphase I ensure that gametes are genetically diverse.
- Meiotic errors can result in abnormal numbers of chromosomes in the resulting gametes and offspring.

concept 7.5 Programmed Cell Death Is a Necessary Process in Living Organisms

- A cell may die by **necrosis**, or it may self-destruct by **apoptosis**, a genetically programmed series of events that includes the fragmentation of its nuclear DNA.
- Apoptosis is regulated by external and internal signals. These signals result in activation of a class of enzymes called **caspases** that hydrolyze proteins in the cell. **Review Figure 7.14**

Inheritance, Genes, and Chromosomes

8

In the Middle Eastern desert 1,800 years ago, a rabbi faced a dilemma. A Jewish woman had given birth to a son. As required by ancient Jewish custom, the mother brought her 8-day-old son to the rabbi for ritual penile circumcision. The rabbi knew that the woman's two previous sons had bled to death when their foreskins were cut. Yet the biblical requirement remained: unless he was circumcised, the boy could not be counted among those with whom their God had made a solemn covenant. After consultation with other rabbis, it was decided to exempt this third son.

Almost 1,000 years later, in the twelfth century, the physician and biblical commentator Moses Maimonides reviewed this and other cases in the rabbinical literature and stated that in such instances the third son should not be circumcised. Furthermore, the exemption should apply whether the mother's son was "from her first husband or from her second husband." The bleeding disorder, he reasoned, was clearly carried by the mother and passed on to her sons. In all cases, the parents did not show any evidence of having the disease.

Without any knowledge of our modern concepts of genes and genetics, the rabbis had linked a human disease with a *pattern of inheritance*. We now have a name for the disease, hemophilia A, which affects about 18,000 people in the United States—mostly males. The bleeding disorder is due to the absence of a specific protein called factor VIII, which is important in the formation of blood clots. When a person without hemophilia gets cut there is usually some bleeding, but then a clot forms to prevent further bleeding. In the case of hemophilia, the bleeding can continue until the person dies. Indeed, well into the twentieth century

the slightest accident could be lethal in such a person. Internal bleeding is also an extremely serious problem for people with this disease, and permanent joint damage due to bleeding in the joints is a common problem for untreated patients.

Treatment of hemophilia A by injection of factor VIII into the bloodstream is now possible, because factor VIII can be isolated from donated blood or made in the laboratory using biotechnology. An issue has been whether people with hemophilia A should be injected with factor VIII all the time as a preventive measure (an expensive proposition) or just take it as needed. Based on reductions in joint damage in children treated by the preventive approach, recent studies have concluded that this approach is best.

A male infant undergoes ritual circumcision in accordance with Jewish laws. Sons of Jewish mothers who carry the gene for hemophilia may be exempted from this ritual.

How is hemophilia inherited through the mother, and why is it more frequent in males?

KEY CONCEPTS

- 8.1** Genes Are Particulate and Are Inherited According to Mendel's Laws
- 8.2** Alleles and Genes Interact to Produce Phenotypes
- 8.3** Genes Are Carried on Chromosomes
- 8.4** Prokaryotes Can Exchange Genetic Material

concept 8.1 Genes Are Particulate and Are Inherited According to Mendel's Laws

Genetics, the field of biology concerned with inheritance, has a long history. There is good evidence that people were deliberately breeding animals (horses) and plants (the date palm tree) for desirable characteristics as long as 5,000 years ago. The general idea was to examine the natural variation among the individuals of a species and “breed the best to the best and hope for the best.” This was a hit-or-miss method—sometimes the resulting offspring had all the good characteristics of the parents, but often they did not.

By the mid-nineteenth century, two theories had emerged to explain the results of breeding experiments:

- The theory of *blending inheritance* proposed that gametes contained hereditary determinants (what we now call genes) that blended when the gametes fused during fertilization. Like inks of different colors, the two different determinants lost their individuality after blending and could never be separated. For example, if a plant that made smooth, spherical seeds was mated (crossed) with a plant that made wrinkled seeds, the offspring would be intermediate between the two and the determinants for the two parental characteristics would be lost.
- The theory of *particulate inheritance* proposed that each determinant had a physically distinct nature; when gametes fused in fertilization, the determinants remained intact. According to this theory, if a plant that made spherical seeds was crossed with a plant that made wrinkled seeds, the offspring (no matter the shape of their seeds) would still contain the determinants for the two characteristics.

The story of how these competing theories were tested provides a great example of how the *scientific method* can be used to support one theory and reject another. In the following sections we will look in detail at experiments performed in the 1860s by an Austrian monk–scientist, Gregor Mendel, whose work clearly supported the particulate theory.

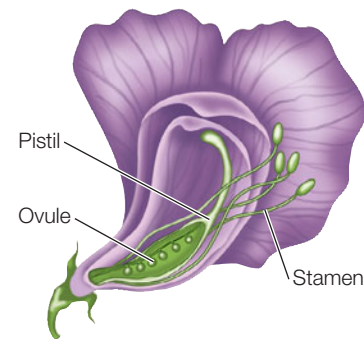

Mendel used the scientific method to test his hypotheses

After entering the priesthood at a monastery in Brno, in what is now the Czech Republic, Gregor Mendel was sent to the University of Vienna, where he studied biology, physics, and mathematics. He returned to the monastery in 1853 to teach. The abbot in charge had set up a small plot of land to do experiments with plants and encouraged Mendel to continue with them. Over seven years, Mendel made crosses with many thousands of plants. Analysis of his meticulously gathered data suggested to him that inheritance was due to particulate factors.

Mendel presented his theories in a public lecture in 1865 and a detailed written publication in 1866, but his work was ignored by mainstream scientists until 1900. By that time, the discovery of chromosomes had suggested to biologists that genes might be carried on chromosomes. When they read Mendel's

work on particulate inheritance, the biologists connected the dots between genes and chromosomes.

Mendel chose to study the common garden pea because of its ease of cultivation and the feasibility of making controlled crosses. Pea flowers have both male and female sex organs: stamens and pistils, which produce gametes contained within the pollen tubes and ovules, respectively:

Pea flowers normally self-fertilize. However, the male organs can be removed from a flower so that it can be manually fertilized with pollen from a different flower.

There are many varieties of pea plants with easily recognizable characteristics. A **character** is an observable physical feature, such as seed shape. A **trait** is a particular form of a character, such as spherical or wrinkled seeds. Mendel worked with seven pairs of varieties with contrasting traits for characters such as seed shape, seed color, and flower color. These varieties were *true-breeding*: that is, when he crossed a plant that produced wrinkled seeds with another of the same variety, all of the offspring plants produced wrinkled seeds.

Mendel performed his crosses in the following manner:

- He removed the stamens from (emasculated) flowers of one parental variety so that it couldn't self-fertilize. Then he collected pollen from another parental variety and placed it on the pistils of the emasculated flowers. The plants providing and receiving the pollen were the **parental generation**, designated **P**.
- In due course, seeds formed and were planted. The seeds and the resulting new plants constituted the **first filial generation**, or **F₁**. (The word “filial” refers to the relationship between offspring and parents, from the Latin *filius*, “son.”) Mendel examined each F₁ plant to see which traits it bore and then recorded the number of F₁ plants expressing each trait.
- In some experiments the F₁ plants were allowed to self-pollinate and produce a **second filial generation**, the **F₂**. Again, each F₂ plant was characterized and counted.

Mendel's first experiments involved monohybrid crosses

The term *hybrid* refers to the offspring of crosses between organisms differing in one or more characters. In Mendel's first experiments, he crossed parental (P) varieties with contrasting traits for a single character, producing monohybrids (from the Greek *monos*, “single”) in the F₁ generation. He subsequently planted the F₁ seeds and allowed the resulting plants

to self-pollinate to produce the F_2 generation. This technique is referred to as a **monohybrid cross**.

Mendel performed the same experiment for seven pea characters. His method is illustrated in **FIGURE 8.1**, using seed shape as an example. When he crossed a strain that made spherical seeds with one that made wrinkled seeds, the F_1 seeds were spherical—it was as if the wrinkled seed trait had disappeared completely. However, when F_1 plants were allowed to self-pollinate to produce F_2 seeds, about one-fourth of the seeds were wrinkled. These observations were key to distinguishing the two theories noted above:

- The F_1 offspring were not a blend of the two traits of the parents. Only one of the traits was present (in this case, spherical seeds).
- Some F_2 offspring had wrinkled seeds. The trait had not disappeared.

These observations led to a rejection of the blending theory of inheritance and provided support for the particulate theory. We now know that hereditary determinants are not actually “particulate,” but they are physically distinct entities: sequences of DNA carried on chromosomes (see Concept 8.3).

All seven crosses between varieties with contrasting traits gave the same kind of data (see Figure 8.1). In the F_1 generation only one of the two traits was seen, but the other one reappeared in about one-fourth of the offspring in the F_2 generation. Mendel called the trait that appeared in the F_1 and was more abundant in the F_2 the **dominant** trait, and the other trait **recessive**.

Mendel went on to expand on the particulate theory. He proposed that hereditary determinants—we will call them *genes* here, though Mendel did not use that term—occur in pairs and segregate (separate) from one another during the formation of gametes. He concluded that each pea plant has two genes for each character (such as seed shape), one inherited from each parent. We now use the term *diploid* to describe the state of having two copies of each gene; *haploids* have just a single copy.

LINK The characteristics of haploid and diploid organisms are discussed in Concept 7.1

Mendel concluded that while each gamete contains one copy of each gene, the resulting zygote contains two copies, because it is produced by the fusion of two gametes. Furthermore, different traits arise from different forms of a gene (now called **alleles**) for a particular character. For example, Mendel studied two alleles for seed shape: one that caused smooth seeds and the other causing wrinkled seeds.

An organism that is **homozygous** for a gene has two alleles that are the same (for example, two copies of the allele for spherical seeds). An organism that is **heterozygous** for a gene has two different alleles (for example, one allele for spherical seeds and one allele for wrinkled seeds). In a heterozygote, one of the two alleles may be dominant (such as spherical, *S*) and the other recessive (wrinkled, *s*). By conven-

INVESTIGATION

FIGURE 8.1 Mendel's Monohybrid Experiments

Mendel performed crosses with pea plants and carefully analyzed the outcomes to show that genetic determinants are particulate.

Characteristic	Dominant	Recessive
Seed shape	5474 spherical	1850 wrinkled
Seed color	6022 yellow	2001 green
Flower color	705 purple	224 white
Pod color	428 green	152 yellow
Stem height	787 tall	277 short

- Calculate the phenotypic ratio of dominant:recessive in the F_2 offspring.
- What can you conclude about the behavior of alleles during gamete formation in a plant that is heterozygous for a trait?
- Perform a chi square analysis to evaluate the statistical significance of these data (refer to Appendix B).

tion, dominant alleles are designated with uppercase letters and recessive alleles with lowercase letters.

The physical appearance of an organism is its **phenotype**. Mendel proposed that the phenotype is the result of the **genotype**, or genetic constitution, of the organism showing the phenotype. Spherical seeds and wrinkled seeds are two phenotypes resulting from three possible genotypes: the wrinkled seed phenotype is produced by the genotype ss , whereas the spherical seed phenotype is produced by either of the genotypes SS or Ss (because the S allele is dominant to the s allele).

Mendel's first law states that the two copies of a gene segregate

How do Mendel's theories explain the proportions of traits seen in the F_1 and F_2 generations of his monohybrid crosses? Mendel's first law—the **law of segregation**—states that *when any individual produces gametes, the two copies of a gene separate, so that each gamete receives only one copy*. Thus, gametes from a parent with the SS genotype will all be S ; gametes from an ss parent will all be s ; and the progeny derived from a cross between these parents will all be Ss , producing seeds with a smooth phenotype (FIGURE 8.2).

Now let's consider the composition of the F_2 generation. Because the alleles segregate, half of the gametes produced by the F_1 generation will have the S allele and the other half will have the s allele. What genotypes are produced when these gametes fuse to form the next (F_2) generation?

The allele combinations that will result from a cross can be predicted using a **Punnett square**, a method devised in 1905 by the British geneticist Reginald Punnett. This device ensures that we consider all possible combinations of gametes when calculating expected genotype frequencies. A Punnett square looks like this:

	Male gametes	
	S	s
Female gametes	S	
	s	

It is a simple grid with all possible male gamete (haploid sperm) genotypes shown along the top and all possible female gamete (haploid egg) genotypes along the left side. The grid is completed by filling in each square with the diploid genotype that can be generated from each combination of gametes. In this example, to fill in the top right square, we put in the S from the female gamete (the egg cell) and the s from the male gamete (the sperm cell in the pollen tube), yielding Ss .

Once the Punnett square is filled in, we can readily see that there are four possible combinations of alleles in the F_2 generation: SS , Ss , sS , and ss (see Figure 8.2). Since S is dominant, there are three ways to get spherical-seeded plants in the F_2 generation (SS , Ss , or sS), but only one way to get a plant with wrinkled seeds (ss). Therefore, we predict a 3:1 ratio of these phenotypes in the F_2 generation, remarkably close to the values Mendel found experimentally for all seven of the traits he compared.

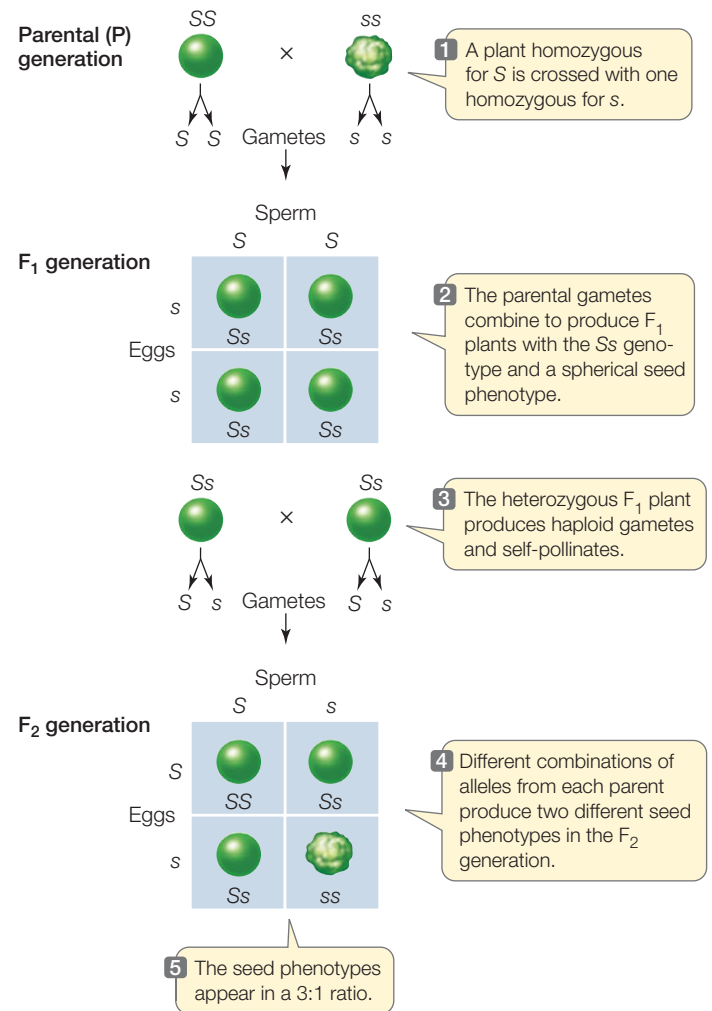

FIGURE 8.2 Mendel's Explanation of Inheritance Mendel concluded that inheritance depends on discrete factors from each parent that do not blend in the offspring.

Mendel did not live to see his theories placed on a sound physical footing with the discoveries of chromosomes and DNA. Genes are now known to be relatively short sequences of DNA (usually one to a few thousand base pairs in length) found on the much longer DNA molecules that make up chromosomes (which are often millions of base pairs long). Today we can picture the different alleles of a gene segregating as chromosomes separate during meiosis I (FIGURE 8.3).

LINK The process of meiosis is described in Concept 7.4

Genes determine phenotypes mostly by producing proteins with particular functions, such as enzymes. So in many cases a dominant gene is expressed (transcribed and translated) to produce a functional protein, while a recessive gene is mutated so that it is no longer expressed, or it encodes a mutant protein that is nonfunctional. For example, the molecular nature of the wrinkled pea seed phenotype is the absence of the enzyme $SBE1$, which is essential for starch synthesis. With less starch, the developing seed has more sucrose and this causes an inflow

FIGURE 8.3 Meiosis Accounts for the Segregation of Alleles Although Mendel had no knowledge of chromosomes or meiosis, we now know that a pair of alleles resides on homologous chromosomes, and that those alleles segregate during meiosis.

the spherical phenotype. Mendel verified this hypothesis by performing test crosses with F_1 seeds derived from a variety of other crosses. A **test cross** is used to determine whether an individual showing a dominant trait is homozygous or heterozygous. The individual in question is crossed with an individual that is homozygous for the recessive trait—an easy individual to identify, because all individuals with the recessive phenotype are homozygous for that trait.

The recessive homozygote for the seed shape gene has wrinkled seeds and the genotype ss . The individual being tested may be described initially as S_* because we do not yet know the identity of the second allele. We can predict two possible results:

- If the individual being tested is homozygous dominant (SS), all offspring of the test cross will be Ss and show the dominant trait (spherical seeds) (**FIGURE 8.4, LEFT**).
- If the individual being tested is heterozygous (Ss), then approximately half of the offspring of the test cross will be heterozygous and show the dominant trait (Ss), and the other half will be homozygous for the recessive trait (ss) (**FIGURE 8.4, RIGHT**).

Mendel obtained results consistent with both of these predictions; thus his hypothesis accurately predicted the results of his test crosses.

Mendel's second law states that copies of different genes assort independently

Consider an organism that is heterozygous for two genes ($SsYy$). In this example, the dominant S and Y alleles came from one true-breeding parent, and the recessive s and y alleles came from the other true-breeding parent. When this organism produces gametes, do the S and Y alleles always go together in one gamete, and s and y alleles in another? Or can a single gamete receive one recessive and one dominant allele (S and y or s and Y)?

Mendel performed another series of experiments to answer these questions. He began with peas that differed in *two* characters: seed shape and seed color. One parental variety produced only spherical, yellow seeds ($SSYY$), and the other produced only wrinkled, green ones ($ssyy$). A cross between these two varieties produced an F_1 generation in which all the plants were $SsYy$. Because the S and Y alleles were dominant, the F_1 seeds were all spherical and yellow.

Mendel continued this experiment into the F_2 generation by performing a **dihybrid cross**—a cross between individuals that are identical *double heterozygotes*. In this case, he simply allowed the F_1 plants, which were all double heterozygotes, to self-pollinate (**FIGURE 8.5**). Depending on whether the alleles

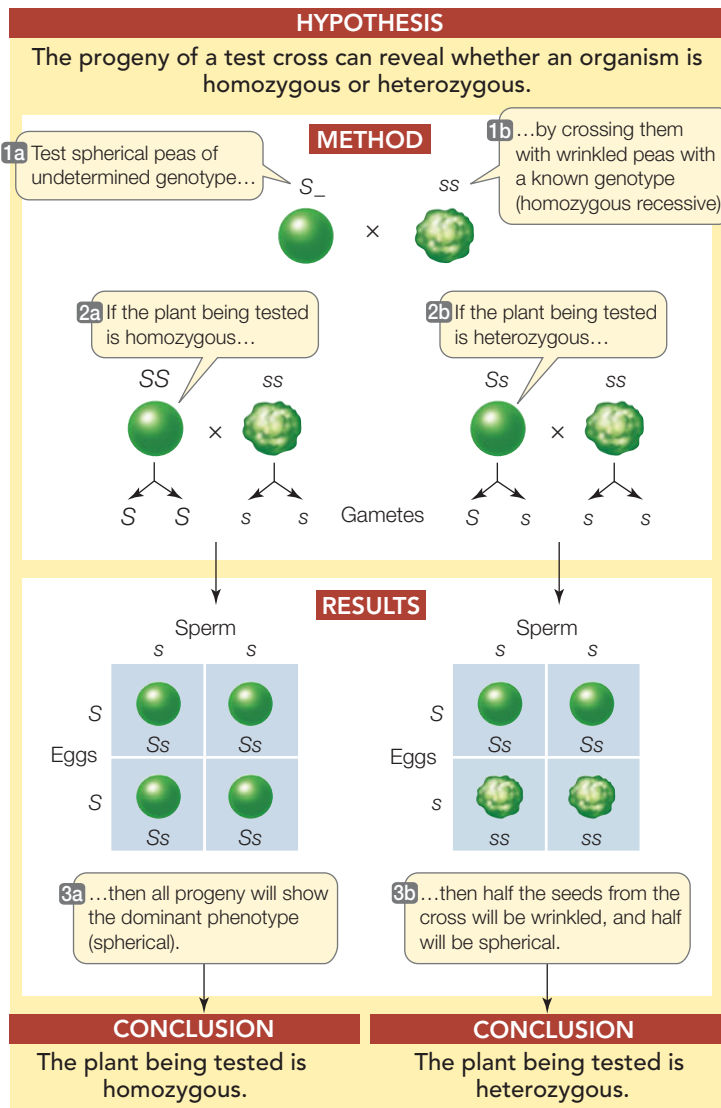

of water by osmosis. When the seed matures and dries out, this water is lost, leaving a shrunken seed.

Mendel verified his hypotheses by performing test crosses

As mentioned above, Mendel arrived at his laws of inheritance by developing a series of hypotheses and then designing experiments to test them. One such hypothesis was that there are two possible allele combinations (SS or Ss) for seeds with

INVESTIGATION

FIGURE 8.4 Homozygous or Heterozygous? An individual with a dominant phenotype may have either a homozygous or a heterozygous genotype. The test cross determines which.

ANALYZE THE DATA

A tall plant was crossed with a short plant to produce three F_1 plants (A, B, and C). Each of the F_1 plants was test crossed with these results:

F_1	Tall progeny	Short progeny
A	34	0
B	18	15
C	21	0

- For each test cross, what were the genotypes and phenotypes of both parents?
- Choose and perform a statistical test from Appendix B to evaluate the significance of these data.

yourBioPortal.com

Go to WEB ACTIVITY 8.1
Homozygous or Heterozygous?

of the two genes are inherited together or separately, there are two possible outcomes, as Mendel saw:

- The alleles could maintain the associations they had in the parental generation—they could be linked. If this were the case, the F_1 plants would produce two types of gametes (SY and sy). The F_2 progeny resulting from self-pollination of these F_1 plants would consist of two phenotypes: spherical yellow and wrinkled green in the ratio of 3:1, just as in the monohybrid cross.
- The segregation of S from s could be independent of the segregation of Y from y —the two genes could be unlinked. In this case, four kinds of gametes would be produced in equal numbers: SY , Sy , sY , and sy . When these gametes combine at random, they should produce an F_2 having nine different genotypes. The nine genotypes would produce four phenotypes (spherical yellow, spherical green, wrinkled yellow, wrinkled green). Putting these possibilities into a Punnett square, we can predict that these four phenotypes would occur in a ratio of 9:3:3:1.

FIGURE 8.5 Independent Assortment The 16 possible combinations of gametes in this dihybrid cross result in nine different genotypes. Because S and Y are dominant over s and y , respectively, the nine genotypes result in four phenotypes in a ratio of 9:3:3:1. These results show that the two genes segregate independently.

Mendel's dihybrid crosses supported the second prediction: four different phenotypes appeared in the F_2 generation in a ratio of about 9:3:3:1 (see Figure 8.5). On the basis of such experiments, Mendel proposed his second law—the **law of independent assortment**: *alleles of different genes assort independently of one another during gamete formation*. In the example above, the segregation of the S and s alleles is independent of the segregation of the Y and y alleles. As you will see in Concept 8.3, this is not as universal as the law of segregation because it does not apply to genes located near one another on the same chromosome. However, it is correct to say that *chromosomes segregate independently during the formation of gametes*, and so do any two genes located on separate chromosome pairs (FIGURE 8.6).

Probability is used to predict inheritance

One of Mendel's major contributions to the science of genetics was his use of a quantitative approach and probability to analyze the large amounts of data he gathered. His mathematical analyses revealed clear patterns that allowed him to formulate his theories. Ever since his work became widely recognized, geneticists have used simple mathematics in the same ways

that Mendel did. Geneticists use probabilities to predict the ratios of genotypes and phenotypes in the progeny of a given cross or mating. They use statistics to determine whether the actual results match the prediction.

You can think of probabilities by considering a coin toss. For any given toss of a fair coin, the probability of heads is independent of what happened in all the previous tosses. The basic conventions of probability are simple:

- If an event is absolutely certain to happen, its probability is 1.
- If it cannot possibly happen, its probability is 0.
- All other events have a probability between 0 and 1.

A coin toss results in heads approximately half the time, so the probability of heads is $\frac{1}{2}$ —as is the probability of tails.

If two coins (say a penny and a dime) are tossed, each acts independently of the other. What is the probability of both coins coming up heads? In half of the tosses, the penny comes up heads; the dime also comes up heads half of the time. Therefore, the *joint probability* of both coins coming up heads is half of one-half, or $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. So, to find the joint probability of independent events, we multiply the probabilities of the individual events (FIGURE 8.7).

Probability applies to a monohybrid cross (see Figure 8.2) in the same way. After the self-pollination of an Ss F_1 plant, the probability that an F_2 plant will have the genotype SS is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$, because the chance that the sperm will have the genotype S is $\frac{1}{2}$, and the chance that the egg will have the genotype S is also $\frac{1}{2}$. Similarly, the probability of ss offspring is also $\frac{1}{4}$.

You will note in Figures 8.2 and 8.7 that there are *two ways* to get an Ss plant or a head and a tail in a coin toss. In the case of the seed shape gene, the S allele can come from a sperm and the s from an egg (probability $\frac{1}{4}$). Or the S allele could come from the egg and the s from the sperm (probability $\frac{1}{4}$). *The probability of an event that can occur in two or more different ways is the sum of the individual probabilities of those ways*. Thus the probability that an F_2 plant will be a heterozygote is equal to the sum of the probabilities of the two ways of forming a heterozygote: $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$.

FIGURE 8.6 Meiosis Accounts for Independent Assortment of Alleles We now know that copies of genes on different chromosomes are segregated independently during metaphase I of meiosis. Thus a parent of genotype $SsYy$ can form gametes with four different genotypes.

Independent Assortment of Alleles

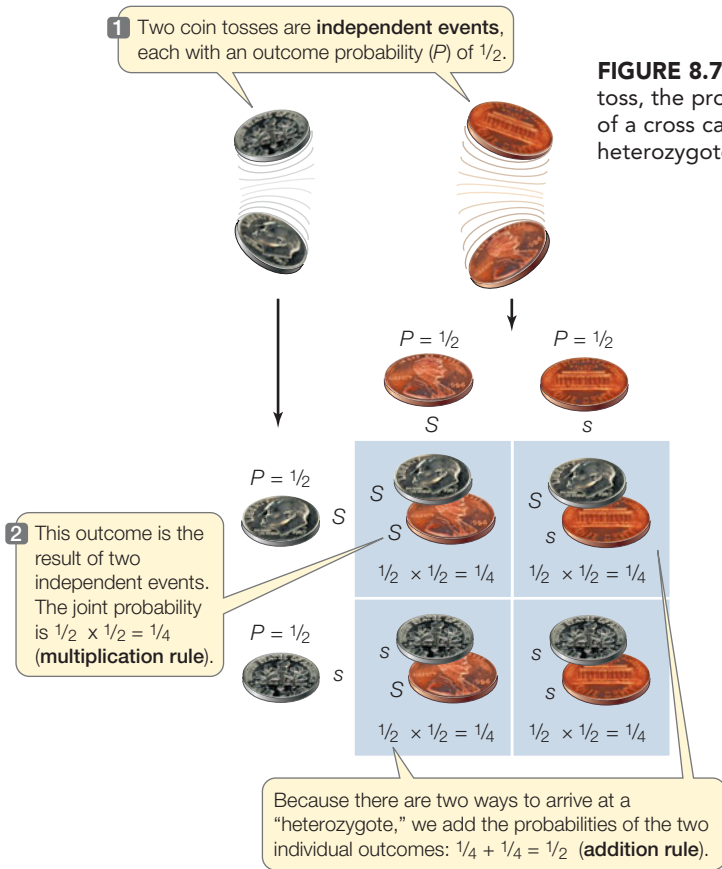

FIGURE 8.7 Using Probability Calculations in Genetics Like the results of a coin toss, the probability of any given combination of alleles appearing in the offspring of a cross can be obtained by multiplying the probabilities of each event. Since a heterozygote can be formed in two ways, these two probabilities are added together.

Mendel's laws can be observed in human pedigrees

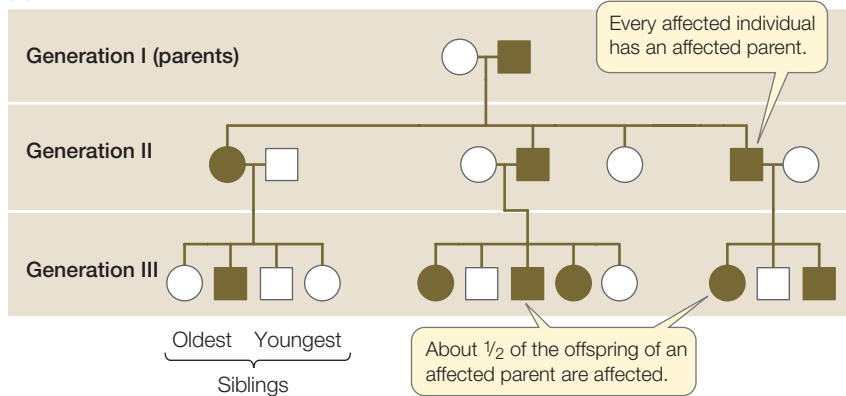

Mendel developed his theories by performing many planned crosses and counting many offspring. This approach is not possible with humans, so human geneticists rely on **pedigrees**: family trees that show the occurrence of inherited phenotypes in several generations of related individuals (**FIGURE 8.8**).

Because humans have relatively few offspring, human pedigrees do not show the clear proportions of phenotypes that Mendel saw in his pea plants. For example, when a man and a woman who are both heterozygous for a recessive allele (say, *Aa*) have children together, each child has a 25 percent probability of being a recessive homozygote (*aa*). But the offspring of a single couple are likely to be too few to reliably show the one-fourth proportion. In a family with only two children, for example, both could easily be *aa* (or *Aa*, or *AA*).

Despite this limitation, pedigrees do show inheritance patterns that can provide information about the allele(s)

Pedigree Analysis

(A) Dominant inheritance

(B) Recessive inheritance

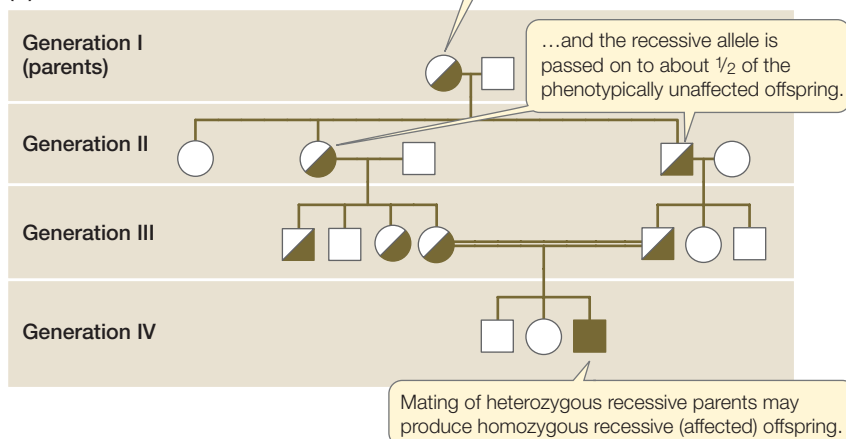

FIGURE 8.8 Pedigree Analysis and Inheritance (A) This pedigree represents a family affected by Huntington's disease, which results from a rare dominant allele. Everyone who inherits this allele is potentially affected. (B) The family in this pedigree carries the allele for albinism, a recessive trait. Because the trait is recessive, heterozygotes do not have the albino phenotype, but they can pass the allele on to their offspring. Affected persons must inherit the allele from two heterozygous parents, or (rarely) from one homozygous recessive and one heterozygous parent, or (very rarely) two homozygous recessive parents. In this family, the heterozygous parents in generation III are cousins; however, the same result would occur if the parents were unrelated.

controlling a particular phenotype. For example, it is useful to know whether a particular rare allele that causes an abnormal phenotype is dominant or recessive. Figure 8.8A is a pedigree showing the pattern of inheritance of a rare *dominant* allele. The following are the key features to look for in such a pedigree:

- Every person with the abnormal phenotype (affected) has an affected parent.
- Either all (in the case of a homozygous parent) or about half (in the case of a heterozygous parent) of the offspring in an affected family are affected.

Compare this pattern with the one shown in Figure 8.8B, which is typical for the inheritance of a rare *recessive* allele:

- Affected people often have two parents who are not affected.
- In affected families, about one-fourth of the children of unaffected parents are affected.

Other patterns of inheritance can arise in special cases, such as sex-linked characters (see Concept 8.3).

Do You Understand Concept 8.1?

- What are the differences between genes and alleles? Between homozygous and heterozygous conditions? Between genotype and phenotype? Between Mendel's definition of a gene and the current definition?
- In a monohybrid cross, how do the events of meiosis explain Mendel's first law? In a dihybrid cross, how does meiosis explain Mendel's second law?
- Using the cross shown in Figure 8.5, calculate the probability that an F_2 seed will be spherical and yellow.

The laws of inheritance as articulated by Mendel remain valid today, and his discoveries laid the groundwork for all future studies of genetics. However, as we will see in the next concept, the relationship of one gene to one phenotype turns out to be complicated by interactions between alleles and between genes.

concept 8.2 Alleles and Genes Interact to Produce Phenotypes

Phenotypes do not always follow the simple patterns of inheritance shown by the pairs of alleles for seed color and seed shape in peas, described in Concept 8.1. Existing alleles are subject to change by mutation and can give rise to new alleles—in fact, a single gene can have many alleles. In addition, alleles do not always show simple dominant–recessive relationships. A single allele may have multiple phenotypic effects, and a single character may be controlled by multiple genes. The expression of a gene is generally affected by interactions with other genes and with the environment.

New alleles arise by mutation

Genes are subject to **mutations**, which are rare, stable, and inherited changes in the genetic material. In other words, an allele can mutate (change) to become a different allele. For example, we can envision that at one time all pea plants made spherical seeds and had the seed shape allele S . At some point a mutation in S resulted in a new allele, s (wrinkled). If this mutation occurred in a cell that underwent meiosis, some of the resulting gametes would carry the s allele, and some offspring of this pea plant would carry the s allele in all of their cells. By producing phenotypic variety, mutations are the raw material for evolution. A new allele may become more or less prevalent in a population, depending on its effect on the fitness of the individuals carrying it (see Concept 15.3).

Geneticists usually define one particular allele of a gene as the **wild type**; this is the allele that is present in most individuals in nature (“the wild”). Other alleles of that gene are usually called mutant alleles, and they may produce different phenotypes. The wild-type and mutant alleles are inherited according to Mendelian laws. A gene with a wild-type allele that is present less than 99 percent of the time (the rest of the alleles being mutant) is said to be **polymorphic** (Greek *poly*, “many”; *morph*, “form”).

Mendel developed his theories by studying just two alleles of each gene. But often a gene has *multiple alleles*, and the alleles may

Possible genotypes	CC, Cc^{chd}, Cc^h, Cc	$c^{chd}c^{chd}, c^{chd}C$	c^hc^h, c^hC	cc
Phenotype	Dark gray	Chinchilla	Point restricted	Albino

FIGURE 8.9 Multiple Alleles for Coat Color in Rabbits These photographs show the phenotypes conferred by four alleles of the C gene for coat color in rabbits. Different combinations of two alleles give different coat colors and pigment distributions.

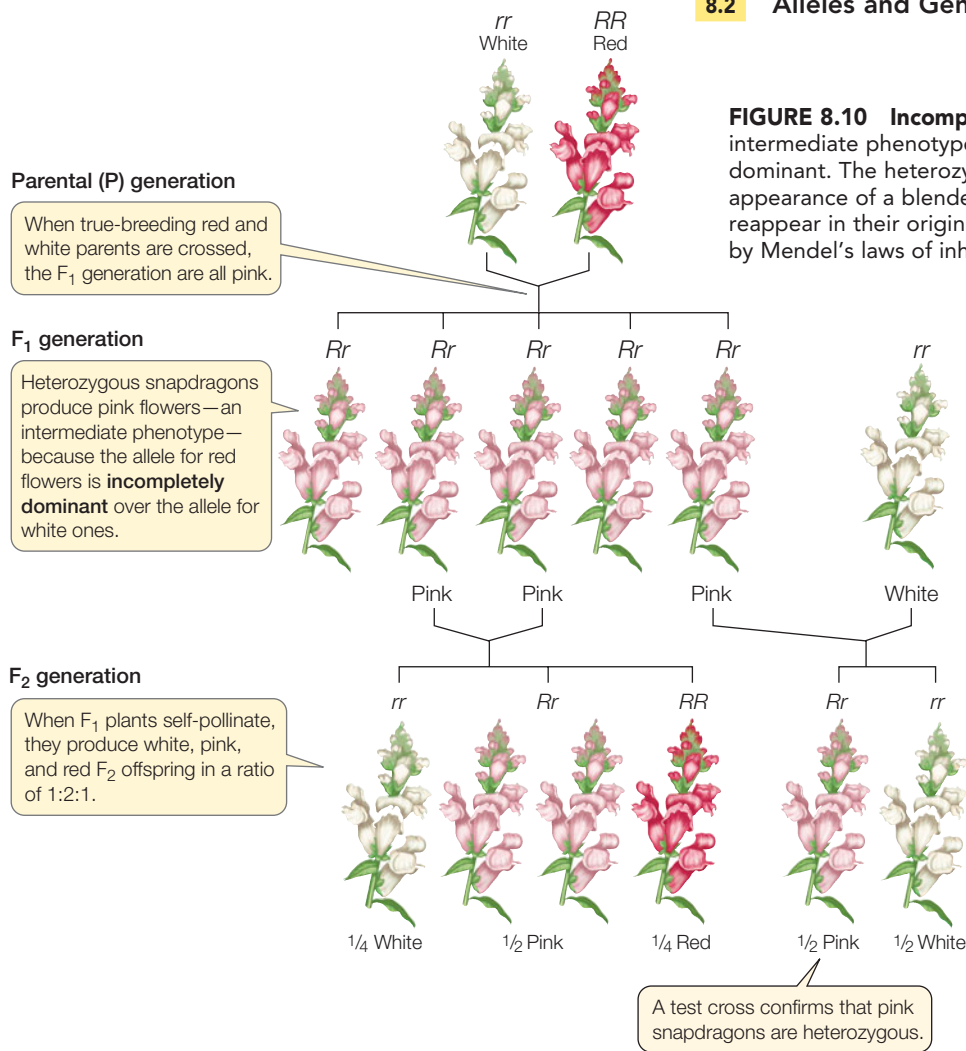

FIGURE 8.10 Incomplete Dominance Follows Mendel's Laws An intermediate phenotype can occur in heterozygotes when neither allele is dominant. The heterozygous phenotype (here, pink flowers) may give the appearance of a blended trait, but the traits of the parental generation reappear in their original forms in succeeding generations, as predicted by Mendel's laws of inheritance.

with any of the four) is dark gray. The c^{chd} and c^h alleles encode enzymes with specific defects. Both are dominant over the c allele, giving either light gray (c^{chd}) or point restricted (c^h) phenotypes. The homozygous recessive, cc , is albino because there is no tyrosinase for pigment production.

Dominance is not always complete

Many genes have alleles that are neither dominant nor recessive to one another. Instead, the heterozygotes have an *intermediate phenotype* in a situation called **incomplete dominance**. For example, if a true-breeding red snapdragon is crossed with a white one, all the F₁ flowers are an intermediate pink. Such cases appear to support the old blending theory of inheritance. However, further crosses indicate that this apparent blending can still be explained in terms of Mendelian genetics (**FIGURE 8.10**). The red and white snapdragon alleles have not disappeared, as those colors reappear in the F₂ generation.

show a hierarchy of dominance when present in heterozygous individuals. An example is coat color in rabbits (**FIGURE 8.9**):

- C determines dark gray
- c^{chd} determines chinchilla, a lighter gray
- c^h determines Himalayan, where pigment is restricted to the extremities (point restricted)
- c determines albino, no pigment

The C gene encodes the enzyme tyrosinase, which is involved in pigment production. Any rabbit with the C allele (paired

Sometimes two alleles of a gene both produce their phenotypes when present in a heterozygote—a phenomenon called **codominance**. For example, in humans the gene I encodes an enzyme involved in attachment of sugars to a glycoprotein on the surface of red blood cells. There are three alleles of the gene: I^A , I^B , and I^O . The I^A and I^B alleles both encode active enzymes, but the enzymes attach different sugars to the glycoprotein; the I^O allele does not encode an active enzyme, so no sugar is attached at that position on the glycoprotein. When two different alleles (e.g., I^A and I^B) are present, both alleles are expressed (both enzymes are made, so both types of glycoproteins are made). The A and B glycoproteins are antigenic: if a red blood cell with the

A glycoprotein on its surface gets into the bloodstream of a person who lacks the I^A allele, the recipient mounts an immune response and produces antibodies against the “nonself” cells (**FIGURE 8.11**). While the A and B glycoproteins are antigenic in people who do not have the I^A or I^B alleles, respectively, the O glycoprotein

Blood type of cells	Genotype	Blood cell types that body rejects	Reaction to added antibodies	
			Anti-A	Anti-B
A	$I^A I^A$ or $I^A I^O$	B		
B	$I^B I^B$ or $I^B I^O$	A		
AB	$I^A I^B$	Neither A nor B		
O	$I^O I^O$	A, B, and AB		

Red blood cells that do not react with antibody remain evenly dispersed.

Red blood cells that react with antibody clump together (speckled appearance).

FIGURE 8.11 ABO Blood Reactions Are Important in Transfusions This table shows the results of mixing red blood cells of types A, B, AB, and O with serum containing anti-A or anti-B antibodies. As you look down the columns, note that each of the types, when mixed separately with anti-A and with anti-B, gives a unique pair of results—this is the basic method by which blood is typed.

APPLY THE CONCEPT

Alleles and genes interact to produce phenotypes

1. In the genetic cross $AaBbCcDdEE \times AaBBCcDdEe$ where all the genes are unlinked, what fraction of the offspring will be heterozygous for all of these genes?
2. In a plant species, two alleles control flower color, which can be yellow, blue, or white. Crosses of these plants produce these offspring:

PARENTAL PHENOTYPES	OFFSPRING PHENOTYPES (RATIO)
Yellow \times yellow	All yellow
Blue \times yellow	Blue or yellow (1:1)
Blue \times white	Blue or white (1:1)
White \times white	All white

What will be the phenotypes of the offspring and the ratios among them from a cross of blue \times blue?

3. In chickens, when the dominant alleles of the genes for rose comb (R) and pea comb (A) are present together, the bird has a walnut comb. Birds that are homozygous recessive for both genes have a single comb. A rose-combed bird mated with a walnut-combed bird, and the offspring were:

$3/8$ walnut : $3/8$ rose : $1/8$ pea : $1/8$ single

What were the genotypes of the parents?

does not provoke an immune response. This makes people who are $I^{O}I^O$ good blood donors in transfusions. See Chapter 31 for more about the immune system.

Genes interact when they are expressed

Epistasis occurs when the phenotypic expression of one gene is affected by another gene. For example, two genes (B and E) determine coat color in Labrador retrievers:

- Allele B (black pigment) is dominant to b (brown).
- Allele E (pigment deposition in hair) is dominant to e (no deposition, so hair is yellow).

An EE or Ee dog with BB or Bb is black; one with bb is brown. A dog with ee is yellow regardless of the Bb alleles present. Clearly, gene E determines the phenotypic expression of gene B , and is therefore *epistatic* to B (FIGURE 8.12).

Perhaps the most dramatic example of interacting genes is **hybrid vigor** (or *heterosis*). In 1876, Charles Darwin reported that when he crossed two different genetic varieties of corn, the offspring were 25 percent taller than either of the parent strains. Darwin's observation was largely ignored for the next 30 years. In 1908, George Shull "rediscovered" this idea, reporting that not just plant height but the weight of the corn grain produced was dramatically higher in the offspring:

Parent: $B73$

Hybrid

Parent: $Mo17$

Agricultural scientists took note, and Shull's paper had a lasting impact on the field of applied genetics. The cultivation of hybrid corn spread rapidly, and the practice of hybridization is now used for many other agricultural crops and animals. For example, beef cattle that are crossbred are larger and live longer than cattle bred within their own genetic strains.

What determines the "vigor" in hybrid vigor? A phenotype such as the amount of grain that a variety of corn produces in a given environment is determined by many genes and their alleles. Presumably, the combinations of different alleles and their products from two different varieties lead to increased grain production. Put more generally, *most complex phenotypes are determined by multiple genes*. Traits conferred by multiple genes are often referred to as **quantitative traits**, because they need to be *measured* rather than assessed qualitatively. For example, grain yield must be measured, whereas a simple trait such as Mendel's pea seed color can be assessed by eye.

FRONTIERS With the sequencing of the human genome and dramatic advances in molecular biology, much has been learned about human genes and what they do. A major new goal is to find out how human gene products interact to form complex phenotypes. A familiar example is height, which is a quantitative trait. A new field of bioinformatics has been developed to analyze the network of interactions between multiple gene products.

The environment affects gene action

The phenotype of an individual does not result from its genotype alone. *Genotype and environment interact to determine the phenotype of an organism*. This is especially important to remember in the era of genome sequencing (see Chapter 12). When the sequence of the human genome was completed in 2003, it was hailed as the "book of life," and public expectations of the benefits gained from this knowledge were (and are) high. But this kind of "genetic determinism"—the idea that an organism's genome sequence determines all of its phenotype—is wrong. Common knowledge tells us that environmental variables such

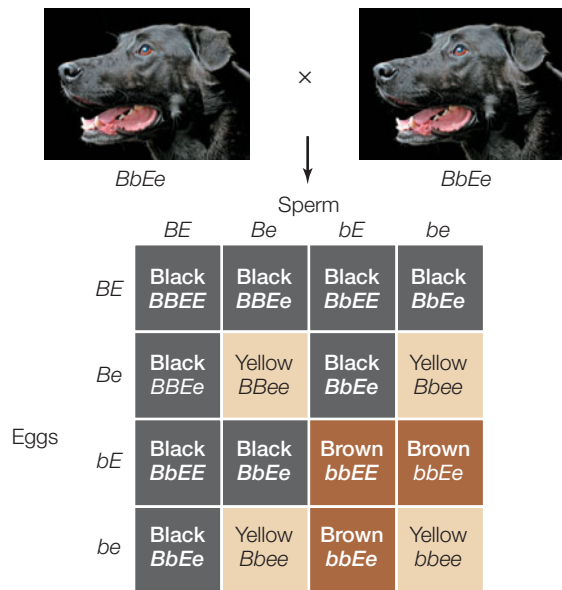

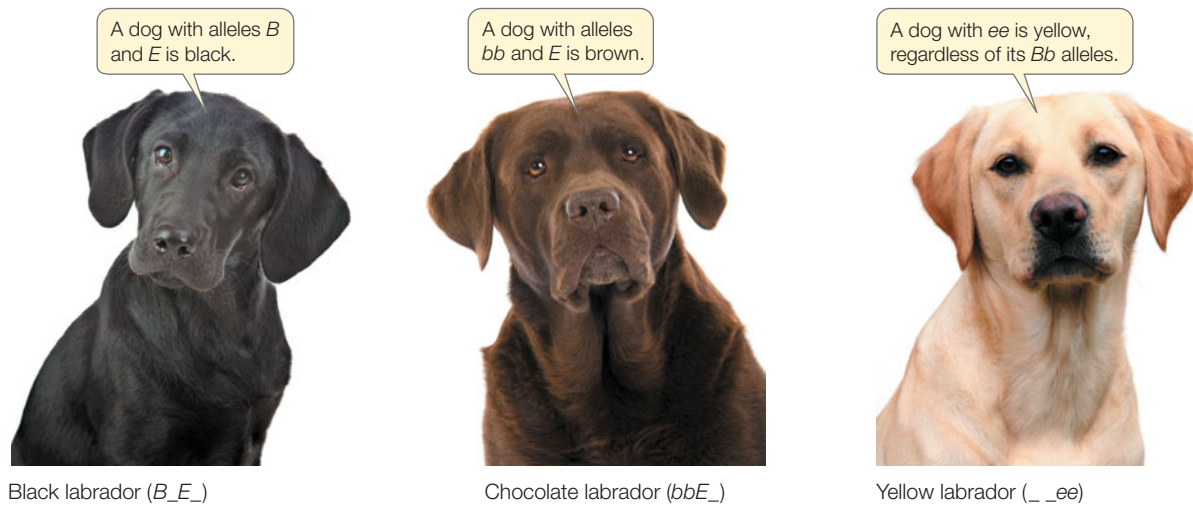

FIGURE 8.12 Genes Interact Epistatically Epistasis occurs when one gene alters the phenotypic effect of another gene. In Labrador retrievers, the E gene determines the expression of the B gene.

as light, temperature, and nutrition can affect the phenotypic expression of a genotype. Clearly a person's height is determined not only by multiple genes but also by the quality of nutrition available.

Two parameters describe the effects of genes and environment on phenotype:

- **Penetrance** is the proportion of individuals in a group with a given genotype that actually show the expected phenotype. For example, many people who inherit a mutant allele of the gene $BRCA1$ develop breast cancer in their lifetimes. But for reasons that are not yet clear and must involve other genes and/or the environment, some people with the mutation do not develop breast cancer. So the $BRCA1$ mutation is said to be incompletely penetrant.

- **Expressivity** is the degree to which a genotype is expressed in an individual. For example, a woman with the $BRCA1$ allele may develop both breast and ovarian cancer as part of the phenotype, but another woman with the same mutation may only get breast cancer. So the mutation is said to have variable expressivity.

Do You Understand Concept 8.2?

- What is the difference between incomplete dominance and codominance?
- A point restricted rabbit (see Figure 8.9) was mated with a light gray rabbit. The two offspring were albino and chinchilla. What were the genotypes of the parents?
- If a dominant allele of one gene, A , is necessary for hearing in humans, and the dominant allele of another gene, B , results in deafness regardless of the presence of other genes, what fraction of offspring in a marriage of $AaBb$ and $Aabb$ individuals will be deaf?
- Give an example from your own experience of a genotype whose expression is affected by the environment.

So far in this chapter we have considered genes that obey Mendel's law of independent assortment. But many genes are inherited together. This apparent anomaly can be explained by the presence of multiple genes on a single chromosome.

concept 8.3

Genes Are Carried on Chromosomes

Genes are parts of chromosomes. More specifically, a gene is a sequence of DNA that resides at a particular site on a chromosome, called a **locus** (plural *loci*). You have seen how the

behavior of chromosomes during meiosis can explain Mendel's laws of segregation (see Figure 8.3) and independent assortment (see Figure 8.6). However, the **genetic linkage** of genes on a single chromosome alters their pattern of inheritance.

Genetic linkage was first discovered in the fruit fly *Drosophila melanogaster*. This animal is an attractive experimental subject because it is small, easily bred, and has a short generation time. In fact, the fruit fly has been a *model organism* for experimental genetics for more than a century. In Concept 8.1 we saw how Mendel successfully applied the scientific method to arrive at his laws of inheritance. Now we will examine the work of Thomas Hunt Morgan, who worked at Columbia University early in the twentieth century and used a similar approach to discover genetic linkage.

yourBioPortal.com

Go to ANIMATED TUTORIAL 8.2
Alleles That Do Not Assort Independently

Genes on the same chromosome are linked, but can be separated by crossing over in meiosis

Some of the crosses Morgan performed with fruit flies yielded phenotypic ratios that were not in accordance with those predicted by Mendel's law of independent assortment. Morgan did a test cross of *Drosophila* with two known genotypes: *BbVgvg* and *bbvvgv*. The *B* and *Vg* genes control two characters, body color and wing shape:

- *B* (wild-type gray body), is dominant over *b* (black body)
- *Vg* (wild-type wing) is dominant over *vg* (vestigial, or very small, wing)

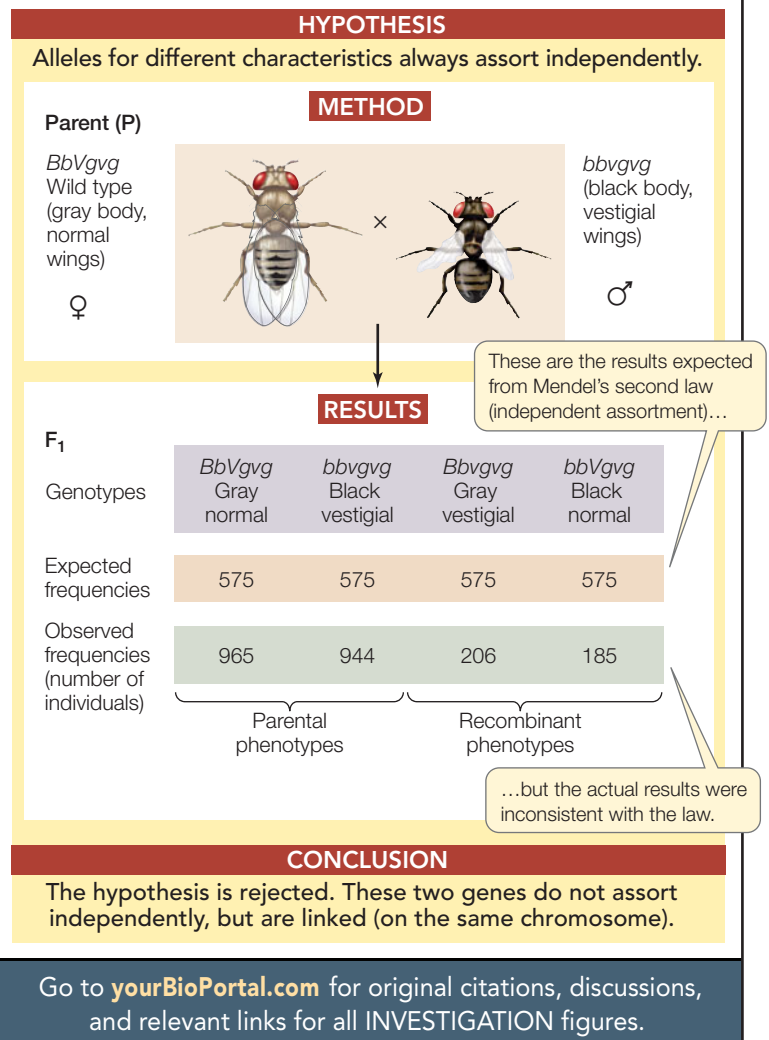

Morgan expected to see four phenotypes in a ratio of 1:1:1:1, but that is not what he observed. The body color gene and the wing size gene did not assort independently; instead, they were frequently *inherited together*, and most of the progeny showed one or the other of the parental phenotypes (FIGURE 8.13).

These results became understandable when Morgan considered the possibility that the two loci were *linked* on the same chromosome. Such genes would not be able to assort independently as predicted by Mendel's second law. In this case, the test cross offspring might be expected to have only the parental phenotypes (gray flies with normal wings or black flies with vestigial wings) in a 1:1 ratio. If linkage were absolute we would *only* see these two types of progeny. However, this did not happen. Why did some of Morgan's flies show phenotypes different from their parents?

Some of Morgan's flies displayed *recombinant phenotypes* because two homologous chromosomes can physically exchange corresponding segments during prophase I of meiosis—that is, by *crossing over* (FIGURE 8.14). Each exchange event involves two of the four chromatids in a tetrad—one from each member of the homologous pair—and can occur at any point along the length of the chromosome. The chromosome segments are exchanged reciprocally, so both chromatids become *recombinant*

INVESTIGATION

FIGURE 8.13 Some Alleles Do Not Assort Independently
Morgan's studies showed that the genes for body color and wing size in *Drosophila* are linked, so that their alleles do not assort independently.

(that is, each chromatid ends up with genes from both of the organism's parents).

LINK The process of crossing over is described in Concept 7.4

As a result of crossing over *between* two linked genes, not all the progeny of a cross have the parental phenotypes. Instead, recombinant offspring appear as well, as they did in Morgan's cross. They generally appear in proportions related to the **recombination frequency** between the two genes, which is calculated by dividing the number of recombinant progeny by the total number of progeny (FIGURE 8.15). Recombination frequencies are *greater for loci that are farther apart on the chromosome* than for loci that are closer together because crossing over is more likely to occur between genes that are far apart. By

calculating recombination frequencies, geneticists can infer the locations of genes along a chromosome and generate a genetic map. Below is a map showing five genes on a fruit fly chromosome. It was constructed using the recombination frequencies generated by test crosses involving various pairs of the genes:

In the chromosome shown above the recombination frequency between y and w is low, so they are close together on the map.

FIGURE 8.14 Crossing Over Results in Genetic Recombination Recombination accounts for why linked alleles are not always inherited together. Alleles at different loci on the same chromosome can be recombined by crossing over and then being separated from one another. Such recombination occurs during prophase I of meiosis.

Recombination between y and v is more frequent, so they are farther apart. The recombination frequencies are converted to *map units*, which in this case correspond to the distances from y ($y = 0$).

The era of gene sequencing has made mapping less important in some areas of genetics research. However, mapping is still one way to verify that a particular DNA sequence corresponds with a particular phenotype. The phenomenon of linkage has allowed biologists to isolate genes and to create genetic markers that are linked to important genes, making it easy to identify individuals carrying particular alleles. This is particularly important in breeding new crops and animals for agriculture, and for identifying humans carrying medically significant mutations.

Linkage is also revealed by studies of the X and Y chromosomes

The fruit fly genome has four pairs of chromosomes: in three pairs, the chromosomes are similar in size to one another and are called *autosomes*. The fourth pair has two chromosomes of different sizes. These determine the sex of the fly and are called the *sex chromosomes*:

Note that the female fly has two X chromosomes and that the male has only one, the other being the Y chromosome: females are XX and males are XY. It turns out that in addition to being different sizes, *many genes on the X chromosome are not present on the Y*. The X chromosome was one of the first to have specific genes assigned to it.

Morgan identified a gene that controls eye color in *Drosophila*. The wild-type allele of the gene confers red eyes, whereas a recessive mutant allele confers white eyes. Morgan's experimental crosses with flies carrying the mutant allele demonstrated that this eye color locus is on the X chromosome. If we abbreviate the eye color alleles as R (red eyes) and r (white eyes), the presence of the alleles on the X chromosome is designated by X^R and X^r .

Morgan crossed a homozygous red-eyed female ($X^R X^R$) with a white-eyed male. The male is designated $X^r Y$ because the Y does not carry any allele for this gene. (Any gene that is present as a single copy in a diploid organism is called **hemizygous**.)

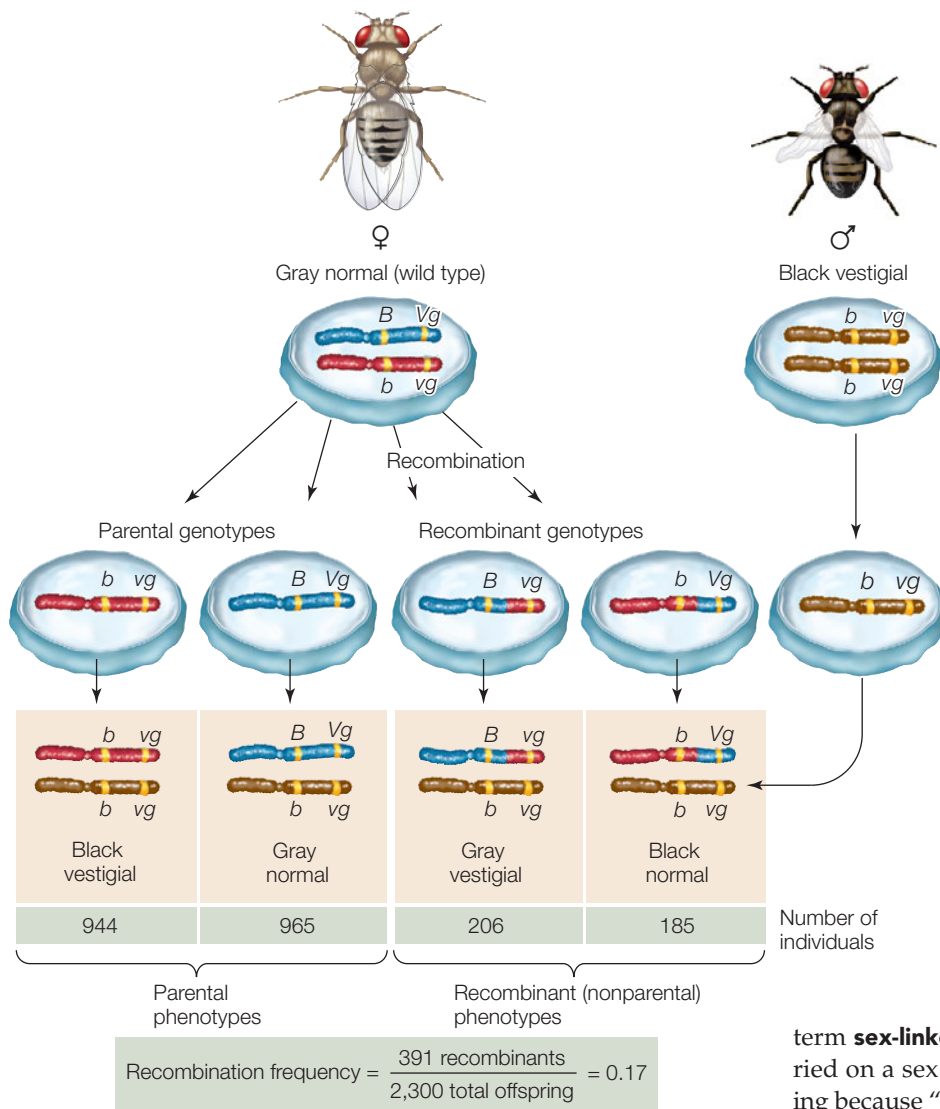

FIGURE 8.15 Recombination Frequencies
The frequency of recombinant offspring (those with a phenotype different from either parent) can be calculated.

an autosome rather than a sex chromosome. In that case, the male would have been homozygous recessive—*rr*.

When Morgan performed the reciprocal cross, in which a white-eyed female (X^rX^r) was mated with a red-eyed male (X^RY), the results were unexpected: *all the sons were white-eyed and all the daughters were red-eyed* (FIGURE 8.16B). The sons from the reciprocal cross inherited their only X chromosome from their white-eyed mother and were therefore hemizygous for the white allele. The daughters, however, got an X chromosome bearing the white allele from their mother and an X chromosome bearing the red allele from their father; therefore they were red-eyed heterozygotes. When these heterozygous females were mated with red-eyed males, half their sons had white eyes but all their daughters had red eyes. Together, these results showed that eye color was carried on the X chromosome and not on the Y.

These and other experiments led to the term **sex-linked inheritance**: inheritance of a gene that is carried on a sex chromosome. (This term is somewhat misleading because “sex-linked” inheritance is not really linked to the sex of an organism—after all, both males and females carry X chromosomes.) In mammals, the X chromosome is larger and carries more genes than the Y. For this reason, most examples of sex-linked inheritance involve genes that are carried on the X chromosome.

Many sexually reproducing species, including humans, have sex chromosomes. As in fruit flies, human males are XY,

All the sons and daughters from this cross had red eyes, because red (*R*) is dominant over white (*r*) and all the progeny had inherited a wild-type X chromosome (X^R) from their mother (FIGURE 8.16A). Note that this phenotypic outcome would have occurred even if the *R* gene had been present on

APPLY THE CONCEPT

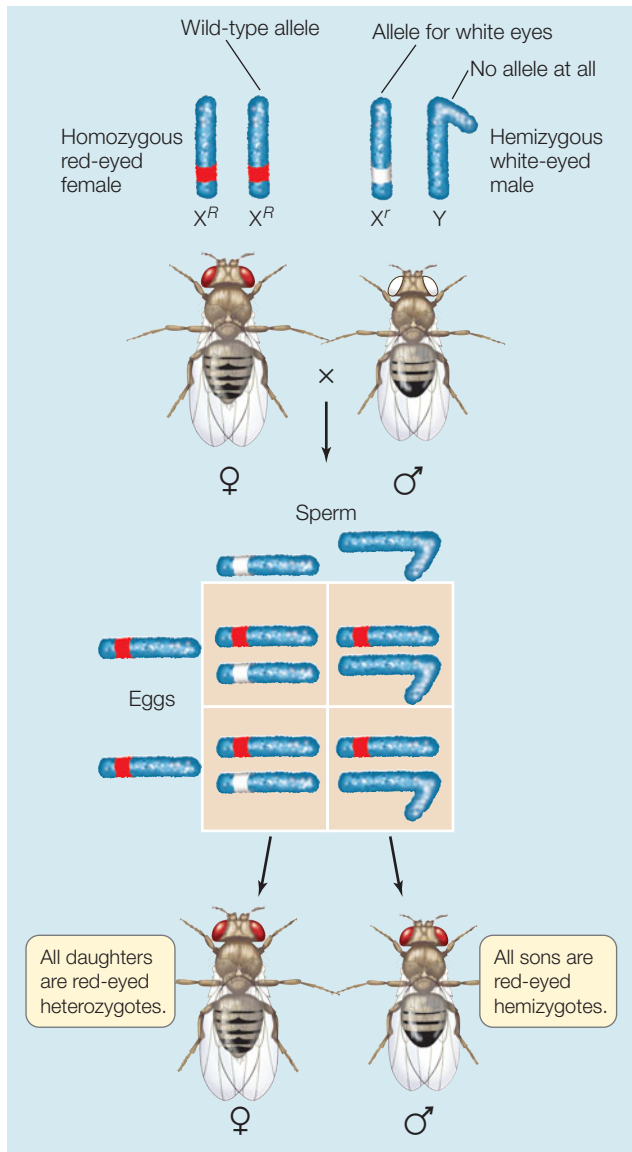

Genes are carried on chromosomes

The pedigree shows the inheritance pattern of a rare mutant phenotype in humans, congenital cataract (filled-in symbols).

1. Are cataracts inherited as an autosomal dominant? Autosomal recessive? Sex-linked dominant? Sex-linked recessive?
2. Person #5 in the second generation marries a man who does not have cataracts. Two of their four children, a boy and a girl, develop cataracts. What is the probability that their next child will be a girl with cataracts?

(A)

(B)

FIGURE 8.16 A Gene for Eye Color Is Carried on the *Drosophila* X Chromosome Morgan demonstrated that a mutant allele that causes white eyes in *Drosophila* is carried on the X chromosome. Note that in this case, the reciprocal crosses do not have the same results.

females are XX, and relatively few of the genes that are present on the X chromosome are present on the Y. Pedigree analyses of X-linked recessive phenotypes like the one in **FIGURE 8.17** reveal the following patterns (compare with the pedigrees of non-X-linked phenotypes in Figure 8.8):

- The phenotype appears much more often in males than in females, because only one copy of the rare allele is needed for its expression in males, whereas two copies must be present in females.
- A male with the mutation can pass it on only to his daughters; all his sons get his Y chromosome.

- Daughters who receive one X-linked mutation are **heterozygous carriers**. They are phenotypically normal, but they can pass the mutant allele to their sons or daughters. On average, half their children will inherit the mutant allele since half of their X chromosomes carry the normal allele.
- The mutant phenotype can skip a generation if the mutation passes from a male to his daughter (who will be phenotypically normal) and then to her son.

Some genes are carried on chromosomes in organelles

The nucleus is not the only organelle in a eukaryotic cell that carries genetic material. Mitochondria and plastids each contain several copies of a small chromosome that carries a small number of genes. For example, in humans there are about 24,000 genes in the nuclear genome and 37 in the mitochondrial genome.

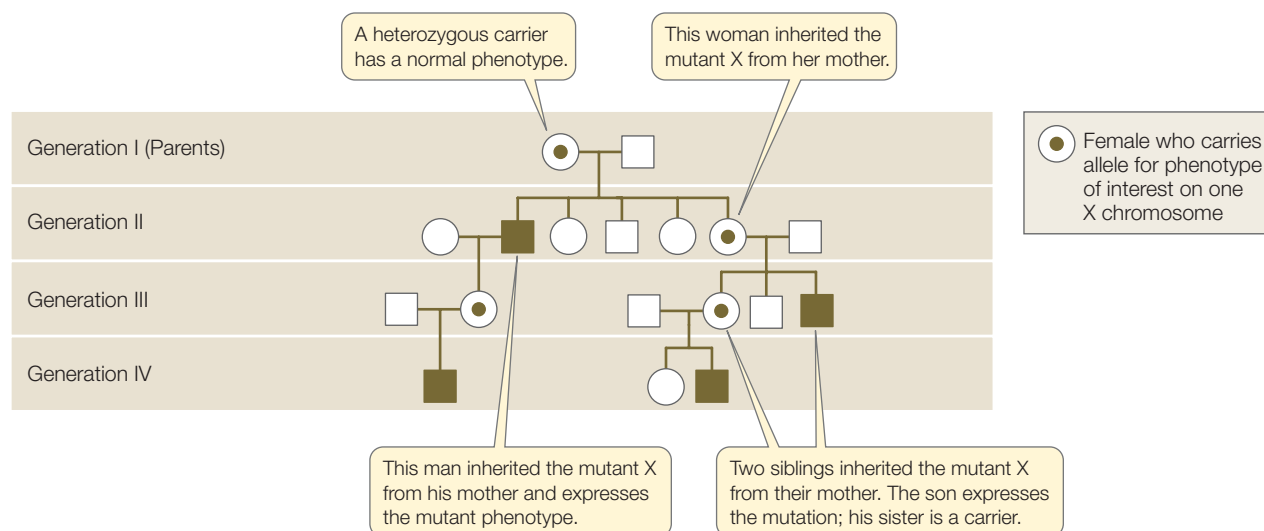

FIGURE 8.17 Red-Green Color Blindness Is Carried on the Human X Chromosome The mutant allele for red-green color blindness is expressed as an X-linked recessive trait, and therefore is always expressed in males when they carry that allele.

The inheritance of organelle genes differs from that of nuclear genes because in most organisms, *mitochondria and plastids are inherited only from the mother*. Most egg cells in plants and animals contain abundant cytoplasm and organelles, but the only part of the sperm that survives to take part in the union of haploid gametes is the nucleus. You have inherited your mother's mitochondria (with their genes) but not your father's. The inheritance of organelles and their genes is therefore non-Mendelian and is described as maternal or *cytoplasmic inheritance*, since the inherited organelles come from the maternal cytoplasm. **FIGURE 8.18** illustrates the cytoplasmic inheritance of a mutant plastid gene that confers white color to leaves.

FIGURE 8.18 Cytoplasmic Inheritance In four o'clock plants, leaf color is inherited through the female plant only. In the parent plant with some white leaves, the white leaf color is caused by a chloroplast mutation that occurred during the life of the plant; the leaves that formed before the mutation occurred are green. When this plant is used as a pollen donor in a cross with an all green plant, the offspring are all green. But when the same plant is used as an egg donor, the offspring inherit the mutation cytoplasmically and are entirely white.

Do You Understand Concept 8.3?

- Describe the differences in patterns of inheritance between a gene present in the nucleus and a gene present in the mitochondria.
- Explain the concept of linkage. If you performed a test cross with a fruit fly that is heterozygous for two genes, how would you conclude that the two genes are linked?
- Red-green color blindness is inherited as a sex-linked recessive. Two parents with normal color vision have a child who is red-green color-blind. Is it a boy or girl? Draw a pedigree of the family. Draw a Punnett square to show gametes and offspring with regard to the X and Y chromosomes and the normal and color-blind alleles.

Like eukaryotes, prokaryotes contain genes that determine their phenotypes. Sexual reproduction in eukaryotes involves two sets of chromosomes and meiosis, giving rise to haploid gametes. Let's look next at how reproduction and inheritance differ in prokaryotes, which are haploid.

concept 8.4 Prokaryotes Can Exchange Genetic Material

As described in Concept 4.2, prokaryotic cells lack nuclei; they contain their genetic material mostly as single chromosomes in central regions of their cells. Prokaryotes reproduce asexually by binary fission, a process that gives rise to progeny that are virtually identical genetically (see Concept 7.2). That is, the offspring of cell reproduction in prokaryotes constitute a clone.

How then do prokaryotes evolve? Mutations occur in prokaryotes just as they do in eukaryotes, and the resulting new alleles increase genetic diversity. You might expect, therefore, that there is no way for individuals of these organisms to exchange genes, as in sexual reproduction. It turns out, however, that prokaryotes do have a process for transferring genes between cells. Along with mutation, this process provides for genetic diversity among prokaryotes. This transfer of genes from one organism to another without sexual reproduction is called horizontal (or lateral) gene transfer, to distinguish it from the vertical gene transfer that occurs from parent to offspring.

LINK The evolutionary consequences of lateral gene transfer are discussed in Concepts 15.6 and 19.1

Bacteria exchange genes by conjugation

To illustrate genetic exchange in bacteria, let's consider two strains of the bacterium *E. coli* with different alleles for each of six genes (each of the genes coding for the synthesis of a certain small molecule). Simply put, the two strains have the following genotypes (remember that bacteria are haploid):

where capital letters stand for wild-type alleles and lowercase letters stand for mutant alleles.

When the two strains are grown together in the laboratory, most of the cells produce clones. That is, almost all of the cells that grow have the original genotypes:

However, out of millions of bacteria, a few occur that have the genotype:

How could these completely wild-type bacteria arise? One possibility is *mutation*: in the *abcDEF* bacteria, the *a* allele could have mutated to *A*, the *b* allele to *B*, and the *c* allele to *C*. The problem with this explanation is that a mutation at any particular point in an organism's DNA sequence is a very rare event (about 1 in a million). The probability of all three events

occurring in the same cell is extremely low—much lower than the actual rate of appearance of cells with the *ABCDEF* genotype. So the mutant cells must have acquired wild-type genes some other way—and this turns out to be the transfer of DNA between cells.

Electron microscopy shows that genetic transfers between bacteria can happen via physical contact between the cells (**FIGURE 8.19A**). Contact is initiated by a thin projection called a **sex pilus** (plural *pili*), which extends from one cell (the donor), attaches to another (the recipient), and draws the two cells together. Genetic material can then pass from the donor cell to the

FIGURE 8.19 Bacterial Conjugation and Recombination

(A) A sex pilus draws two bacteria into close contact, so that a cytoplasmic bridge (conjugation tube) can form. DNA is transferred from the donor cell to the recipient cell via the conjugation tube. (B) DNA from a donor cell can become incorporated into a recipient cell's chromosome through crossing over.

FIGURE 8.20 Gene Transfer by Plasmids When plasmids enter a cell via conjugation, their genes can be expressed in the recipient cell.

recipient through a thin cytoplasmic bridge called a *conjugation tube*. There is no reciprocal transfer of DNA from the recipient to the donor. This process is referred to as **bacterial conjugation**.

Once the donor DNA is inside the recipient cell, it can recombine with the recipient cell's genome. In much the same way that chromosomes pair up, gene for gene, in prophase I of meiosis, the donor DNA can line up beside its homologous genes in the recipient, and crossing over can occur. Gene(s) from the donor can become integrated into the genome of the recipient, thus changing the recipient's genetic constitution (**FIGURE 8.19B**), although only about half the transferred genes become integrated in this way. When the recipient cells proliferate, the integrated donor genes are passed on to all progeny cells, and the other transferred genes are lost.

Plasmids transfer genes between bacteria

In addition to their main chromosome, many bacteria harbor additional smaller, circular DNA molecules called **plasmids**. Plasmids typically contain at most a few dozen genes, which may fall into one of several categories:

- Genes for unusual metabolic capacities, such as the ability to break down hydrocarbons. Bacteria carrying these plasmids can be used to clean up oil spills.
- Genes for antibiotic resistance. Plasmids carrying such genes are called R factors, and since they can be transferred between bacteria via conjugation, they are a major threat to human health.

FRONTIERS Methicillin-resistant *Staphylococcus aureus* (MRSA) is a bacterial strain that is resistant to multiple antibiotics because it contains a chromosome harboring resistance genes. This bacterium causes serious infections in hospital settings. Multidrug resistance is now spreading rapidly through the wider community, because MRSA DNA has been transferred to other bacterial strains. Scientists are trying to fully understand how this DNA transfer occurs and to design new antibiotics to kill the genetically transformed strains.

Plasmids can move between cells during conjugation, thereby transferring new genes to the recipient bacterium (**FIGURE 8.20**). A single strand of the donor plasmid is transferred to the recipient; synthesis of complementary DNA strands results in two complete copies of the plasmid, one in the donor and one in the recipient. Because plasmids can replicate independently of the main chromosome, they do not need to recombine with

the main chromosome to add their genes to the recipient cell's genome.

Do You Understand Concept 8.4?

- How does recombination occur in prokaryotes?
- What is the evolutionary advantage of recombination in prokaryotes?
- What are the differences between recombination after conjugation in prokaryotes and recombination during meiosis in eukaryotes?

How is hemophilia inherited through the mother, and why is it more frequent in males?

ANSWER The ancient rabbis in the opening story were dealing with babies that had the blood-clotting disease hemophilia A. The mutant allele for factor VIII, the clotting factor missing in these babies, must be recessive since the babies' parents did not suffer from the disease (Concept 8.1). Usually, the disease occurred in boys, and any relatives with the disease were males on the mother's side of the family. This

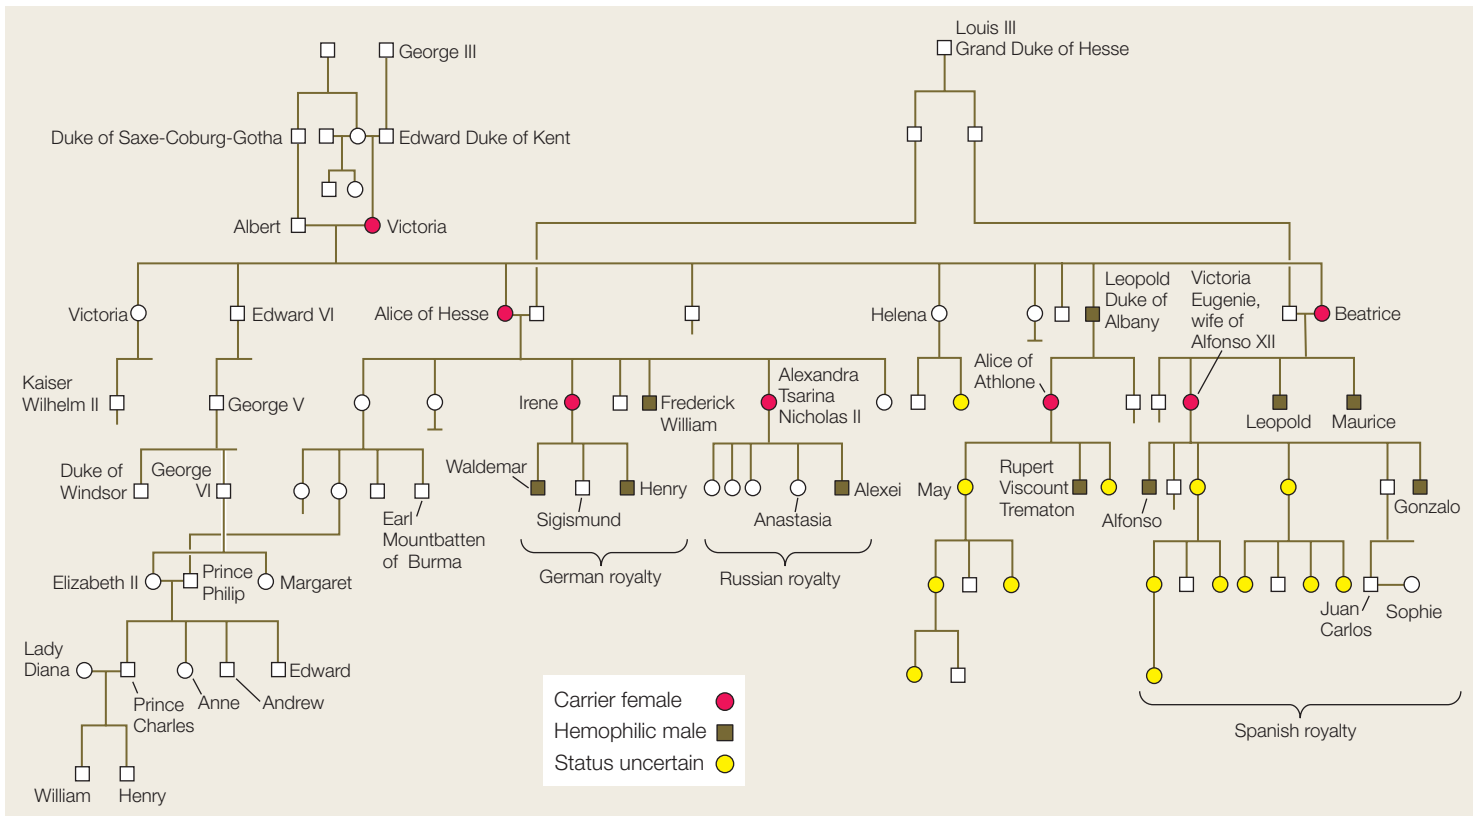

FIGURE 8.21 Sex Linkage in Royal Families of Europe

England's Queen Victoria passed an X chromosome carrying the mutant allele for hemophilia to three of her children.

was because the gene for factor VIII is carried on the human X chromosome and its inheritance is sex-linked, with all boys receiving their single X chromosomes from their mothers (Concept 8.3).

Hemophilia played a role in the history of modern Europe. England's Queen Victoria, who ruled in the nineteenth century, had nine children, and one of them, Leopold, had hemophilia and died after a minor accident at age 31. The queen

did not have the disease, nor was it present in any of her forbears; so it is probable that a mutation arose on Victoria's X chromosome or in that of her father (Concept 8.2). Three of Victoria's grandchildren had hemophilia, indicating that their mothers, two of Victoria's daughters, were carriers of the mutant allele. This spread the mutation to the royal families of Spain, Germany, and Russia in the twentieth century (FIGURE 8.21). While there are many descendants of Queen Victoria still living (including Queen Elizabeth II), none have hemophilia; however, it is possible that some of Victoria's female descendants are carriers.

8

SUMMARY

concept 8.1 Genes Are Particulate and Are Inherited According to Mendel's Laws

- Mendel's experiments on pea plants supported the particulate theory of inheritance stating that discrete units (now called genes) are responsible for the inheritance of specific traits. **Review Figure 8.1**
- Mendel's first law, the **law of segregation**, states that when any individual produces gametes, the two copies of a gene separate, so that each gamete receives only one member of the pair. **Review Figures 8.2 and 8.3**
- Mendel used a **test cross** to find out whether an individual showing a dominant phenotype was homozygous or heterozygous. **Review Figure 8.4 and WEB ACTIVITY 8.1**

- Mendel's use of **dihybrid crosses** to study the inheritance of two characters led to his second law: the **law of independent assortment**. The independent assortment of genes in meiosis leads to recombinant phenotypes. **Review Figures 8.5 and 8.6 and ANIMATED TUTORIAL 8.1**
- Pedigree** analysis can determine whether an allele is **dominant** or **recessive**. **Review Figure 8.8 and INTERACTIVE TUTORIAL 8.1**

concept 8.2 Alleles and Genes Interact to Produce Phenotypes

- New alleles arise by random mutation. Many genes have multiple alleles. A **wild-type** allele gives rise to the predominant form of a

trait. When the wild-type allele is present at a locus less than 99 percent of the time, the locus is said to be polymorphic.

- In **incomplete dominance**, neither of two alleles is dominant. The heterozygous phenotype is intermediate between the homozygous phenotypes. **Review Figure 8.10**
- **Codominance** exists when two alleles at a locus produce two different phenotypes that both appear in heterozygotes. **Review Figure 8.11**
- In **epistasis**, one gene affects the expression of another. **Review Figure 8.12**
- Environmental conditions can affect the expression of a genotype.

concept 8.3 Genes Are Carried on Chromosomes

- Each chromosome carries many genes, and the genes on a single chromosome show **genetic linkage**. **Review Figure 8.13 and ANIMATED TUTORIAL 8.2**
- Genes on the same chromosome can recombine by crossing over. The resulting recombinant chromosomes have new combinations of alleles. **Review Figure 8.14**
- Recombination frequencies can be used to generate a genetic map of a chromosome. **Review Figure 8.15**

- In fruit flies and mammals, the X chromosome carries many genes, but the Y chromosome has only a few. Males have only one allele (are hemizygous) for X-linked genes, so recessive sex-linked mutations are expressed phenotypically more often in males than in females. Females may be unaffected **heterozygous carriers** of such alleles. **Review Figure 8.16**
- Some genes are present on the chromosomes of organelles such as plastids and mitochondria. In many organisms, cytoplasmic genes are inherited only from the mother because the male gamete contributes only its nucleus (i.e., no cytoplasm) to the zygote at fertilization. **Review Figure 8.18**

concept 8.4 Prokaryotes Can Exchange Genetic Material

- Prokaryotes reproduce asexually but can transfer genes from one cell to another in a process called **bacterial conjugation**. **Review Figure 8.19**
- **Plasmids** are small, extra DNA molecules in bacteria that carry genes involved in important metabolic processes. Plasmids can be transmitted from one cell to another. **Review Figure 8.20**

See **WEB ACTIVITIES 8.2 and 8.3** for a concept review of this chapter.

DNA and Its Role in Heredity

9

Jurassic Park, in both its literary and film incarnations, featured a fictional theme park populated with live dinosaurs. In the story, scientists isolated DNA from dinosaur blood that they found in the digestive tracts of fossil insects. The insects supposedly sucked the reptiles' blood right before being preserved in amber (fossilized tree resin). This DNA, according to the novel, could be manipulated to produce living individuals of long-extinct organisms such as velociraptors and the ever-memorable *Tyrannosaurus rex*.

The late Michael Crichton got the idea for his novel from an actual scientific paper in which the authors cracked open amber that was 40 million years old and extracted DNA from a bee fossil trapped in the amber. Other scientists had reported on ancient DNA from amber-trapped termites and gnats. Then several reports emerged of DNA from 80-million-year-old dinosaur bones. Unfortunately, upon additional study these "preserved" DNAs turned out to be contamination—either from microorganisms living in the surrounding soil or even from the scientists studying the samples. In fact, one of the supposed dinosaur DNAs turned out to be from the human Y chromosome.

It is unlikely that any long DNA polymers would survive over millions of years. The oldest fossilized insects in amber are about 40 million years old, and dinosaurs died out about 65 million years ago. Nevertheless, the huge success of Crichton's book brought ancient DNA to the attention of millions of people, including biologists who study the evolution of life on Earth. DNA samples have been isolated from organisms preserved for many thousands of years in permafrost, and with

improved methods for DNA analysis, large portions of these organisms' genomes are being sequenced.

As methods to replicate tiny amounts of DNA and keep it from contamination have improved, attention has turned to ancient human DNA. DNAs from human remains not overly prone to environmental contamination have been studied. These include people whose bodies have been preserved in ice, such as the "Ice-man" who died in the Austrian Alps 5,300 years ago. There is even a Neandertal Genome Project to analyze the DNA from preserved specimens of *Homo neanderthalensis*, a species that lived in Europe at the same time as early humans, between 350,000 and 30,000 years ago.

Michael Crichton's novel *Jurassic Park* was based on the fictional premise that DNA retrieved from fossils could produce living dinosaurs, such as these velociraptors.

What can we learn from ancient DNA?

KEY CONCEPTS

- 9.1 DNA Structure Reflects Its Role as the Genetic Material
- 9.2 DNA Replicates Semiconservatively
- 9.3 Mutations Are Heritable Changes in DNA

concept 9.1 DNA Structure Reflects Its Role as the Genetic Material

In Concept 8.1 we describe Mendel's experiments in the 1860s demonstrating that genes are physically distinct entities, and Morgan's work in the early twentieth century showing that genes are associated with chromosomes. We now turn to the actual chemical nature of genes, beginning with the evidence that DNA is the carrier of heritable information. Scientists used two types of evidence to show that DNA is the genetic material: circumstantial and experimental. Below we provide examples of both types.

Circumstantial evidence suggested that DNA was the genetic material

Before DNA was accepted as the genetic material, it had to meet certain criteria. Scientists needed to show that eukaryotic DNA:

- was present in the cell nucleus and in condensed chromosomes
- doubled during S phase of the cell cycle
- was twice as abundant in the diploid cells as in the haploid cells of a given organism
- showed the same patterns of transmission as the genetic information it was supposed to carry.

There was circumstantial evidence for all of these criteria well before there was experimental evidence.

DNA IN THE NUCLEUS DNA was first isolated in 1868 by the young Swiss researcher–physician Friedrich Miescher. At that

time, dividing cells and chromosomes had been seen under the microscope but genes were not yet described. There is no evidence that Miescher had seen Mendel's paper on inheritance. While still a student, Miescher isolated cell nuclei from white blood cells in pus from the bandages of wounded soldiers. When he treated these nuclei chemically, a fibrous substance came out of solution. He called it "nuclein" and found it contained the elements C, H, O, N, and P. With no evidence except for finding it in the nucleus, Miescher boldly proposed that nuclein was the genetic material. His supervising professor was so astounded by Miescher's work that he repeated it himself in the lab and finally allowed his student to publish it in a scientific journal.

DNA IN THE CHROMOSOMES Dyes were developed that react specifically with DNA, turning color only when they bind to it (FIGURE 9.1A). This allowed individual cells to be examined for the location and amount of DNA they contained. When dividing cells were stained with such a dye, only the chromosomes were stained:

DNA IN THE CELLS The amount of dye binding to DNA, and hence the intensity of color observed, was directly related to

(A)

(B)

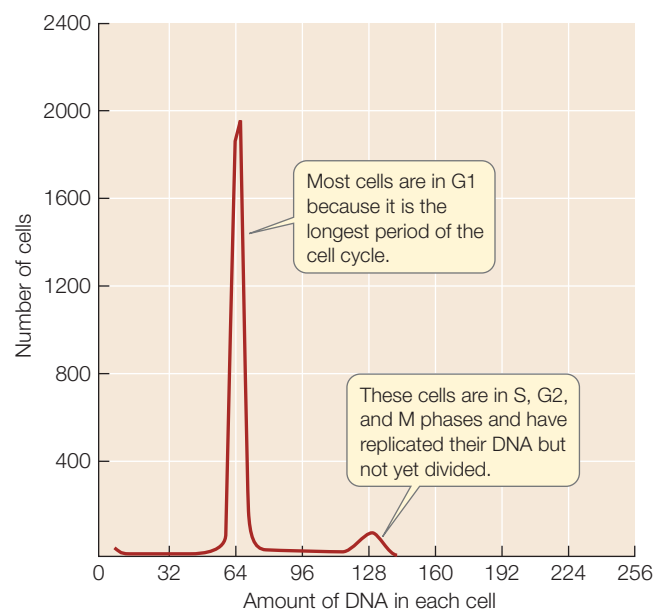

FIGURE 9.1 DNA in the Nucleus and in the Cell Cycle (A) A dye—in this case DAPI—can specifically stain DNA. (B) When dividing cells are stained and analyzed by flow cytometry, there are two populations in terms of DNA content.

the amount of DNA present: the greater the intensity, the more DNA. This allowed scientists to analyze DNA amounts in individual cells during the cell cycle (see Concept 7.2).

When a population of actively dividing cells was stained with dye, the amount of DNA in each cell could be quantified by passing the cells one by one through a *flow cytometer*. In general, two populations of cells were seen: most cells were in G1 and contained half the amount of DNA that was in the remaining cells, which were in S, G2, and M (FIGURE 9.1B).

Such staining experiments confirmed two other predictions for DNA as the genetic material:

- Virtually all nondividing somatic cells of a particular organism have the same amount of nuclear DNA.
- Similar experiments showed that after meiosis, gametes have half the amount of nuclear DNA as somatic cells.

TRANSMISSION OF DNA Chromosomes in eukaryotic cells contain DNA, but they also contain proteins that are bound to DNA. Therefore, it was difficult for scientists to rule out that genetic information might be carried on proteins. Viruses provided an ideal system to explore this question. Many viruses, including **bacteriophage** (viruses that infect bacteria), are composed of DNA and only one or a few kinds of protein. When a bacteriophage infects a bacterium, it takes about 20 minutes for the virus to hijack the bacterium's metabolic capabilities and turn the bacterium into a virus factory. Minutes later, the bacterium is dead and hundreds of viruses are released.

The transition from bacterium to virus producer is a change in the *genetic program* of the bacterial cell. Careful chemical analyses and observations by electron microscope showed that *only the viral DNA* is injected into the cell during infection (FIGURE 9.2). This was further evidence that DNA and not protein was the genetic material.

The Hershey-Chase Experiment

Experimental evidence confirmed that DNA is the genetic material

Circumstantial evidence can show correlations between two situations. However, *scientists rely on experiments* to provide proof of a cause-and-effect relationship. In order to confirm that DNA was the genetic material, biologists used model organisms such as bacteria in **transformation** experiments. They found that the addition of DNA from one strain of bacterium could genetically transform another strain of bacterium:

bacterium strain A + strain B DNA → bacterium strain B

The transformation of mammalian cells carrying genetic mutations provided another model system for showing that DNA is the genetic material. For example, certain cells were found to lack the gene for thymidine kinase, an enzyme that catalyzes the first step in a pathway that converts thymidine into deoxythymidine triphosphate (dTTP, a nucleotide used in DNA

FIGURE 9.2 Viral DNA and Not Protein Enters Host Cells

Bacteriophage T2 infects *E. coli* and depends on the bacterium to produce new viruses. The bacteriophage consists entirely of DNA contained within a protein coat. When the virus infects an *E. coli* cell, its DNA, but not its protein coat, is injected into the host bacterium.

synthesis). Such cells cannot grow in a medium that contains thymidine as the only source for dTTP synthesis. However, when the cells were incubated with DNA containing the gene for thymidine kinase (in a solution containing CaCl_2 ; see below), some of the cells became transformed with the TK gene and were able to grow on the thymidine-containing medium (FIGURE 9.3).

For successful genetic transformation, DNA must pass through the cell membrane into the cytoplasm and (in most cases) get incorporated into a host cell chromosome. In early transformation experiments, a major stumbling block was the first step, because DNA is negatively charged (because of its phosphate groups) and so are the surfaces of cell membranes (because of their phospholipids). Since like charges repel, DNA does not tend to bind to cell membranes. Biologists found they could circumvent this by incubating the DNA and cells in a calcium salt such as CaCl_2 . The positively charged Ca^{2+} neutralized the charges, allowing DNA to bind and even pass through the cell membranes. This simple procedure had enormous consequences because it allowed the artificial transformation of bacterial and mammalian cells.

INVESTIGATION

FIGURE 9.3 Transformation of Eukaryotic Cells The use of a marker gene shows that mammalian cells can be genetically transformed by DNA. Usually, the marker gene is carried on a larger DNA molecule.

Transformation was achieved by adding the DNA in a solution of calcium chloride (CaCl_2) at pH 7. In other experiments, the type or amount of DNA, pH, or CaCl_2 concentration was varied. The transformation efficiency was calculated as the percentage of cells that produced colonies on a medium containing thymidine. Explain these data.

Transformation conditions	Efficiency (%)
Mammalian DNA with TK gene	
10 μg	15
20 μg	55
30 μg	10
40 μg	5
20 μg , no CaCl_2	10
20 μg , pH 6.5	0
20 μg , pH 7.5	0
Bacterial virus DNA with TK gene	
20 μg	0

Many kinds of cells can be transformed in this way—even egg cells. In this case, a whole new genetically transformed organism can result; such an organism is referred to as **transgenic**. These methods form the basis of much applied research, including biotechnology and genetic engineering. The transformation of multicellular eukaryotes provided powerful experimental evidence for DNA as the genetic material.

The discovery of the three-dimensional structure of DNA was a milestone in biology

Mendel showed that genes are physically distinct entities, and further research identified DNA as the genetic material. The history of how the actual structure of DNA was deciphered is worth considering, as it represents not only brilliant scientists working together, but also a landmark in our understanding of nature.

By the mid-twentieth century, the chemical makeup of DNA, as a polymer made up of nucleotide monomers, had been known for several decades. In determining the structure of DNA, scientists hoped to answer two questions:

1. How is DNA replicated between cell divisions?
2. How does it direct the synthesis of specific proteins?

They were eventually able to answer both questions.

The structure of DNA was deciphered only after many types of experimental evidence were considered together in a theoretical framework. The most crucial evidence was obtained using X-ray crystallography. Some chemical substances, when they are isolated and purified, can be made to form crystals. The positions of atoms in a crystallized substance can be inferred from the diffraction pattern of X rays passing through the substance (**FIGURE 9.4A**). The structure of DNA would not have been characterized without the crystallographers prepared in the early 1950s by the English chemist Rosalind Franklin (**FIGURE 9.4B**). Franklin's work, in turn, depended on the success of the English biophysicist Maurice Wilkins, who prepared samples containing very uniformly oriented DNA fibers. These fibers and the crystallographs Franklin prepared from them suggested a spiral or helical molecule.

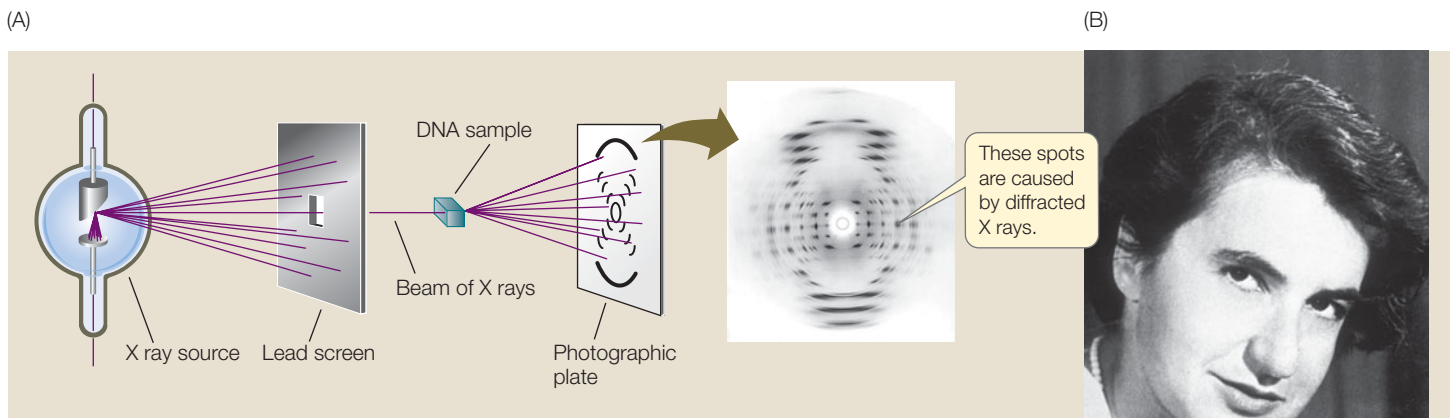

FIGURE 9.4 X-Ray Crystallography Helped Reveal the Structure of DNA (A) The positions of atoms in a crystallized chemical substance can be inferred by the pattern of diffraction of X rays passed through it. The pattern of DNA is both highly regular and repetitive. (B) Rosalind Franklin's crystallographs helped scientists visualize the helical structure of the DNA molecule.

The nucleotide composition of DNA was known

The chemical composition of DNA also provided important clues to its structure. Biochemists knew that DNA is a polymer of nucleotides. Each of these nucleotides consists of a molecule of the sugar deoxyribose, a phosphate group, and a nitrogen-containing base (see Figure 3.1). The only differences among the four nucleotides of DNA are their nitrogenous bases: the purines *adenine* (A) and *guanine* (G), and the pyrimidines *cytosine* (C) and *thymine* (T).

In 1950, biochemist Erwin Chargaff at Columbia University reported an important observation. He and his colleagues had found that DNA samples from many different species—and from different sources within a single organism—exhibited certain regularities. The following rule held for each sample: the amount of adenine equaled the amount of thymine ($A = T$), and the amount of guanine equaled the amount of cytosine ($G = C$). As a result, the total abundance of purines ($A + G$) equaled the total abundance of pyrimidines ($T + C$):

The structure of DNA could not have been worked out without this observation, now known as *Chargaff's rule*.

Watson and Crick described the double helix

Chemical model building is the assembly of three-dimensional structures using known relative molecular dimensions and

known bond angles. The English physicist Francis Crick and the American geneticist James D. Watson (**FIGURE 9.5A**), both then at the Cavendish Laboratory of Cambridge University, used model building to solve the structure of DNA.

Watson and Crick attempted to combine all that had been learned so far about DNA structure into a single coherent model. Rosalind Franklin's crystallography results convinced them that the DNA molecule must be **helical**—it must have a spiral shape like a spring. Density measurements and previous model building results suggested that there are two polynucleotide chains in the molecule. Modeling studies also showed that the strands run in opposite directions, that is, they are **anti-parallel**. The two strands would not fit together in the model if they were parallel.

How are nucleotides oriented in DNA chains? Watson and Crick suggested that:

- the nucleotide bases are on the interior of the two strands, with a sugar-phosphate backbone on the outside.
- to satisfy Chargaff's rule (purines = pyrimidines), a purine on one strand is always paired with a pyrimidine on the opposite strand. These **base pairs** (A-T and G-C) have the same width down the double helix, a uniformity shown by X-ray diffraction.

In late February of 1953, Crick and Watson built a model out of tin that established the general structure of DNA. This structure explained all the known chemical properties of DNA, and it opened the door to understanding its biological functions. There have been minor amendments to that first published structure, but its principal features remain unchanged.

Four key features define DNA structure

Four features summarize the molecular architecture of the DNA molecule (**FIGURE 9.5B**; also review Figure 3.4):

- It is a *double-stranded helix* of uniform diameter.

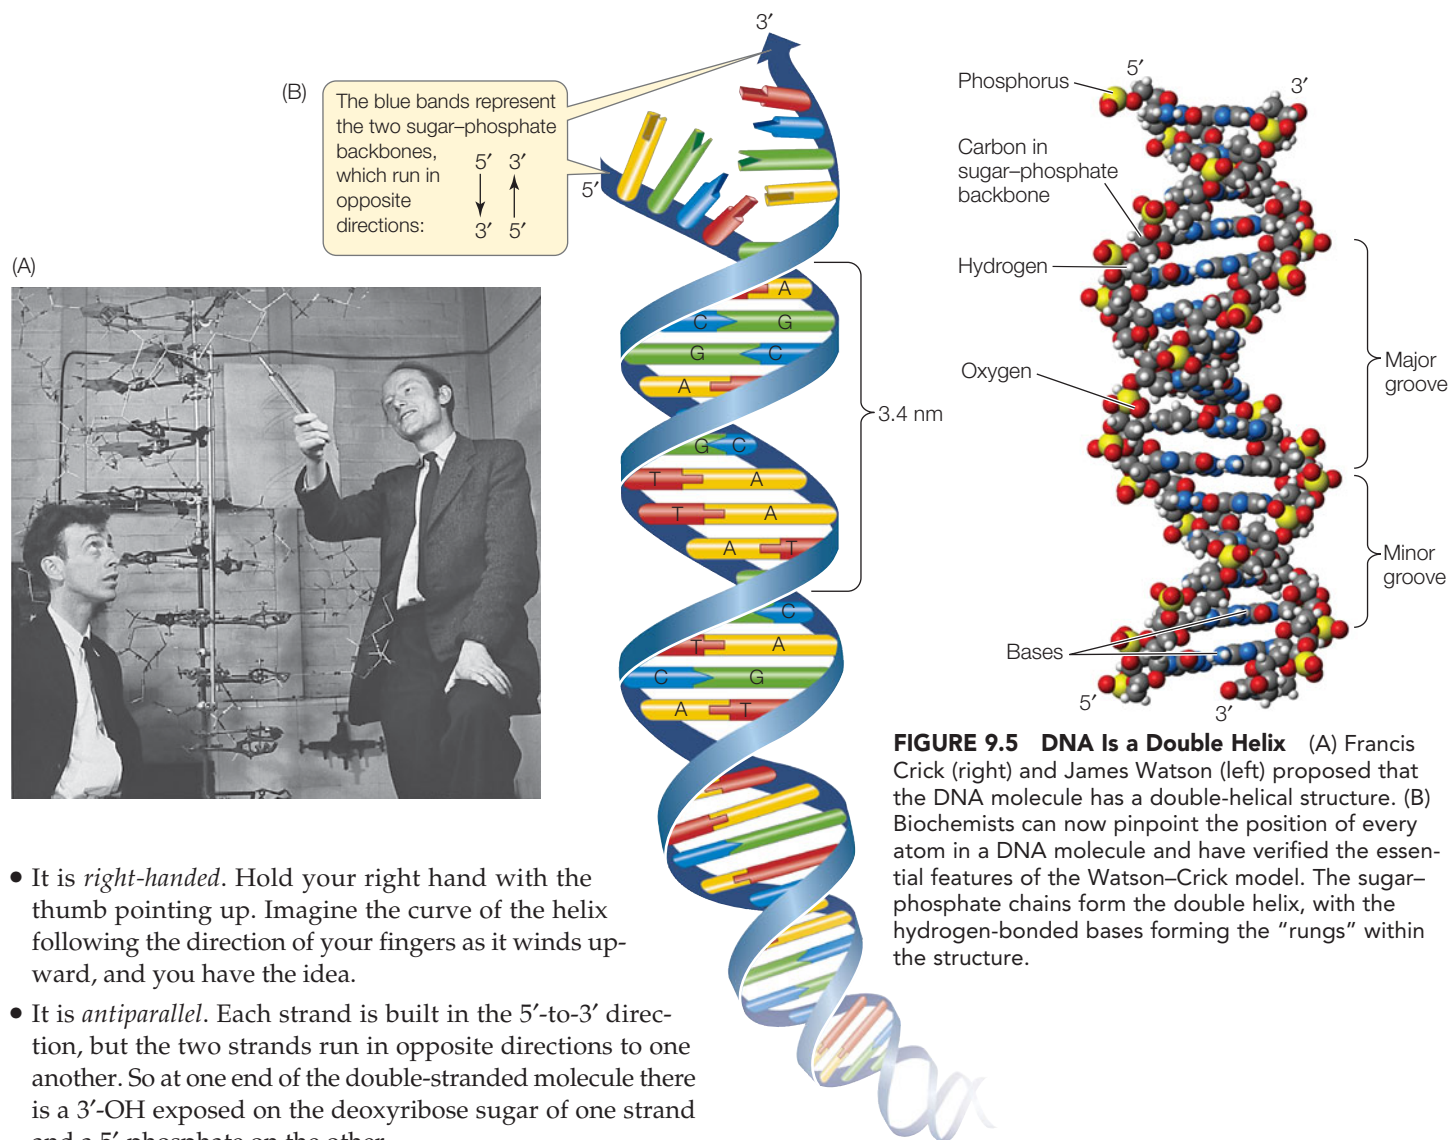

FIGURE 9.5 DNA Is a Double Helix (A) Francis Crick (right) and James Watson (left) proposed that the DNA molecule has a double-helical structure. (B) Biochemists can now pinpoint the position of every atom in a DNA molecule and have verified the essential features of the Watson–Crick model. The sugar-phosphate chains form the double helix, with the hydrogen-bonded bases forming the “rungs” within the structure.

- It is *right-handed*. Hold your right hand with the thumb pointing up. Imagine the curve of the helix following the direction of your fingers as it winds upward, and you have the idea.
- It is *antiparallel*. Each strand is built in the 5'-to-3' direction, but the two strands run in opposite directions to one another. So at one end of the double-stranded molecule there is a 3'-OH exposed on the deoxyribose sugar of one strand and a 5'-phosphate on the other.
- The outer edges of the nitrogenous bases are exposed in the *major and minor grooves*. These grooves exist because the helices formed by the backbones of the two DNA strands are not evenly spaced relative to one another (see Figure 9.5B). **FIGURE 9.6** shows the four possible configurations of the flat, hydrogen-bonded base pairs within the major and minor grooves. The exposed outer edges of the base pairs are accessible for additional hydrogen bonding. Notice that the arrangements of unpaired atoms and groups differ in the A-T base pairs compared with the G-C base pairs. Thus the *surfaces of the A-T and G-C base pairs are chemically distinct*, allowing other molecules, such as proteins, to recognize specific base-pair sequences and bind to them. The atoms and groups in the major groove are more accessible, and tend to bind other molecules more frequently, than those in the minor groove. *This binding of proteins to specific base-pair sequences is the key to protein–DNA interactions*, which are necessary for the replication and expression of the genetic information in DNA.

While most DNA is a right-handed helix, there are some regions that are left-handed. So-called Z-DNA does not have

major and minor grooves and is a tighter helix than normal DNA. Z-DNA appears to form in regions of DNA that are being actively transcribed, and it may play a role in stabilizing the DNA during transcription.

The double-helical structure of DNA is essential to its function

The genetic material performs four important functions, and the DNA structure proposed by Watson and Crick was elegantly suited to three of them.

- *Storage of genetic information.* With its millions of nucleotides, the base sequence of a DNA molecule can encode and store an enormous amount of information. Variations in DNA sequences can account for differences among species and individuals.
- *Precise replication during the cell division cycle.* Replication could be accomplished by complementary base pairing, A with T and G with C. In the original publication of their findings in 1953, Watson and Crick coyly pointed out, “It has not

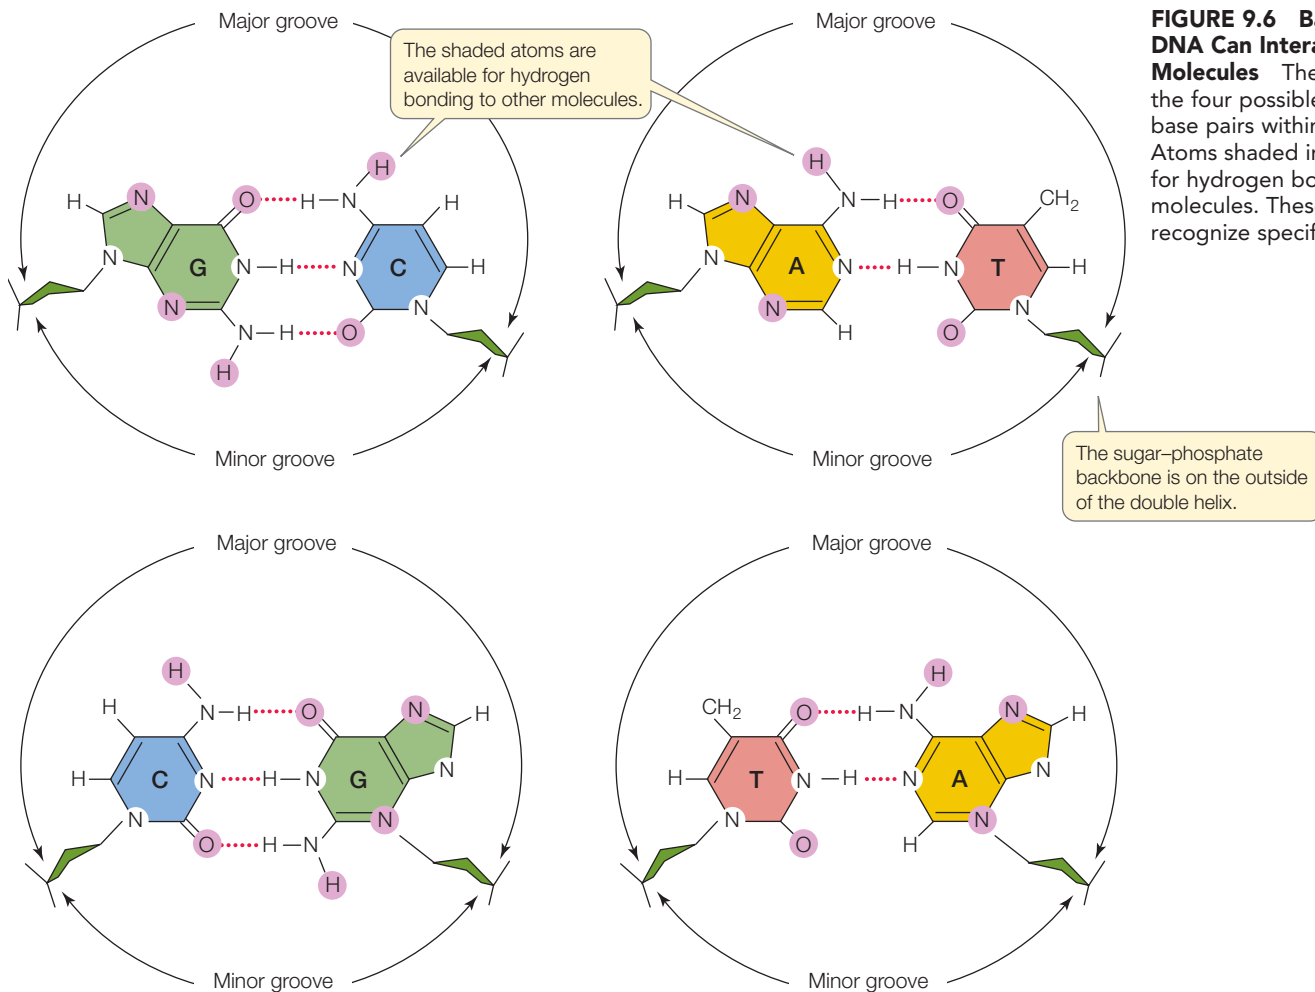

FIGURE 9.6 Base Pairs in DNA Can Interact with Other Molecules These diagrams show the four possible configurations of base pairs within the double helix. Atoms shaded in purple are available for hydrogen bonding with other molecules. These allow proteins to recognize specific DNA sequences.

escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." We will turn to DNA replication in Concept 9.2.

- *Susceptibility to mutations.* The structure of DNA suggested an obvious mechanism for mutations: they might be simple changes in the linear sequence of base pairs. We will discuss mutations in Concept 9.3.
- *Expression of the coded information as phenotypes.* The way this function is accomplished is not obvious in the structure of DNA. However, as we describe briefly in Chapter 3 (see Figure 3.5), the nucleotide sequence of DNA is copied (transcribed) into RNA. The linear sequence of nucleotides in RNA is translated into a linear sequence of amino acids—a protein. The folded forms of proteins determine many of the phenotypes of an organism.

LINK Transcription and translation are described in more detail in Concepts 10.2 and 10.4

Do You Understand Concept 9.1?

- Compare circumstantial evidence with experimental evidence in science, using DNA as an example.
- If a DNA molecule is 20 percent G, what are the percentages of the other three bases?
- Describe the evidence that Watson and Crick used to come up with the double-helix model for DNA.
- What would be the consequences if protein and not DNA were the genetic material? What circumstantial and experimental evidence would be acceptable for this conclusion? How would proteins differ from nucleic acids as informational molecules?

We have seen that a DNA molecule consists of long polymers of nucleotides. An individual DNA strand contains thousands or millions (up to about 1 billion) nucleotides in a precise sequence. How is this huge amount of genetic information replicated?

concept 9.2 DNA Replicates Semiconservatively

An important requirement for the genetic material is that it replicates *both completely and accurately* during the cell division cycle. The double-helix model of DNA suggested to Watson and Crick how this might be accomplished. **Semiconservative replication** means that each strand of the parental DNA acts as a **template** for a new strand, which is added by base pairing:

There is abundant evidence supporting this mechanism. In a typical experiment, the parental DNA (represented by the blue strands above) is labeled in some fashion (for example, with a radioactive isotope) and then allowed to replicate in cells for a generation. As the new DNA strands (red in the diagram) are made, they are unlabeled. A *conservative* mode of replication

would show the parental DNA intact with both strands labeled, and the new DNA with both strands unlabeled. This does not occur. Instead, the resulting DNA molecules are always “hybrids” (one labeled strand and one unlabeled strand), providing experimental evidence to support the semiconservative model of replication.

yourBioPortal.com

Go to ANIMATED TUTORIAL 9.2 Experimental Evidence for Semiconservative DNA Replication

DNA replication involves a number of different enzymes and other proteins. It takes place in two general steps:

1. The DNA double helix is unwound to separate the two template strands and make them available for new base pairing.
2. As new nucleotides form complementary base pairs with template DNA, they are covalently linked together by phosphodiester bonds, forming a polymer whose base sequence is complementary to the bases in the template strand. The template DNA is read in the 3'-to-5' direction.

During DNA synthesis, *nucleotides are added to the 3' end of the growing new strand*—the end at which the DNA strand has a free hydroxyl (—OH) group on the 3' carbon of its terminal

FIGURE 9.7 Each New DNA Strand Grows by the Addition of Nucleotides to Its 3' End The DNA strand at the right (blue) is the template for the synthesis of the complementary strand that is growing at the left (pink). Here dCTP (circled) is being added.

deoxyribose (FIGURE 9.7; see also Figure 3.2). As we noted in Concept 3.1, a free nucleotide can have one to three phosphate groups attached to its pentose sugar. The raw materials for DNA synthesis are the four nucleotides deoxyadenosine triphosphate (dATP), deoxythymidine triphosphate (dTTP), deoxycytidine triphosphate (dCTP), and deoxyguanosine triphosphate (dGTP)—collectively referred to as **deoxyribonucleoside triphosphates (dNTPs)** or *deoxyribonucleotides*. As their names imply, these nucleotides each carry three phosphate groups. During DNA synthesis, the two outer phosphate groups are released in an exothermic reaction. This provides energy for the formation of a phosphodiester bond between the third phosphate group of the incoming nucleotide and the 3' position of the sugar at the end of the DNA chain.

Go to ANIMATED TUTORIAL 9.3 DNA Replication, Part 1: Replication of a Chromosome and DNA Polymerization

DNA polymerases add nucleotides to the growing chain

DNA replication begins with the binding of a large protein complex (the *pre-replication complex*) to a specific site on the DNA molecule. This complex contains several different proteins, among them the enzyme **DNA polymerase**, which catalyzes the addition of nucleotides as the new DNA chain grows. All chromosomes have at least one region called the **origin of replication (*ori*)**, to which the pre-replication complex binds.

Binding occurs when proteins in the complex recognize specific DNA sequences within the *ori*.

ORIGINS OF REPLICATION The single circular chromosome of the bacterium *Escherichia coli* has 4×10^6 base pairs (bp) of DNA. The 245 bp *ori* sequence is at a fixed location on the chromosome. Once the pre-replication complex binds to it, the DNA unwinds and replication proceeds in both directions around the circle, forming two **replication forks** (FIGURE 9.8A). The replication rate in *E. coli* is approximately 1,000 bp per second, so it takes about 40 minutes to fully replicate the chromosome (with two replication forks). Rapidly dividing *E. coli* cells divide every 20 minutes. In these cells, new rounds of replication begin at the *ori* of each new chromosome before the first chromosome has fully replicated. In this way the cells can divide in less time than the time needed to finish replicating the original chromosome.

Eukaryotic chromosomes are much longer than those of prokaryotes—up to a billion bp—and are linear, not circular. If replication occurred from a single *ori*, it would take weeks to fully replicate a chromosome. So eukaryotic chromosomes have *multiple origins of replication*, scattered at intervals of 10,000–40,000 bp (FIGURE 9.8B).

FRONTIERS The organization of multiple DNA growing points along a huge eukaryotic chromosome is not clear. Are the *ori* sequences spaced evenly along the chromosome? How are the many replication forks prevented from interfering with one another? By tagging newly replicating DNA with a visible label, biologists can begin to answer these questions.

FIGURE 9.8 The Origin of DNA Replication (A) Prokaryotic chromosomes have a single origin where DNA replication starts and then proceeds in both directions. (B) In the much larger eukaryotic chromosomes there are multiple origins of replication.

DNA REPLICATION BEGINS WITH A PRIMER DNA polymerase elongates a polynucleotide strand by covalently linking new nucleotides to a preexisting strand. However, it cannot begin this process without a short “starter” strand, called a **primer**. In most organisms this primer is a short single strand of RNA (**FIGURE 9.9**), but in some organisms it is DNA. The primer is complementary to the DNA template and is synthesized one nucleotide at a time by an enzyme called a **primase**. The DNA polymerase then adds nucleotides to the 3′ end of the primer and continues until the replication of that section of DNA has been completed. Then the RNA primer is degraded, DNA is added in its place, and the resulting DNA fragments are connected by the action of other enzymes. When DNA replication is complete, each new strand consists only of DNA.

DNA POLYMERASES ARE LARGE DNA polymerases are much larger than their substrates, the dNTPs, and the template DNA, which is very thin (**FIGURE 9.10A**). Molecular models of the enzyme–substrate–template complex from bacteria show that the enzyme is shaped like an open right hand with a palm, a thumb, and fingers (**FIGURE 9.10B**). Within the “palm” is the active site of the enzyme, which brings together each dNTP substrate and the template. The “finger” regions have precise shapes that can recognize the different shapes of the four nucleotide bases. They bind to the bases by hydrogen bonding and rotate inward.

Most cells contain more than one kind of DNA polymerase, but only one of them is responsible for chromosomal DNA replication. The others are involved in primer removal and DNA repair. Fifteen DNA polymerases have been identified in humans, whereas the bacterium *E. coli* has five DNA polymerases.

FIGURE 9.9 DNA Forms with a Primer The DNA polymerase requires a primer: a “starter” strand of RNA or DNA to which new nucleotides can be added.

APPLY THE CONCEPT

DNA replicates semiconservatively

Each eukaryotic chromosome is composed of a double-stranded DNA molecule. It is possible to use a microscope to distinguish between a chromosome that has been labeled with radioactivity and one that is unlabeled. Plant cells were grown in the lab in the presence of radioactive thymidine for many generations. The cells were then grown for three cell doublings in nonradioactive thymidine so that any new DNA strands would be unlabeled. These cultured cells had synchronized cell cycles. They were examined when they were in anaphase of mitosis.

DOUBLINGS	LABELED CHROMOSOMES (%)
0	100
1	100
2	50
3	25

1. Use diagrams of double-stranded DNA to explain these data.
2. What would the data and diagrams look like if DNA replicated conservatively?

The two DNA strands grow differently at the replication fork

A single replication fork opens up in one direction. Study **FIGURE 9.11** and try to imagine what is happening over a short period of time. For the purpose of understanding the process, imagine that the DNA opens from one end like a zipper (as we have seen, it actually opens up from within the molecule and replication extends in both directions). Remember two things:

- The two DNA strands are antiparallel—that is, the 3' end of one strand is paired with the 5' end of the other.
- DNA replicates in a 5'-to-3' direction.

One newly synthesized strand—the **leading strand**—is oriented so that it can grow continuously at its 3' end as the fork opens up. The other new strand—the **lagging strand**—must be synthesized differently because it grows in the direction away from the replication fork.

Synthesis of the lagging strand requires the synthesis of relatively short, *discontinuous stretches* of sequence (100–200 nucleotides in eukaryotes; 1,000–2,000 nucleotides in prokaryotes). These discontinuous stretches are synthesized just as the leading strand is, by the addition of new nucleotides one at a time to the 3' end, but the new strand grows away from the replication fork. These stretches of new DNA are called **Okazaki fragments** after their discoverer, the Japanese biochemist Reiji Okazaki. To summarize, while the leading strand grows continuously “forward,” the lagging strand grows in shorter, “backward” stretches with gaps between them.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 9.4**
DNA Replication, Part 2: Coordination of
Leading and Lagging Strand Synthesis

FIGURE 9.11 The Two New Strands Form in Different Ways As the parent DNA unwinds, both new strands are synthesized in the 5'-to-3' direction, although their template strands are antiparallel. The leading strand grows continuously forward, but the lagging strand grows in short, discontinuous stretches called Okazaki fragments. Okazaki fragments in eukaryotes are 100 to 200 nucleotides long.

A single primer is needed to initiate synthesis of the leading strand, but each Okazaki fragment requires its own primer to be synthesized by the primase. DNA polymerase then synthesizes an Okazaki fragment by adding nucleotides to one primer until it reaches the primer of the previous fragment. At this point, a different DNA polymerase removes the old primer and replaces it with DNA. Left behind is a tiny nick—the final phosphodiester linkage between the adjacent Okazaki fragments is missing. The enzyme **DNA ligase** catalyzes the formation of that bond, linking the fragments and making the lagging strand whole (**FIGURE 9.12**).

DNA replication may appear complex (we have simplified it considerably), but it occurs with astonishing speed and accuracy. As we mentioned earlier, the rate of replication in *E. coli* is about 1,000 base pairs per second, yet the polymerase commits very few errors—less than 1 base in a million. How do DNA polymerases work so fast? We saw in Concept 3.3 that an enzyme catalyzes a chemical reaction through a series of events:

substrate binds to enzyme → one product is formed →
enzyme is released → cycle repeats

DNA replication would not proceed as rapidly as it does if DNA polymerase went through such a cycle for each nucleotide. Instead, DNA polymerase is **processive**—that is, it *catalyzes many sequential polymerization reactions each time it binds to a DNA molecule*:

substrates bind to enzyme → many products are formed →
enzyme is released → cycle repeats

Typically, a DNA polymerase can add thousands of nucleotides before it detaches from DNA.

Telomeres are not fully replicated in most eukaryotic cells

As we have just seen, replication of the lagging strand occurs by the addition of Okazaki fragments to RNA primers. When the terminal RNA primer is removed from the replicating end of a linear eukaryotic chromosome, no DNA can be synthesized to replace it because there is no 3' end to extend (**FIGURE 9.13A**). So the new chromosome has a bit of single-stranded DNA at each end. This situation activates a mechanism for cutting off the single-stranded region, along with some of the intact double-stranded DNA. Thus the chromosome becomes slightly shorter with each cell division.

Another problem with chromosome ends is that they must be protected from being joined to other chromosomes by the DNA repair system. When DNA is damaged by external or internal agents (e.g., radiation), it is repaired by a combination of DNA polymerase and DNA ligase activities. This system might mistakenly recognize chromosome ends as breaks and join two chromosomes together. This would create havoc with genomic integrity.

To prevent chromosomes from joining, many eukaryotes have strings of repetitive sequences at the ends of their chromosomes called **telomeres**. In humans and other vertebrates, the repeated sequence is TTAGGG, and in humans it is repeated about 2,500 times. These repeats bind special proteins

FIGURE 9.12 The Lagging Strand Story In bacteria, DNA polymerases and DNA ligase cooperate to complete the complex task of synthesizing the lagging strand.

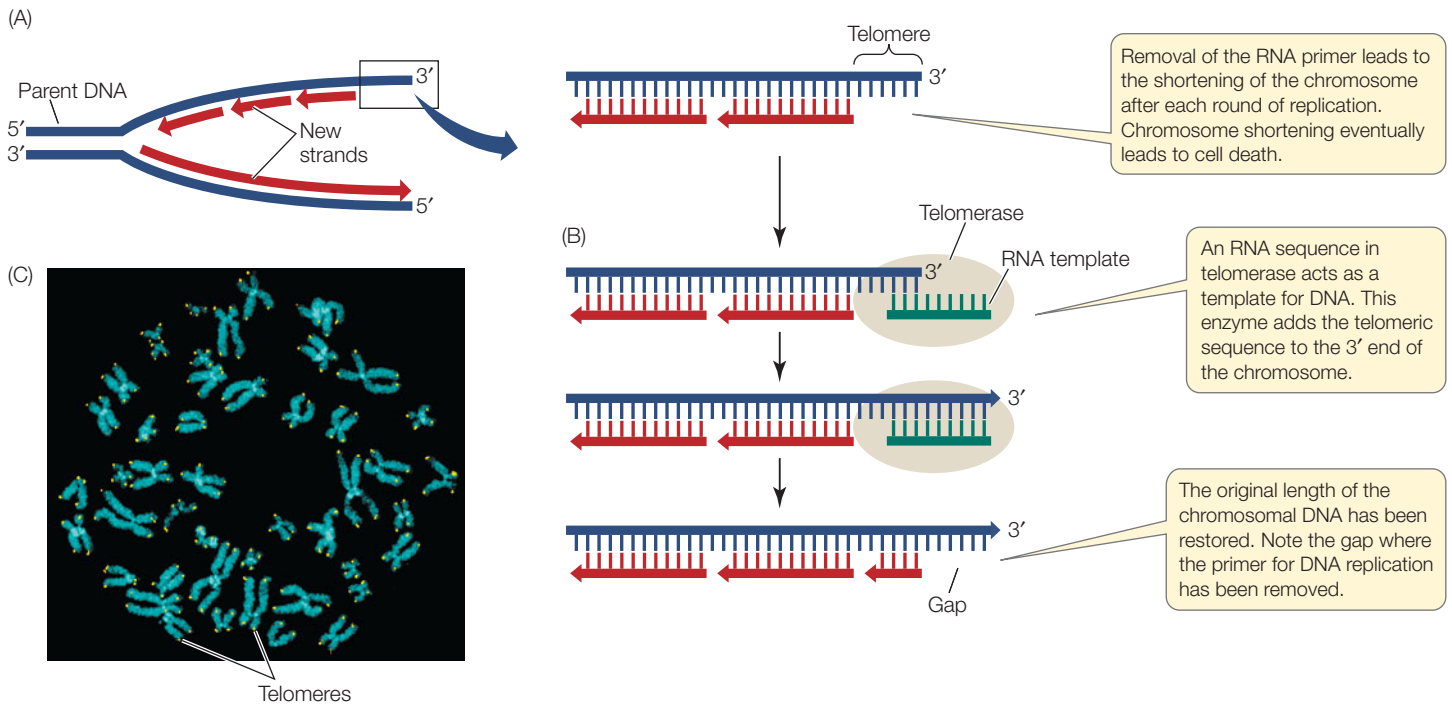

FIGURE 9.13 Telomeres and Telomerase (A) The chromosome ends contain regions of repetitive DNA called telomeres. Removal of the RNA primer at the 3' end of the template for the lagging strand leaves a short sequence that is unreplicated. (B) In continuously dividing cells, the enzyme telomerase binds to the 3' end and extends the lagging strand of DNA, so the chromosome does not get shorter. (Although shown here as a single short sequence, actual telomeres are much longer, with many repeats of a short sequence.) (C) Bright fluorescent staining marks the telomeric regions on these blue-stained human chromosomes.

that protect the ends from being joined together by the DNA repair system. In addition, the repeats form loops that have a similar protective role. So telomeres act like the plastic tips of shoelaces to prevent fraying.

Each human chromosome can lose 50–200 bp of telomeric DNA after each round of DNA replication and cell division. After 20–30 cell divisions, the chromosome ends become short enough to lose their protective role, and the chromosomes lose their integrity. Apoptosis (programmed cell death) ensues, and the cell dies. This phenomenon explains, in part, why many cell lineages do not last the entire lifetime of the organism: their telomeres are lost. Yet continuously dividing cells, such as bone marrow stem cells and gamete-producing cells, maintain their telomeric DNA. An enzyme, appropriately called **telomerase**, catalyzes the addition of any lost telomeric sequences in these cells (**FIGURE 9.13B**). Telomerase contains an RNA sequence that acts as a template for the telomeric DNA repeat sequence.

There is a relationship between telomere length and aging: the average telomere length is shorter in older individuals. Furthermore, when a gene expressing high levels of telomerase is added to human cells in culture, their telomeres do not shorten. Instead of living 20–30 cell generations and then dying, the cells become immortal. It remains to be seen how this finding relates to the aging of a whole organism.

FRONTIERS Telomerase is expressed in more than 90 percent of human cancers and may be an important factor in the ability of cancer cells to divide continuously. Since most normal cells do not have this ability, telomerase is an attractive target for drugs designed to attack tumors specifically.

Errors in DNA replication can be repaired

We have stressed that DNA must be accurately replicated; the accurate transmission of genetic information is essential for the proper functioning and even the life of a single cell or multicellular organism. Yet the replication of DNA is not perfectly accurate. DNA polymerases sometimes insert a base that is not complementary to the template (for example, putting an A in the new DNA strand opposite a C in the template strand). In eukaryotes, the error rate is about 1 incorrect base in 100,000 (a 10^{-5} error rate). With a genome size of 4×10^9 bp, this would produce 40,000 errors after every cell division. This is an intolerable mutation rate for survival in the long term. However, if eukaryotic DNA sequences are studied before and after a cell cycle, the actual frequency of DNA errors is 10^{-10} per cell cycle. This means that most of the errors are repaired. There are two major repair mechanisms:

- **Proofreading** occurs right after DNA polymerase inserts a nucleotide (**FIGURE 9.14A**). When a DNA polymerase recognizes a mispairing of bases, it removes the improperly introduced nucleotide and tries again.
- **Mismatch repair** occurs after DNA has been replicated (**FIGURE 9.14B**). A second set of proteins surveys the newly replicated molecule and looks for mismatched base pairs that were missed in proofreading. A portion of the DNA including the incorrect nucleotide is removed and replaced by DNA polymerase.

FIGURE 9.14 DNA Repair Mechanisms (A) During replication, the DNA polymerase checks for incorrect bases in the new DNA strand and immediately replaces them with correct ones. This process is called proofreading. (B) After replication, mismatch repair proteins search for incorrect bases that were missed by DNA polymerase and replace them.

The basic mechanisms of DNA replication can be used to amplify DNA in a test tube

The principles underlying DNA replication in cells have been used to develop a laboratory technique that has been vital in analyzing DNA, genes, and genomes. The **polymerase chain reaction (PCR)** allows researchers to make multiple copies of short DNA sequences in a test tube—a process referred to as *DNA amplification*. The PCR technique uses:

- a sample of double-stranded DNA, often from a biological sample, to act as the template
- two short, artificially synthesized primers that are complementary to the ends of the sequence to be amplified
- the four dNTPs (dATP, dTTP, dCTP, and dGTP)
- a DNA polymerase that can tolerate high temperatures without becoming denatured
- salts and a buffer to maintain a near-neutral pH.

PCR is a cyclic process in which a sequence of steps is repeated over and over again (**FIGURE 9.15**). Since DNA replication is fast even in a test tube, it takes only a short time to go from 1 to 2 to 4 to million short segments of DNA. The PCR technique requires that the base sequences at each end of the amplified fragment be known ahead of time, so that complementary primers, usually 15–30 bases long, can be made in the laboratory. Because of the uniqueness of DNA sequences, a pair of

yourBioPortal.com

Go to **INTERACTIVE TUTORIAL 9.1**
Polymerase Chain Reaction (PCR): Identifying Pathogens

primers this length will usually bind to only a single region of DNA in an organism's genome. This specificity is a key to the power of PCR to amplify just a small part of a larger DNA molecule. Some of the most striking applications of PCR will be described in Chapters 11 through 13. These applications range from the identification of individuals by their DNA to the detection of diseases.

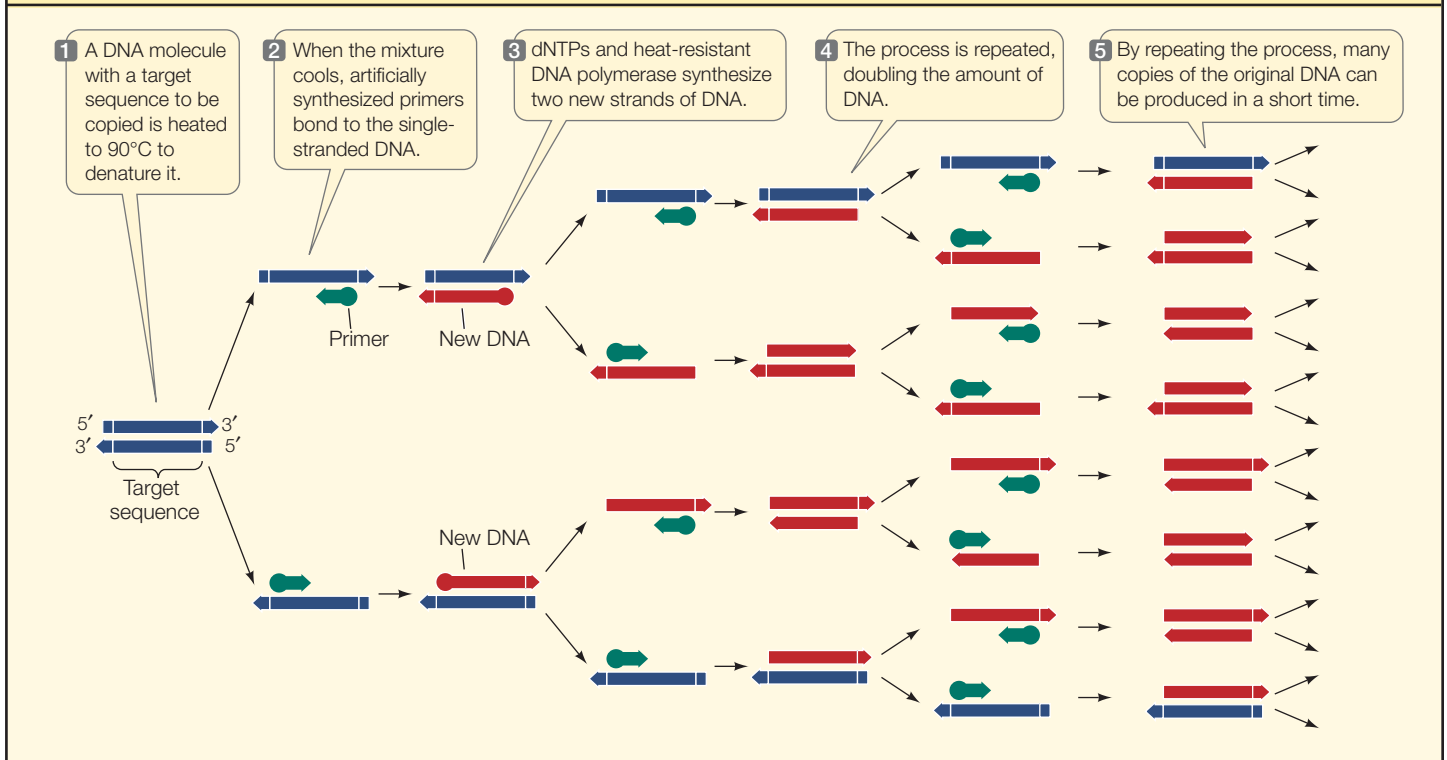

Do You Understand Concept 9.2?

- What is semiconservative DNA replication?
- Why does the leading strand in DNA replicate continuously and the lagging strand discontinuously?
- Cells from older people have shorter telomeres than cells from younger people. How might this relate to aging?
- If you have a small amount of a large chromosome of 20 million bp and want to amplify a short sequence of 1,000 bp, how would you do it? Explain the role of primers in this process.

We have described how the precise replication of DNA satisfies one of the requirements for proving that DNA is the genetic material. A less obvious requirement is its ability to mutate. Mutation is needed to create variability in DNA, which is the raw material for evolution.

RESEARCH TOOLS

FIGURE 9.15 The Polymerase Chain Reaction The steps in this cyclic process are repeated many times to produce millions of identical copies of a DNA fragment. This makes enough DNA for chemical analysis and genetic manipulations.

concept 9.3 Mutations Are Heritable Changes in DNA

In Chapter 8 we describe mutations as inherited changes in genes. A mutation may result in a new allele of a gene, and different alleles may produce different phenotypes (for example, pea plants with wrinkled seeds versus spherical seeds). With reference to the chemical nature of genes, we can state that *mutations are changes in the nucleotide sequence of DNA that are passed on from one cell, or organism, to another.*

Mutations occur by a variety of processes. For example, in Concept 9.2 we described how DNA polymerases make errors. Repair systems such as proofreading are in place to correct them, but some errors escape being corrected and are passed on to the daughter cells.

Mutations in multicellular organisms can be divided into two types:

- **Somatic mutations** occur in somatic (body) cells. They are passed on to the daughter cells during mitosis, and in turn to the offspring of those cells. For example, a mutation in a single skin cell could result in a patch of skin cells that all have the same mutation. However, somatic mutations are not passed on to sexually produced offspring. (Exceptions occur in plants, where germline cells can arise from somatic cells and thus pass on somatic mutations.)

- **Germline mutations** occur in the cells of the *germ line*—the specialized cells that give rise to gametes. A gamete with the mutation passes it on to a new organism at fertilization.

In either case, the mutations may or may not have phenotypic effects.

Mutations can have various phenotypic effects

An organism's genome is the total DNA sequence present in all of its chromosomes (or in its single chromosome, in the case of prokaryotes). Depending on the organism, it can consist of millions or billions of base pairs of DNA. As we discuss further in Chapter 12, most genomes include both genes and regions of DNA that are not expressed:

- Genes are transcribed into RNAs. In most cases these RNAs are in turn translated into the amino acid sequences of proteins. Some other genes are transcribed to produce RNA molecules with catalytic functions, such as ribosomal RNAs. All genes consist of the transcribed region and regions at the 5' and 3' ends, which are not transcribed but have sequences that bind proteins involved in transcription. A protein-coding gene has sequences within the transcribed region that are translated—these are called the *coding regions*.
- Most genomes also contain extensive regions of DNA that are not expressed (see Chapter 12 for more information on those regions).

FIGURE 9.16 Mutation and Phenotype Mutations may or may not affect the function of a protein.

Mutations are often discussed in terms of their effects on protein-coding genes and their functions (FIGURE 9.16):

- **Silent mutations** do not affect gene function. They can be mutations in DNA that is not expressed, or mutations within an expressed region that do not have any effect on the encoded protein. *Most mutations in large genomes are silent.*

LINK Silent mutations are a source of neutral alleles in evolution; see Concept 15.2

- **Loss-of-function mutations** can result in either the loss of expression of a gene or in the production of a nonfunctional protein or RNA. Some loss-of-function mutations prevent a gene from being transcribed or cause transcription to terminate too soon. In other cases the gene is transcribed and translated, but the resulting protein no longer works as a structural protein or enzyme (as illustrated in Figure 9.16). Loss-of-function mutations almost always show recessive inheritance in a diploid organism, because the presence of one wild-type allele usually results in sufficient functional protein for the cell. For example, the wrinkled seed phenotype studied by Mendel (see Figure 8.1) is due to a recessive, loss-of-function mutation in the gene for starch branching enzyme 1 (*SBE1*). Even in plants with only one copy of the wild-type allele, there is enough *SBE1* enzyme to produce the wild-type, spherical phenotype.
- **Gain-of-function mutations** lead to a protein with an altered function. This kind of mutation usually shows dominant

inheritance, because the presence of the wild-type allele does not prevent the mutant allele from functioning. This type of mutation is common in cancer. For example, a receptor for a growth factor normally requires binding of the growth factor (the ligand) to activate the cell division cycle. Some cancers are caused by mutations in genes that encode these receptors so that the receptors are “always on,” even in the absence of their ligands. This leads to the unrestrained cell proliferation that is characteristic of cancer cells.

- **Conditional mutations** cause their phenotypes only under certain *restrictive* conditions. The wild-type phenotype is expressed under other, *permissive* conditions. Many conditional mutants are temperature-sensitive; that is, they show the altered phenotype only at a certain temperature. For example, in cats and rabbits the *C* gene encodes the enzyme tyrosinase, which is involved in pigment production (see Figure 8.9). Some breeds carry the conditional mutant allele c^H , which encodes a tyrosinase protein that denatures easily at temperatures above 35°C. In animals with no dominant wild-type (*C*) allele, the body fur is pale because there is no functional pigment-producing enzyme at body temperature (37°C). However, the extremities—feet, ears, nose, and tail—are cooler, typically less than 30°C, so they are dark:

All mutations are alterations in the nucleotide sequence of DNA. At the molecular level, we can divide mutations into two categories:

- A **point mutation** results from the gain, loss, or substitution of a single nucleotide. After DNA replication, the altered nucleotide becomes a mutant base pair. If a point mutation occurs within a gene, it results in a new allele of that gene. The new allele may or may not result in a new phenotype.
- **Chromosomal mutations** are extensive changes in the chromosomal structure. They may change the position or orientation of a DNA segment without actually removing any genetic information, or they may cause a segment of DNA to be duplicated or irretrievably lost.

Point mutations change single nucleotides

Point mutations result from the addition or subtraction of a nucleotide base, or the substitution of one base for another. Point mutations can arise because of errors in DNA replication that are not corrected during proofreading, or they may be caused by environmental **mutagens**: substances that cause mutations, such as radiation or certain chemicals.

Some point mutations that occur within genes are loss-of-function mutations because they prevent the gene from being

properly transcribed. In other cases the gene is transcribed normally. A point mutation in the coding region of a gene may result in changes in the RNA, but changes in the RNA may or may not result in a change in the amino acid sequence of the protein. If the protein is not changed, the mutation is silent.

LINK The genetic code explains why some point mutations in coding regions of DNA are silent; see Figure 10.11

Other mutations result in altered amino acid sequences, and in some cases these changes can have drastic phenotypic effects. An example of a point mutation with a significant effect on phenotype is the one that causes *sickle-cell disease*, a heritable blood disorder. The disease occurs in people who carry two copies of the sickle allele of the gene for human β -globin (a subunit of hemoglobin, the protein in human blood that carries oxygen—see p. 44). The sickle allele differs from the normal allele by one base pair, resulting in a polypeptide that differs by one amino acid from the normal protein. Individuals who are homozygous for this recessive allele have defective, sickle-shaped red blood cells:

The deformed cells tend to block narrow capillaries, which results in tissue damage. Not all changes in the amino acid sequence of a protein affect its function. For example, a hydrophilic amino acid may be substituted for another hydrophilic amino acid, so that the shape of the protein is unchanged. Or a mutation might result in a protein that has reduced efficiency but is not completely inactivated. Individuals homozygous for a point mutation of this type may survive if enough of the protein's function is retained.

In some cases, gain-of-function point mutations occur. An example is a class of mutations in the human gene *TP53*, which encodes the tumor suppressor protein p53. The p53 protein normally functions to inhibit the cell cycle, but certain mutations cause the protein to promote the cell cycle and prevent programmed cell death. So a p53 protein mutated in this way has a gain of oncogenic (cancer-causing) function.

Chromosomal mutations are extensive changes in the genetic material

The most dramatic changes that can occur in the genetic material are chromosomal mutations. Whole chromosomes can

break and rejoin, grossly disrupting the sequences of genes. There are four types of chromosomal mutations: *deletions*, *duplications*, *inversions*, and *translocations*. This kind of severe damage to chromosomes can result from mutagens or from drastic errors in chromosome replication.

- **Deletions** result in the removal of part of the genetic material (FIGURE 9.17A). Their consequences can be severe or even fatal. It is easy to imagine one mechanism that could produce a deletion: a DNA molecule might break at two points and the two end pieces might rejoin, leaving out the DNA between the breaks.
- **Duplications** can be produced at the same time as deletions (FIGURE 9.17B). A duplication would arise if homologous chromosomes broke at different positions and then reconnected to the wrong partners. One of the two chromosomes produced by this mechanism would lack a segment of DNA (it would have a deletion), and the other would have two copies (a duplication) of the segment that was deleted from the first chromosome.

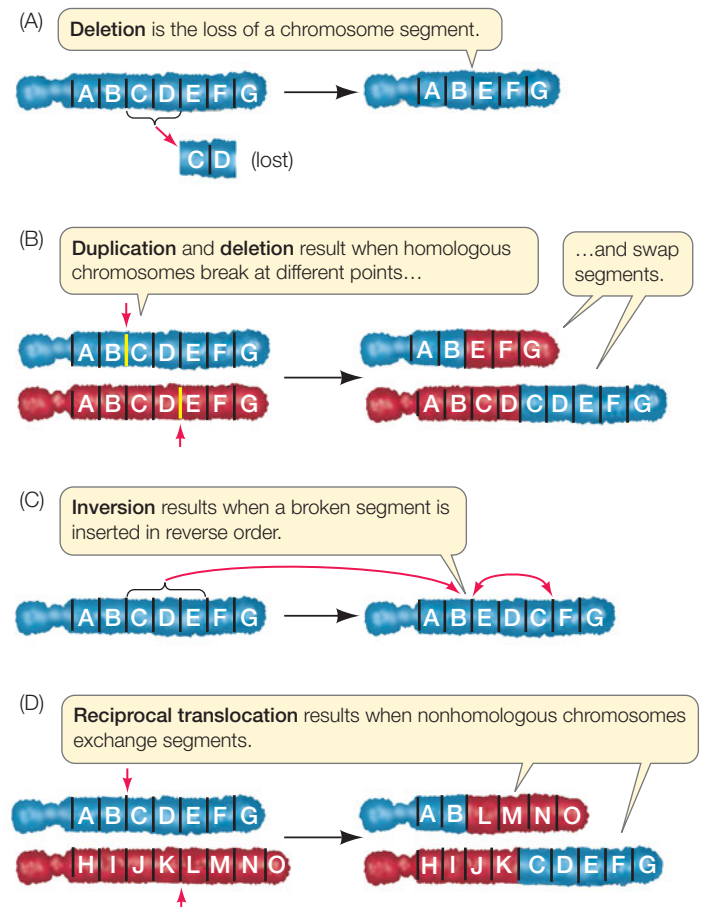

FIGURE 9.17 Chromosomal Mutations Chromosomes may break during replication, and parts of chromosomes may then rejoin incorrectly. The letters on these illustrations represent large chromosomal segments containing anywhere from zero to hundreds or thousands of genes.

- **Inversions** can also result from the breaking and rejoining of chromosomes. A segment of DNA may be removed and reinserted into the same location in the chromosome, but “flipped” end over end so that it runs in the opposite direction (**FIGURE 9.17C**). If either break site occurs within a gene, it is likely to cause a loss-of-function mutation in that gene.
- **Translocations** result when segments of chromosomes break off and become joined to different chromosomes. Translocations may involve reciprocal exchanges of chromosome segments, as in **FIGURE 9.17D**. Translocations often lead to duplications and deletions and may result in sterility if normal chromosome pairing cannot occur during meiosis.

LINK Another way mutations can occur is through mobile DNA elements called transposons; see Figure 12.6

Mutations can be spontaneous or induced

When thinking about the causes of mutations, it is useful to distinguish between mutations that are *spontaneous* and those that are *induced*.

Spontaneous mutations are permanent changes in the genetic material that occur without any outside influence. In other words, they occur simply because cellular processes are imperfect. Spontaneous mutations may occur by several mechanisms:

- *DNA polymerase can make errors in replication.* Most of these errors are repaired by the proofreading function of the replication complex, but some errors escape detection and become permanent.
- *The four nucleotide bases of DNA have alternate structures that affect base pairing.* Each nucleotide can exist in two different forms (called *tautomers*), one of which is common and one rare. When a base temporarily forms its rare tautomer, it can pair with the wrong base (**FIGURE 9.18A, C**).
- *Bases in DNA may change because of spontaneous chemical reactions.* One such reaction is the *deamination* (conversion of an amino group to a keto group) in cytosine to form the base uracil, which pairs with A rather than G. Usually these errors are repaired, but since the repair mechanism is not perfect, the altered nucleotide will sometimes remain and cause a permanent base change after replication.
- *Meiosis is not perfect.* Sometimes errors occur during the complex process of meiosis. This can result in nondisjunction and

(A) A spontaneous mutation

(B) An induced mutation

(C) The consequences of either mutation

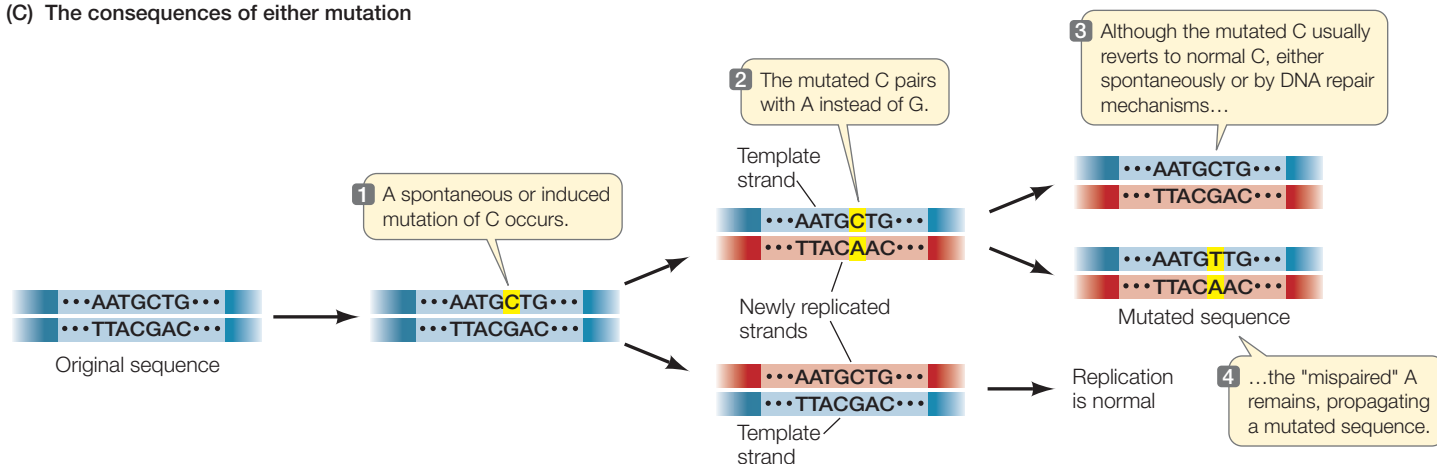

FIGURE 9.18 Spontaneous and Induced Mutations (A) Each nitrogenous base exists in both a common (prevalent) form and a rare form. When a base spontaneously switches to its rare tautomer, it can pair with a different base. (B) Mutagens such as nitrous acid

can induce changes in the bases. (C) The results of both spontaneous and induced mutations are permanent changes in the DNA sequence following replication.

aneuploidy (see Concept 7.4) or chromosomal breakage and rejoining (discussed above).

- *Gene sequences can be disrupted.* Random chromosome breakage and rejoining can produce deletions, duplications, inversions, or translocations.

Induced mutations occur when some agent from outside the cell—a mutagen—causes a permanent change in the DNA sequence:

- *Some chemicals alter the nucleotide bases.* For example, nitrous acid (HNO_2) reacts with cytosine and converts it to uracil by deamination (FIGURE 9.18B). This alteration has the same result as spontaneous deamination: instead of a G, DNA polymerase inserts an A (see Figure 9.18C).
- *Some chemicals add groups to the bases.* An example is benzopyrene, a component of cigarette smoke that adds a large chemical group to guanine, making it unavailable for base pairing. When DNA polymerase reaches such a modified guanine, it inserts any one of the four bases, resulting in a high frequency of mutations.
- *Radiation damages the genetic material.* Radiation can damage DNA in three ways. First, ionizing radiation (including X rays, gamma rays, and particles emitted by unstable isotopes) can detach electrons from atoms or molecules and produce highly reactive chemicals called *free radicals*. Free radicals can change bases in DNA to forms that are not recognized by DNA polymerase. Second, ionizing radiation can also break the sugar–phosphate backbone of DNA, causing chromosomal abnormalities. And third, ultraviolet radiation (from the sun or a tanning lamp) can cause thymine bases to form covalent bonds with adjacent thymines. This, too, plays havoc with DNA replication by distorting the double helix, and can result in a mutation.

Some base pairs are more vulnerable than others to mutation

DNA sequencing has revealed that mutations occur most often at certain base pairs. These “hotspots” are often located where cytosine has been methylated to 5-methylcytosine. (Methylation of DNA is a normal process in the regulation of chromatin structure and gene expression; see Concept 11.3.)

As we discussed above, unmethylated cytosine can lose its amino group to form uracil (see Figure 9.18B). This error is usually repaired because uracil (which normally occurs in RNA) is recognized by the repair mechanism as an inappropriate component of DNA. When 5-methylcytosine loses its amino group, however, the product is thymine, a natural base in DNA. The DNA repair mechanism ignores the thymine, and in this case, half of the new DNA molecules contain A-T base pairs instead of the original G-C pair (FIGURE 9.19). Thus the frequency of mutation is much greater in regions containing 5-methylcytosine.

FIGURE 9.19 5-Methylcytosine in DNA Is a “Hotspot” for Mutations If cytosine has been methylated to 5-methylcytosine and then becomes deaminated, the mutation is usually not repaired, and a C-G base pair is replaced with a T-A base pair.

Mutagens can be natural or artificial

Many people associate mutagens with materials made by humans, but there are also many naturally occurring mutagens. Plants (and to a lesser extent animals) make thousands of small molecules that serve a range of purposes, including defense against pathogens (see Concept 28.1). Some of these are mutagenic and potentially carcinogenic. An example of a naturally occurring mutagen is aflatoxin, which is made by the mold *Aspergillus*. When mammals ingest the mold, the aflatoxin is converted into a product that binds to guanine and causes mutations, just as benzopyrene from cigarette smoke does.

Radiation can be human-made or natural. Some of the isotopes made in nuclear reactors and nuclear bomb explosions are certainly harmful—as was shown by the increased mutation rates in survivors of the atom bombs dropped on Japan in 1945. A certain amount of radiation comes from space in the form of cosmic radiation, and as mentioned above, natural ultraviolet radiation in sunlight also causes mutations.

Biochemists have estimated how much DNA damage occurs in the human genome under normal circumstances: among the haploid genome’s 3 billion base pairs, there are about 16,000 DNA-damaging events per cell per day, of which 80 percent are repaired.

Mutations have both benefits and costs

What is the overall effect of mutation? For a species as a whole, the evolutionary benefits are clear. But there are costs as well as benefits for individual organisms.

BENEFITS OF MUTATIONS Mutations are the raw material of evolution. As you will see in Part 3 of this book, mutation alone does not drive evolution, but it provides the genetic diversity that makes natural selection possible. A mutation in a germline cell may have no immediate selective advantage to the organism, but it may cause a phenotypic change in the offspring. If

APPLY THE CONCEPT

Mutations are changes in DNA

Nitrosamines (R-N-NO₂) are potent mutagens. They can be formed from the reaction of nitrites (R-NO₂) with amino groups in proteins. So there are concerns about using nitrites to preserve meats, which contain amino groups. An experiment was performed to test the effect of vitamin C (ascorbate) on mutagenesis by meats cured with nitrites. Bacterial cells were incubated with cured meat extracts in the presence or absence of ascorbate. The rate of mutation (number of mutant bacteria per total bacteria) was determined:

1. What did the experiment with no extract and no ascorbate show?
2. What did the experiments with increasing amounts of extract and no ascorbate show?
3. What was the effect of ascorbate on the mutation rate?
4. In the bacterium tested, the wild-type DNA had the sequence 5'-ACTTAT-3', and the mutated strain had the

sequence 5'-ATTTAT-3'. What does this tell you about the nature of the mutation involved? Clearly outline the steps in mutagenesis, noting DNA replication(s).

the environment changes in a later generation, that mutation may be advantageous, enabling the species as a whole to adapt to changing conditions. A mutation in a somatic cell can sometimes benefit the individual organism, particularly if it occurs in a stem cell that produces a large number of offspring cells.

COSTS OF MUTATIONS Mutations can be harmful if they result in the loss of function of genes (and their protein products) or other DNA sequences that are needed for survival. A harmful mutation in a germline cell may be inherited in heterozygous form by the organism's descendants. If two individuals carrying the mutation mate, some of the offspring may be homozygous for the mutation. In their extreme form, such mutations produce phenotypes that are lethal. Lethal mutations can kill an organism during early development, or the organism may die before it matures and reproduces.

In Chapter 7 we described how mutations in somatic cells can lead to cancer. Typically these are mutations in *oncogenes* that result in the stimulation of cell division, or mutations in *tumor suppressor genes* that result in a lack of inhibition of cell division. These mutations can occur by either spontaneous or induced mutagenesis.

MINIMIZING EXPOSURE TO MUTAGENS While spontaneous mutagenesis is not in our control, we can certainly try to avoid mutagenic substances and radiation. Not surprisingly, many things that cause cancer (carcinogens) are also mutagens. A good example is benzopyrene (discussed above), which is found in coal tar, car exhaust fumes, and charbroiled foods, as well as in cigarette smoke.

A major public policy goal is to minimize the effects of both human-made and natural mutagens on human health. For example, the Montreal Protocol is the only international environmental agreement signed and adhered to by all nations. It bans

chlorofluorocarbons and other substances that cause depletion of the ozone layer in the upper atmosphere of Earth. The ozone layer is important for screening out ultraviolet radiation from the sun. Ultraviolet radiation can cause somatic mutations that lead to skin cancer. Similarly, bans on cigarette smoking have rapidly spread throughout the world. Cigarette smoking causes cancer because of the increased exposure of lung and other cells to benzopyrene and other carcinogens.

Do You Understand Concept 9.3?

- What are the differences between a germline mutation and a somatic mutation?
- Describe how the same base, cytosine, can be mutated spontaneously or by a mutagen. In which case would the mutation be efficiently repaired?
- The mutation *Bar eyes* in fruit flies was found in genetic crosses to be inherited as an autosomal (non-X chromosome) dominant. Would you expect the mutant allele to be a loss-of-function or a gain-of-function mutation? Explain your answer.

What can we learn from ancient DNA?

ANSWER As we described in the opening story of this chapter, studying the DNA of fossils is a challenge. DNA is a large polymer that is rather stable (Concept 9.1). However, during the formation of fossils, most of the soft tissues and

cells are broken down and their contents consumed by organisms in the environment. So it is not surprising that research on ancient DNA has been focused on places where DNA is likely to be preserved intact, such as frozen specimens and the interior of bones.

The polymerase chain reaction (PCR; Concept 9.2) has been invaluable in amplifying tiny amounts of ancient DNA to be sequenced. However, even a single molecule of contaminating DNA can ruin the experiment, because it too will be amplified. This has been a major challenge in studies of ancient DNA related to humans.

The Neandertal Genome Project involves an international team of scientists who are extracting DNA from the bones of skeletons of Neanderthals who lived in Europe over 50,000 years ago, amplifying it by PCR and then examining the genes. The entire DNA sequence has been completed. It is over 99 percent identical to our human DNA, justifying the classification of Neanderthals as part of the same genus, *Homo*.

Comparisons of humans and Neanderthals with regard to specific genes and mutations (Concept 9.3) is ongoing and has already shown several interesting facts:

- The gene *MC1R* is involved in skin and hair pigmentation. A point mutation found in Neanderthals but not humans caused lower activity of the MC1R protein when it was induced in cell cultures. Such lower activity of MC1R is known to result in fair skin and red hair in humans. So it appears that at least some Neanderthals may have had pale skin and red hair (FIGURE 9.20).
- The gene *FOXP2* is involved in vocalization in many organisms, including birds and mammals. Mutations in this gene result in severe speech impairment in humans. The Neanderthal *FOXP2* gene is identical to that of humans, whereas that of chimpanzees is slightly different. This has led to speculation that Neanderthals may have been capable of speech.
- While the two genome sequences are very similar, there are differences in many point mutations and larger

FIGURE 9.20 A Neanderthal Child This reconstruction of a Neanderthal child who lived about 60,000 years ago was made using bones recovered at Gibraltar, as well as phenotypic projections made from DNA analyses.

chromosomal arrangements (Concept 9.3). There are distinctive “human” DNA sequences and also distinctive “Neanderthal” sequences. There is some mixture of the two, suggesting that humans and Neanderthals may have interbred.

These fascinating reconstructions of ancient DNAs and their phenotypic expression are being repeated for many other species. They serve to underline the universality of DNA as the genetic material.

From DNA to Protein: Gene Expression

10

Humans have more prokaryotic cells on and in their bodies than they have eukaryotic cells of their own. Among the billions of bacteria that inhabit the skin and noses of many people is *Staphylococcus aureus*. Healthy people can carry this bacterium without symptoms, but sometimes, especially when the immune system has been weakened by age or disease, *S. aureus* can cause major skin infections and may even enter the body through the nose or a wound site. In these cases, much more serious infections of organs such as the heart and lungs can occur, and may even result in death.

Until recently, most *S. aureus* infections were successfully treated with penicillin and related drugs, including methicillin. These antibiotics block several related enzymes known as penicillin binding proteins, which are involved in the assembly of bacterial cell walls. Bacteria treated with these antibiotics have defective cell walls, and because of this, new bacterial cells cannot survive after cell division. Unfortunately, some *S. aureus* strains have acquired mutant versions of a penicillin binding protein that can assemble cell walls in the presence of the antibiotics, thus conferring antibiotic resistance to these strains. The mutant penicillin binding protein has an altered shape that doesn't bind the antibiotics. This protein is encoded by the *mecA* gene, which can be passed from one bacterium to another by bacterial conjugation (see Concept 8.4). At a more general level, the mutant phenotype demonstrates that a *gene is expressed as a protein*.

By the late 1990s these bacterial strains were being called "superbugs," with the formal name "methicillin resistant *S. aureus*," or MRSA. The first decade of

the new millennium saw a dramatic rise in MRSA infections. At first, most cases occurred in hospitals and nursing homes, but more recently MRSA has become rampant in communities as well. Resistant strains have a selective advantage because of the extensive use of antibiotics in health care. With close to 100,000 serious MRSA infections and 20,000 deaths in the United States each year, more people are dying from this infection than from AIDS.

MRSA can be treated if detected early. Antibiotics such as tetracycline, which targets bacterial protein synthesis, are effective in some strains. But there is reasonable concern that MRSA may become resistant to these antibiotics as well.

Although these *Staphylococcus aureus* cells look like normal bacteria, they have genes for resistance to multiple antibiotics and are difficult to eradicate. This is an increasing challenge to public health.

How do antibiotics such as tetracycline target bacterial protein synthesis?

concept 10.1 Genetics Shows That Genes Code for Proteins

Following Mendel's definition of the gene as a physically distinct entity (see Concept 8.1), biologists identified the genetic material as DNA (see Concept 9.1). In this chapter we will show that in most cases, genes code for proteins, and it is proteins that determine phenotypes. The connection between protein and phenotype was made before it was known that DNA is the genetic material.

Observations in humans led to the proposal that genes determine enzymes

The identification of a gene product as a protein began with a mutation. In the early twentieth century, the English physician Archibald Garrod saw several children with a rare disease. One symptom was that the urine turned dark brown or black in air, and for this reason the disease was named *alkaptonuria* ("black urine").

Garrod noticed that the disease was most common in children whose parents were first cousins. Mendelian genetics had just been "rediscovered," and Garrod realized that because first cousins share some alleles from each of their grandparents, the children of first cousins are more likely than other children to inherit rare mutant alleles in the homozygous condition. He proposed that alkaptonuria was a phenotype caused by a recessive, mutant allele.

Garrod took the analysis a step further by identifying the biochemical abnormality in the affected children. He isolated from them an unusual substance, homogentisic acid, which accumulated in the blood, joints (where it crystallized and caused severe pain), and urine (where it turned black when exposed to air).

Enzymes as biological catalysts had just been discovered, and Garrod proposed that in healthy individuals, homogentisic acid might be broken down to a harmless product by an enzyme. He speculated that the synthesis of this enzyme is determined by the wild-type allele of the gene that was mutated in alkaptonuria patients. These and other studies led Garrod to correlate *one gene to one enzyme*, and to coin the term "inborn error of metabolism" to describe this kind of genetically determined biochemical disease.

But Garrod's hypothesis needed direct confirmation by the identification of the specific enzyme and the specific gene mutation involved. In 1958 the enzyme was identified as homogentisic acid oxidase, which breaks down homogentisic acid to a harmless product, just as Garrod predicted (FIGURE 10.1). The specific DNA mutation was described in 1996.

Homogentisic acid is part of a biochemical pathway that catabolizes proteins, with the amino acids phenylalanine and tyrosine as intermediate products. Another genetic disease involving this pathway was discovered several decades after Garrod did his work. In *phenylketonuria*, the enzyme that converts phenylalanine to tyrosine is nonfunctional (see Figure 10.1). Untreated, this disease leads to significant mental

FIGURE 10.1 Metabolic Diseases and Enzymes Both phenylketonuria and alkaptonuria are caused by abnormalities in specific enzymes in a pathway that breaks down proteins.

retardation. Fortunately, the accumulation of phenylalanine can be easily detected in the blood of a newborn infant, and if the child consumes a diet low in proteins containing phenylalanine, mental retardation is avoided.

FRONTIERS Inborn errors of metabolism cause multiple symptoms, which usually vary in severity. While the specific gene mutations and resulting enzyme defects are known for many of these genetic diseases, we don't know why many of them cause mental retardation in infants if untreated, or why some infants are relatively less affected than others. Animal models for these diseases will be useful in answering these questions.

The concept of the gene has changed over time

The phenotypic expression of mutations underlying alkaptonuria and phenylketonuria led to the *one gene–one protein* hypothesis. Once it was known that proteins are polymers of amino acids, and that the sequence of amino acids determines

APPLY THE CONCEPT

Genetics shows that genes code for proteins

Wild-type bacteria can synthesize the amino acid tryptophan (T) using a biochemical pathway that begins with chorismate (C). But strains with mutant alleles for enzymes involved in this pathway cannot synthesize tryptophan, and it must be supplied as a nutrient in the growth medium. The pathway involves four intermediates that we will call D, E, F, and G. In the table are the phenotypes of various mutant strains, each of which has a mutation in a gene for a different enzyme. “+” means the strain grew with the indicated compound added to the medium, and “0” means it did not grow.

Based on these data, order the compounds (C, D, E, F, and T) and enzymes (1, 2, 3, 4, and 5) in a biochemical pathway. Hint: Mutant strain 5 will not grow if any compound

MUTANT STRAIN	ADDITION TO THE MEDIUM					
	C	D	E	F	G	T
1	0	0	0	0	+	+
2	0	+	+	0	+	+
3	0	+	0	0	+	+
4	0	+	+	+	+	+
5	0	0	0	0	0	+

except T is supplied, so it must carry a loss-of-function mutation in the enzyme that transforms another molecule (C, D, E, F, or G) into T. Thus, enzyme 5 is the final enzyme in the pathway.

protein function, it became clear that *a mutant phenotype arises from a change in the protein's amino acid sequence*. However, scientists soon realized that the one gene–one protein hypothesis was an oversimplification. Once again, studies of human mutations were a key to this realization.

In humans, the oxygen-carrying protein hemoglobin has a quaternary structure: it is made up of four polypeptide chains—two α -chains and two β -chains (see the illustration in Concept 3.2, p. 44). In Concept 9.3 we introduce sickle-cell disease, which is caused by a point mutation in the gene for β -globin and is inherited as an autosomal recessive (carried on an autosome rather than a sex chromosome). One of the 146 amino acids in the β -globin chain is abnormal: at position 6, the normal glutamic acid has been replaced by valine. This replacement changes the charge of the protein (glutamic acid is negatively charged and valine is neutral), causing it to form long, needlelike aggregates in the red blood cells. The phenotypic result is anemia, an impaired ability of the blood to carry oxygen.

Because hemoglobin is easy to isolate and study, its variations in the human population have been extensively documented (FIGURE 10.2). Hundreds of single amino acid alterations in β -globin have been reported. For example, at the same position that is mutated in sickle-cell disease (resulting in hemoglobin S), the normal glutamic acid may be replaced by lysine, causing hemoglobin C disease. In this case, the resulting anemia is usually not severe. Many alterations of hemoglobin do not affect the protein's function. That is fortunate, because about 5 percent of all humans are carriers for one of these variants.

Studies of proteins like hemoglobin, which are made up of multiple polypeptides, resulted in a modification of the one gene–one protein hypothesis. Scientists began to think of the relationship as **one gene–one polypeptide**. This remains a powerful and useful concept today. However, as you will see later in this chapter and in Chapter 11, we are learning that this, too, is an oversimplification.

The mutations we have been discussing result in alterations in amino acid sequences. But not all genes code for polypeptides. As we will see below and in Chapter 11, there are many DNA sequences that are transcribed into RNA molecules that are *not* translated into polypeptides, but instead have other functions. Like any DNA sequences, these RNA genes are also subject to mutations that can affect the functions of the RNAs they produce.

Genes are expressed via transcription and translation

Molecular biology is the study of nucleic acids and proteins, and it often focuses on gene expression. As we describe briefly in

	Amino acid position (of 146)									
	2	6	7	16	24	26	56	63	95	
A (Wild type)	His	Glu	Glu	Gly	Gly	Glu	Gly	His	Lys	
Tokuchi	Tyr									
S		Val								
C		Lys								
G			Gly							
J Baltimore				Asp						
Savannah					Val					
E						Lys				
Bangkok							Asp			
Zürich								Arg		
M Saskatoon								Tyr		
N Baltimore									Glu	

Only three hemoglobin variants (S, C, and E) lead to clinical problems.

FIGURE 10.2 Gene Mutations and Amino Acid Changes Each of these mutant alleles (e.g., hemoglobin Tokuchi) codes for a β -globin polypeptide with an alteration in one of its 146 amino acids (e.g., a change from His to Tyr at position 2 of the polypeptide).

Chapter 3, genes are expressed as RNAs, some of which are translated into proteins. This process involves two steps:

- During **transcription**, the information in a DNA sequence (a gene) is copied into a complementary RNA sequence.
- During **translation**, this RNA sequence is used to create the amino acid sequence of a polypeptide.

Here we will consider three types of RNA with regard to their roles in protein synthesis:

- **Messenger RNA and transcription:** When a particular gene is expressed, one of the two DNA strands in the gene is transcribed (copied) to produce a complementary RNA strand, which is then modified to produce a **messenger RNA (mRNA)**. In eukaryotic cells, the mRNA travels from the nucleus to the cytoplasm, where it is translated into a polypeptide (**FIGURE 10.3**). The nucleotide sequence of the mRNA determines the ordered sequence of amino acids in the polypeptide chain, which is built by a ribosome.
- **Ribosomal RNA and translation:** The **ribosome** is essentially a protein synthesis factory with multiple proteins and several **ribosomal RNAs (rRNAs)**. One of the rRNAs catalyzes peptide bond formation between amino acids to form a polypeptide.
- **Transfer RNA mediates between mRNA and protein:** A third RNA called **transfer RNA (tRNA)** can both bind a specific amino acid and recognize a specific sequence of nucleotides in mRNA, by complementary base pairing (A with U, and G with C). It is the tRNA that recognizes which amino acid should be added next to a growing polypeptide chain (see Figure 10.3).

In Chapter 11 we will consider other RNAs that play roles in the regulation of gene expression.

Do You Understand Concept 10.1?

- What is the difference between the “one gene–one enzyme” and “one gene–one polypeptide” hypotheses?
- What is the difference between gene transcription and translation?
- Could a person inherit alleles for both alkaptonuria and phenylketonuria? If so, what would the symptoms be?
- Defining phenotype as the presence of a polypeptide chain of a particular amino acid sequence, would you expect the Zürich variant of β -globin (see Figure 10.2) to be inherited as a dominant, recessive, or codominant? Explain your answer.

In this section we have shown how the connection between genes and phenotypes can be understood in terms of DNA and proteins. We will now turn to some details of the process of gene expression, which is at the heart of what genes do.

FIGURE 10.3 From Gene to Protein This diagram summarizes the processes of gene expression in eukaryotes.

yourBioPortal.com

Go to WEB ACTIVITY 10.1
Eukaryotic Gene Expression

concept 10.2 DNA Expression Begins with Its Transcription to RNA

Transcription—the formation of a specific RNA sequence from a specific DNA sequence—requires several components:

- A *DNA template* for complementary base pairing
- The appropriate *nucleoside triphosphates* (ATP, GTP, CTP, and UTP) to act as substrates
- An *RNA polymerase* enzyme

In addition to mRNA, other types of RNA are produced by transcription. The same process is responsible for the synthesis of tRNA and rRNA, whose important roles in protein synthesis will be described in Concepts 10.3 and 10.4. Like mRNA, these RNAs are encoded by specific genes. There are in fact many kinds of RNA with other functions in the cell. For example, *small nuclear RNAs* are components of snRNPs (see below); and *microRNAs* play roles in stimulating or inhibiting gene expression (see Concept 11.4).

RNA polymerases share common features

RNA polymerases from both prokaryotes and eukaryotes catalyze the synthesis of RNA from the DNA template. There is only one kind of RNA polymerase in bacteria and archaea,

FIGURE 10.4 RNA Polymerase This enzyme from bacteriophage T7 is smaller than most other RNA polymerases, but has an active site similar to the bacterial and eukaryotic enzymes.

whereas there are several kinds in eukaryotes. However, they all share a common structure (FIGURE 10.4). Like DNA polymerases, RNA polymerases are *processive*; that is, a single enzyme–template binding event results in the polymerization of hundreds of RNA nucleotides. But unlike DNA polymerases, RNA polymerases do not require a primer.

Transcription occurs in three steps

Transcription can be divided into three distinct processes: initiation, elongation, and termination. You can follow these processes in FIGURE 10.5.

INITIATION Transcription begins with initiation, which requires a **promoter**, a special DNA sequence to which the RNA polymerase binds very tightly (see Figure 10.5A). Promoters are important control sequences that “tell” the RNA polymerase two things:

- Where to start transcription
- Which of the two DNA strands to transcribe

The promoter has a nucleotide sequence that can be “read” in a particular direction and orients the RNA polymerase, thus “aiming” it at the correct strand to use as a template. A promoter

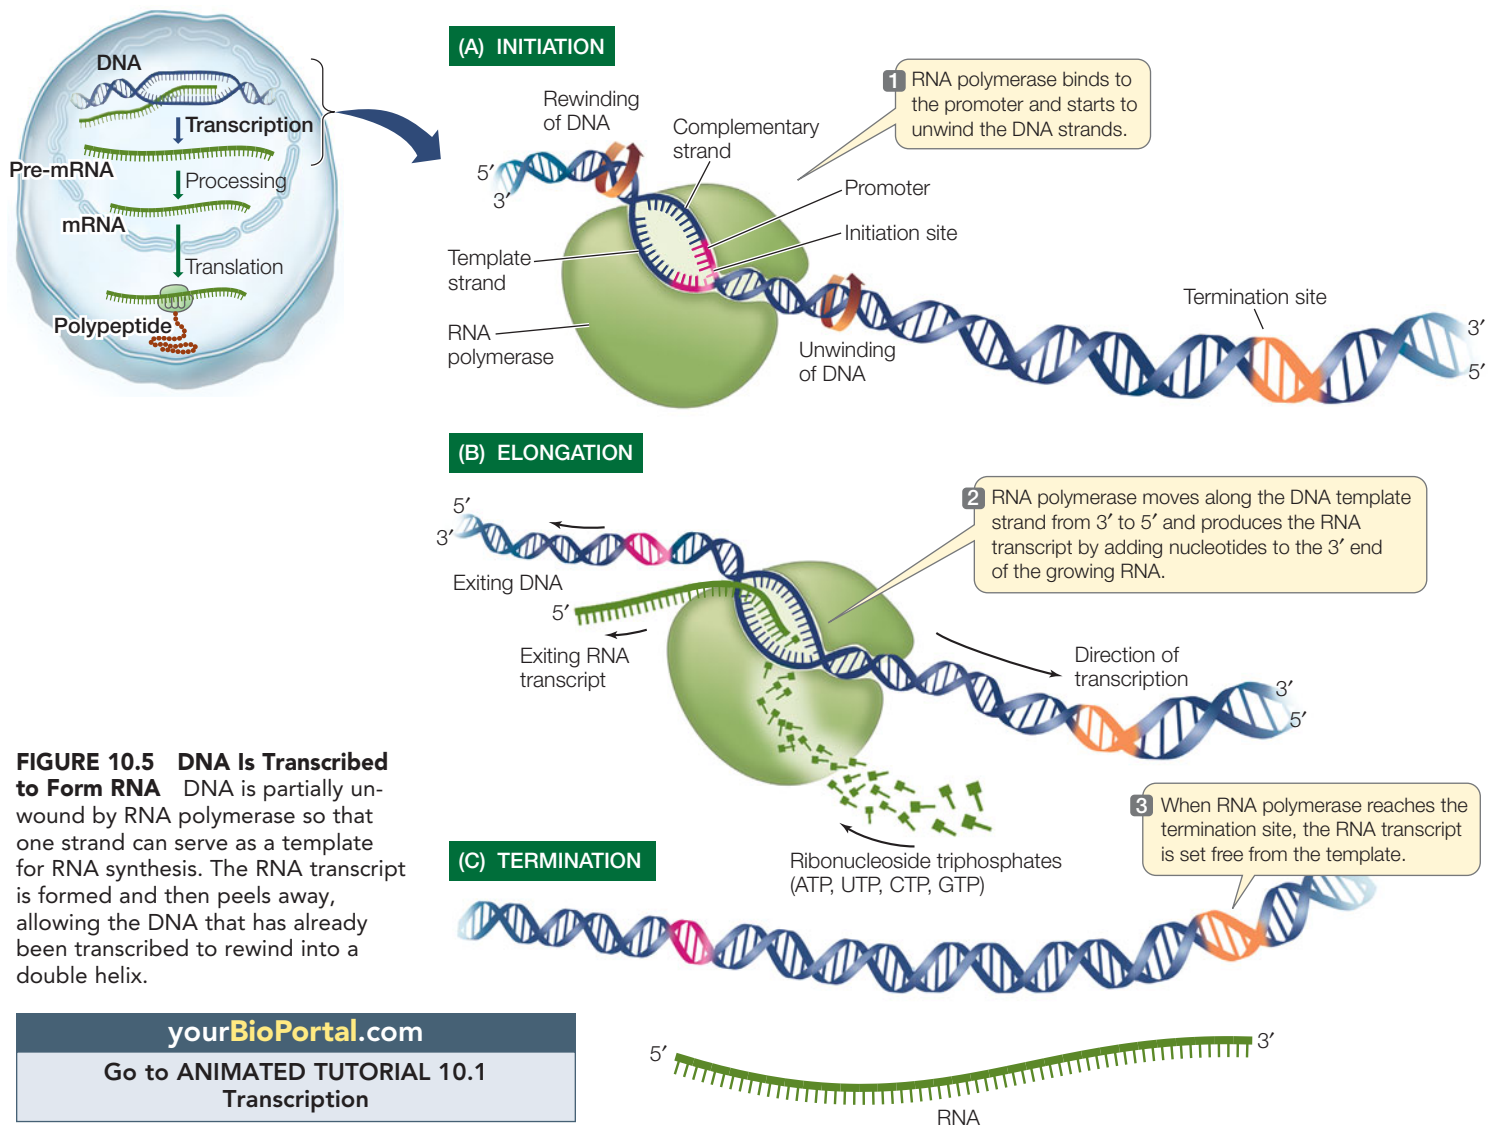

FIGURE 10.5 DNA Is Transcribed to Form RNA DNA is partially unwound by RNA polymerase so that one strand can serve as a template for RNA synthesis. The RNA transcript is formed and then peels away, allowing the DNA that has already been transcribed to rewind into a double helix.

Transcription

functions somewhat like the capital letter at the beginning of a sentence, indicating how the sequence of words should be read. Part of each promoter is the **transcription initiation site**, where transcription begins. Groups of nucleotides lying “upstream” from the initiation site (5′ on the non-template strand and 3′ on the template strand) are bound by other proteins, which help the RNA polymerase bind.

Although every gene has a promoter, not all promoters are identical. Some promoters are more effective at transcription initiation than others. Furthermore, bacteria, archaea, and eukaryotes differ in the details of transcription initiation. But despite these variations, the basic mechanisms of initiation are the same throughout the living world.

LINK The mechanisms of transcription and translation are discussed in an evolutionary context in Chapter 19

ELONGATION Once RNA polymerase has bound to the promoter, it begins the process of **elongation** (see Figure 10.5B). RNA polymerase unwinds the DNA about 13 base pairs at a time and reads the template strand in the 3′-to-5′ direction. Like DNA polymerase, RNA polymerase adds new nucleotides to the 3′ end of the growing strand, beginning with the first nucleotide at the transcription initiation site. Thus the first nucleotide in the new RNA forms its 5′ end, and the RNA transcript is antiparallel to the DNA template strand.

Remember that the nucleotides of RNA contain ribose rather than deoxyribose but are otherwise structurally similar to those of DNA (see Figure 2.9 and Concept 3.1). The RNA polymerase adds new nucleotides to the RNA molecule by complementary base pairing with nucleotides in the template strand of the DNA. This is similar to DNA replication except that in RNA, the base uracil (rather than thymine) in the RNA molecule is paired with adenine in the DNA molecule. In a mechanism

very similar to that used by DNA polymerase, the RNA polymerase uses the ribonucleoside triphosphates ATP, UTP, GTP, and CTP as substrates and catalyzes the formation of phosphodiester bonds between them, releasing pyrophosphate in the process (see Figure 9.7). As transcription progresses, the two DNA strands rewind and the RNA grows as a single-stranded molecule (see Figure 10.5B).

Like DNA polymerases, RNA polymerases and associated proteins have mechanisms for *proofreading* during transcription, but these mechanisms are not as efficient as those for DNA. Transcriptional errors occur at rates of about 1 for every 10^4 to 10^5 bases. Because many copies of RNA are made, however, and because they often have relatively short life spans, these errors are not as potentially harmful as mutations in DNA.

TERMINATION Just as initiation sites in the DNA template strand specify the starting point for transcription, particular base sequences specify its **termination** (see Figure 10.5C). The mechanisms of termination are complex and of more than one kind. In some genes, the newly formed transcript falls away from the DNA template and the RNA polymerase. In others, a helper protein pulls the transcript away.

Eukaryotic coding regions are often interrupted by introns

Coding regions are sequences within a DNA molecule that are expressed as proteins. In prokaryotes, most of the genomic DNA is made up of coding regions, and the mRNAs are collinear with the DNA sequences that code for them: that is, the mRNA sequence (e.g., UAUUAUCCCC...) can be found in the DNA sequence as its complement (e.g., ATATATAGGGG...). In eukaryotes the situation is different (**TABLE 10.1**).

A diagram of the structure and transcription of a typical eukaryotic gene is shown in **FIGURE 10.6**. In prokaryotes and viruses several adjacent genes sometimes share one promoter, but in eukaryotes each gene has its own promoter. And while the coding region of a prokaryotic gene is usually continuous

FIGURE 10.6 Transcription of a Eukaryotic Gene The β -globin gene diagrammed here is about 1,600 base pairs (bp) long. The three exons contain codons for 146 amino acids plus a stop codon signaling the end of translation. The two introns (noncoding sequences containing almost 1,000 bp between them) are initially transcribed but then are spliced out of the pre-mRNA transcript.

TABLE 10.1 Differences between Prokaryotic and Eukaryotic Gene Expression

CHARACTERISTIC	PROKARYOTES	EUKARYOTES
Transcription and translation occurrence	At the same time in the cytoplasm	Transcription in the nucleus, then translation in the cytoplasm
Gene structure	Transcribed regions not interrupted by introns	Transcribed regions often interrupted by non-coding introns
Modification of mRNA after initial transcription but before translation	None	Introns spliced out; 5' cap and 3' poly A added

(with no interruptions), a eukaryotic gene may contain noncoding sequences called **introns** (*intervening regions*) that interrupt the coding region. The transcribed regions that are interspersed with the introns are called **exons** (*expressed regions*). Both introns and exons appear in the primary mRNA transcript, called **pre-mRNA**, but the introns are removed by the time the mature mRNA leaves the nucleus. Pre-mRNA processing involves cutting introns out of the pre-mRNA transcript and splicing together the exon transcripts (see Figure 10.6). If this seems surprising, you are in good company. For scientists who were familiar with prokaryotic genes and gene expression, the discovery of introns in eukaryotic genes was entirely unexpected.

How can we locate introns within a eukaryotic gene? One way is by **nucleic acid hybridization**, the method that originally

revealed the existence of introns. This method, outlined in **FIGURE 10.7**, has been crucial for studying the relationship between eukaryotic genes and their transcripts and is widely used in many applications. It involves two steps:

- The DNA to be analyzed is denatured by heat to break the hydrogen bonds between the base pairs and separate the two strands.
- A single-stranded nucleic acid from another source (called a **probe**) is incubated with the denatured DNA. If the probe has a base sequence complementary to the target DNA, a probe–target double helix forms by hydrogen bonding between the bases. Because the two strands are from different sources, the resulting double-stranded molecule is called a hybrid.

Biologists used this technique to examine the β -globin gene (**FIGURE 10.8**). The researchers first denatured DNA containing the gene by heating it slowly, then used previously isolated β -globin mRNA as a probe. They were able to view the hybridized molecules using electron microscopy. As expected, the mRNA bound to the DNA by complementary base pairing. The researchers expected to obtain a linear (1:1) matchup of the mRNA to the coding DNA. That expectation was only partially met: there were indeed stretches of RNA–DNA hybrid, but some *unexpected looped structures* were also visible. These loops turned out to be introns, stretches of DNA that did not have complementary base sequences on the mature mRNA.

When pre-mRNA was used instead of mature mRNA to hybridize to the DNA, there was complete hybridization with *no loops*, revealing that the introns were part of the pre-mRNA transcript. Somewhere on the path from primary transcript (pre-mRNA) to mature mRNA, the introns had been removed, and the exons had been spliced together. We will examine this splicing process in the next section.

Introns *interrupt, but do not scramble*, the DNA sequence of a gene. The base sequences of the exons in the template strand, if joined and taken in order, form a continuous sequence that is complementary to that of the mature mRNA. Most (but not all) eukaryotic genes contain introns, and in rare cases, introns are also found in prokaryotes. The largest human gene encodes a muscle protein called titin; it has 363 exons, which together code for 38,138 amino acids.

RESEARCH TOOLS

FIGURE 10.7 Nucleic Acid Hybridization Base pairing permits the detection of a sequence that is complementary to the probe.

INVESTIGATION

FIGURE 10.8 Demonstrating the Existence of Introns When an mRNA transcript of the β -globin gene was hybridized with the double-stranded DNA of that gene, the introns in the DNA “looped

out.” This demonstrated that the coding region of a eukaryotic gene can contain noncoding DNA that is not present in the mature mRNA transcript.

HYPOTHESIS

All regions within the coding sequence of a gene end up in its mRNA.

METHOD

RESULTS

CONCLUSION

The DNA contains noncoding regions within the genes that are not present in the mature mRNA.

Eukaryotic gene transcripts are processed before translation

The primary transcript of a eukaryotic gene is modified in several ways before it leaves the nucleus: introns are removed, and both ends of the pre-mRNA are chemically modified.

SPlicing TO REMOVE INTRONS After the pre-mRNA is made, its introns must be removed. If this did not happen, the extra nucleotides in the mRNA would be translated at the ribosome and a nonfunctional protein would result. A process called **RNA splicing** removes the introns and splices the exons together.

At the boundaries between introns and exons are **consensus sequences**—short stretches of DNA that appear with little variation (“consensus”) in many different genes. As soon as the pre-mRNA is transcribed, the consensus sequences are bound by several **small nuclear ribonucleoprotein particles (snRNPs)**. The RNA in one of the snRNPs has a stretch of bases complementary to the consensus sequence at the 5' exon–intron boundary,

and it binds to the pre-mRNA by complementary base pairing. Another snRNP binds to the pre-mRNA near the 3' intron–exon boundary, and then other proteins accumulate to form a large RNA–protein complex called a **spliceosome**. This complex cuts the pre-mRNA, releases the introns, and joins the ends of the exons together to produce mature mRNA (**FIGURE 10.9**).

Molecular studies of human genetic diseases have provided insights into intron consensus sequences and the splicing machinery. For example, people with the genetic disease β -thalassemia have a defect in the production of one of the hemoglobin subunits. These people suffer from severe anemia because they have an inadequate supply of red blood cells. In some cases, the genetic mutation that causes the disease occurs at an intron consensus sequence in the β -globin gene. Consequently, the β -globin pre-mRNA cannot be spliced correctly, and a defective β -globin mRNA is made. This finding offers another example of how biologists can *use mutations to elucidate cause-and-effect relationships*.

FIGURE 10.9 The Spliceosome: An RNA Splicing Machine Small nuclear ribonucleo-proteins (snRNPs) bind to consensus sequences bordering the introns on pre-mRNA transcripts. Other proteins then bind, forming a large complex called a spliceosome. This structure determines the exact position of each cut in the pre-mRNA with great precision.

RNA Splicing

In Concept 10.1 we mentioned that the one gene–one polypeptide hypothesis is an oversimplification. It has recently become clear that in many cases *alternative splicing* results in *different mRNAs and different polypeptides from a single gene*. This occurs because not all exons may be included in every mRNA: some are spliced out, along with the introns.

LINK See Concept 11.4, especially Figure 11.16, for a discussion of alternative splicing

MODIFICATION AT BOTH ENDS While the pre-mRNA is still in the nucleus it undergoes two processing steps, one at each end of the molecule:

- A **5' cap** (or *G cap*) is added to the 5' end of the pre-mRNA as it is transcribed. The 5' cap is a chemically modified molecule of guanosine triphosphate (GTP). It facilitates the binding of mRNA to the ribosome for translation, and it protects the mRNA from being digested by ribonucleases—enzymes that break down RNAs.
- A **poly A tail** is added to the 3' end of the pre-mRNA at the end of transcription. This sequence of 100 to 300 adenine nucleotides assists in the export of the mRNA from the nucleus and is also important for mRNA stability.

Do You Understand Concept 10.2?

- A DNA template strand has the sequence 5'-ATG-GTGTACG-3' What will be the sequence of the RNA transcribed from this DNA? (Be careful to specify the 5' and 3' ends.)
- What would be the consequences of the following?
 - a. A mutation of a promoter such that it is deleted
 - b. A mutation of the gene coding for RNA polymerase
 - c. Deletion of intron consensus sequences from a gene
- Refer to the experiment shown in Figure 10.8. What would the result have been if there were five exons and four introns? Sketch what this would look like in an electron micrograph.

The transcription of a gene to produce mRNA is only the first step in gene expression. The next step in the pathway from DNA to RNA to protein is translation, the subject of Concepts 10.3 and 10.4. First we will discuss the genetic code, which enables the base sequence in an mRNA to be translated into a specific amino acid sequence in the resulting polypeptide. Then we will look in more detail at the process of translation.

concept
10.3

The Genetic Code in RNA Is Translated into the Amino Acid Sequences of Proteins

The translation of the nucleotide sequence of an mRNA into the amino acid sequence of a polypeptide occurs at the ribosome. In prokaryotes, transcription and translation are coupled: there is no nucleus, and ribosomes often bind to an mRNA as it is being transcribed in the cytoplasm. In eukaryotes, the nuclear envelope separates the locations of mRNA production and translation, the latter occurring at ribosomes in the cytoplasm. In both cases, the key event is the decoding of one chemical “language” (the nucleotide sequence) into another (the amino acid sequence).

The information for protein synthesis lies in the genetic code

The genetic information in an mRNA molecule is a series of sequential, nonoverlapping three-letter “words” called **codons**. Each sequence of three nucleotide bases along the mRNA polynucleotide chain is a codon that specifies a particular amino acid. Each codon in the mRNA is complementary to the corresponding triplet of bases in the DNA molecule from which it was transcribed. The genetic code relates codons to their specific amino acids.

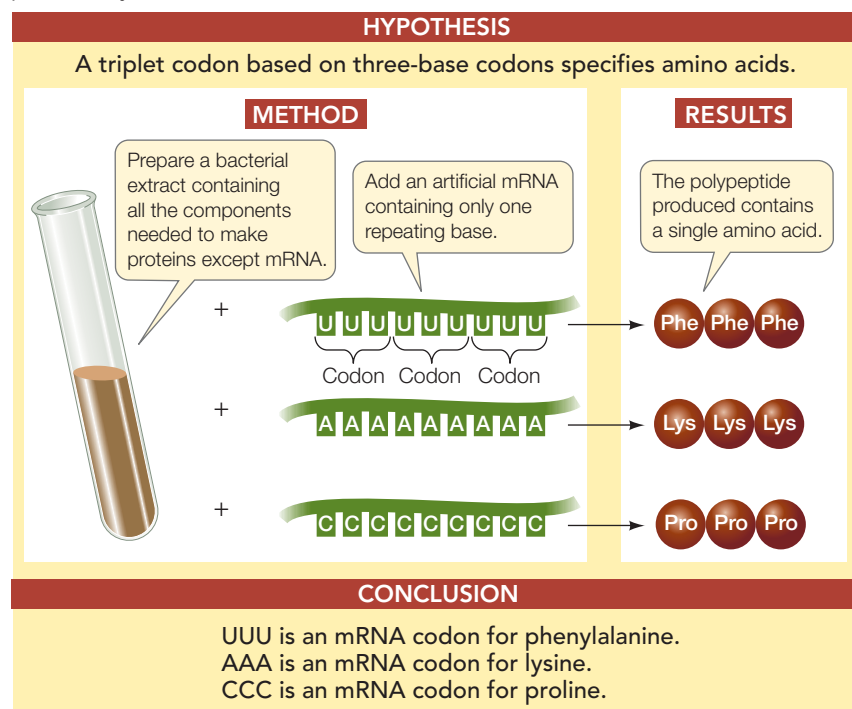

CHARACTERISTICS OF THE GENETIC CODE Molecular biologists “broke” the genetic code in the early 1960s. The problem they addressed was perplexing: how could 20 different amino acids be encoded using only four nucleotide bases (A, U, G, and C)? A triplet code with three-letter codons was considered likely because it was the shortest sequence with enough possible variations to encode all the 20 amino acids. With four available bases, a triplet codon could have $4 \times 4 \times 4 = 64$ variations.

Marshall W. Nirenberg and J. H. Matthaei, at the U.S. National Institutes of Health, made the first decoding breakthrough in 1961 when they realized they could use a simple artificial polynucleotide instead of a complex natural mRNA as a template for polypeptide synthesis in a test tube. They could then identify the polypeptide that the artificial messenger encoded. This led to the identification of the first three codons (**FIGURE 10.10**).

Other scientists later found that simple artificial mRNAs only three nucleotides long—each amounting to one codon—could bind to a ribosome, and that the resulting complex could then bind to the corresponding tRNA with its specific amino acid. Thus, for example, a simple UUU mRNA caused the tRNA carrying phenylalanine to bind to the ribosome. After this discovery, the complete deciphering of the genetic code was relatively simple.

INVESTIGATION

FIGURE 10.10 Deciphering the Genetic Code Nirenberg and Matthaei used a test-tube protein synthesis system to determine the amino acids specified by particular synthetic mRNAs.

ANALYZE THE DATA

Poly U, an artificial mRNA, was added to a test tube with all other components for protein synthesis (“Complete system”). Other test tubes differed from the complete system as indicated in the table. Samples were tested for radioactive phenylalanine incorporation with these results:

Condition	Radioactivity in protein
Complete system	29,500
Minus poly U mRNA	70
Minus ribosomes	52
Minus ATP	83
Plus RNase (hydrolyzes RNA)	120
Plus DNase	27,600
Radioactive glycine instead of phenylalanine	33
Mixture of 19 radioactive amino acids minus phenylalanine	276

Explain the results for each of the conditions.

FIGURE 10.11 The Genetic Code Genetic information is encoded in three-letter units—codons—that are read in the 5′-to-3′ direction on the mRNA. To decode a codon, find its first letter in the left column, then read across the top to its second letter, then read down the right column to its third letter. The amino acid the codon specifies is given in the corresponding row. For example, AUG codes for methionine, and GUA codes for valine.

yourBioPortal.com

Go to **WEB ACTIVITY 10.2**
The Genetic Code

The complete genetic code is shown in **FIGURE 10.11**. Notice that there are many more codons than there are different amino acids in proteins. All possible combinations of the four available bases give 64 (4^3) different three-letter codons, yet these codons determine only 20 amino acids. AUG, which codes for methionine, is also the **start codon**, the initiation signal for translation. Three of the codons (UAA, UAG, and UGA) are **stop codons**, or termination signals for translation. When the translation machinery reaches one of these codons, translation stops and the polypeptide is released from the translation complex.

THE GENETIC CODE IS REDUNDANT BUT NOT AMBIGUOUS The 60 codons that are not start or stop codons are far more than enough to code for the other 19 amino acids—and indeed, there is more than one codon for almost all the amino acids. Thus we say that the genetic code contains redundancies. For example, leucine is represented by six different codons (see Figure 10.11). Only methionine and tryptophan are represented by just one codon each.

A *redundant* code should not be confused with an *ambiguous* code. If the code were ambiguous, a single codon could specify two (or more) different amino acids, and there would be doubt about which amino acid should be incorporated into a growing polypeptide chain. The genetic code is not ambiguous: a given amino acid may be encoded by more than one codon, but each codon encodes only one amino acid.

THE GENETIC CODE IS (NEARLY) UNIVERSAL The same genetic code is used by all the species on our planet. Thus the code must be an ancient one that has been maintained intact throughout the evolution of living organisms. Exceptions are known: within mitochondria and chloroplasts, the code differs slightly from that in prokaryotes and in the nuclei of eukaryotic cells; and in one group of protists, the codons UAA and UAG encode

glutamine rather than functioning as stop codons. The significance of these differences is not yet clear. What is clear is that the exceptions are few.

The common genetic code unifies life, and indicates that all life came ultimately from a common ancestor. The genetic code probably originated early in the evolution of life. The common code also has profound implications for genetic engineering, as we can see in Chapter 13, since it means that the code for a human gene is the same as that for a bacterial gene. It is therefore impressive, but not surprising, that a human gene can be expressed in *Escherichia coli* via laboratory manipulations, since these cells speak the same “molecular language.”

The codons in Figure 10.11 are mRNA codons. The base sequence of the DNA strand that is transcribed to produce the mRNA is complementary and antiparallel to these codons. Thus, for example:

- 3′-AAA-5′ in the template DNA strand corresponds to phenylalanine (which is encoded by the mRNA codon 5′-UUU-3′).
- 3′-ACC-5′ in the template DNA corresponds to tryptophan (which is encoded by the mRNA codon 5′-UGG-3′).

Point mutations confirm the genetic code

Strong support for the assignment of codons in the genetic code comes from point mutations (changes in single nucleotides within a sequence). These have been studied in a wide variety of organisms. When point mutations within the coding region of a gene are compared with the amino acid sequences in the encoded polypeptide, they are consistent with the genetic code.

In Concept 9.3 we discuss mutations in terms of their effects on phenotypes. We can now define types of mutations in terms of their effects on polypeptide sequences (**FIGURE 10.12**):

- *Silent mutations* can occur because of the redundancy of the genetic code. For example, the codons CCG and CCU are

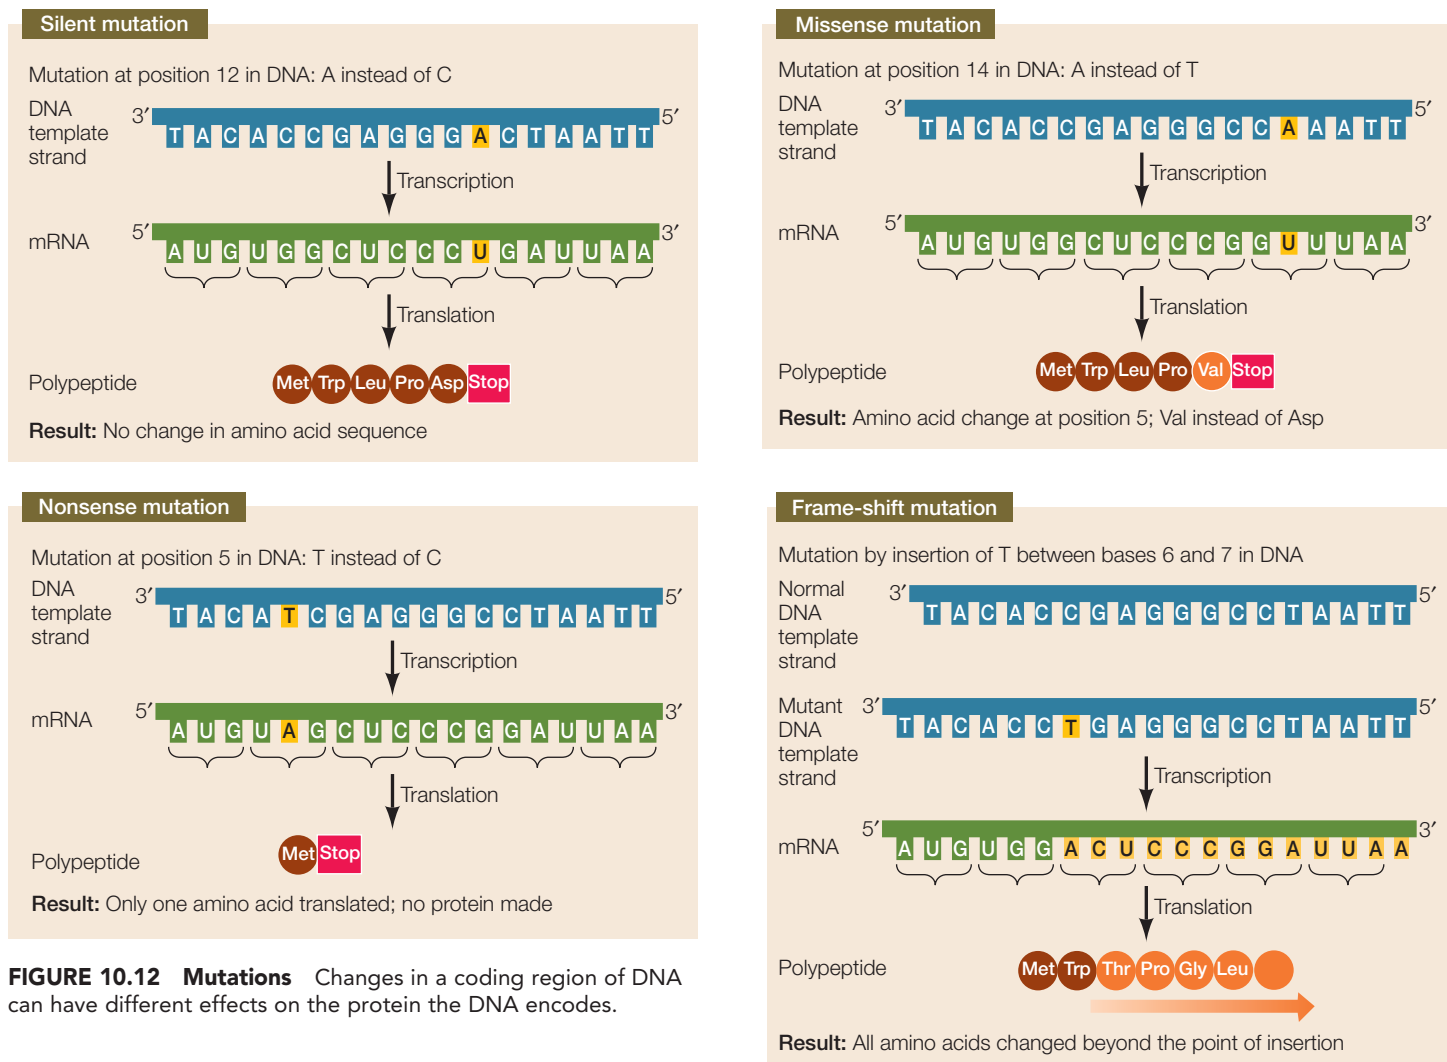

FIGURE 10.12 Mutations Changes in a coding region of DNA can have different effects on the protein the DNA encodes.

both translated from mRNA as proline (Pro). So a change in the template strand of the DNA from 3'-GGC to 3'-GGA (a mutation from C to A) will not cause any change in amino acid sequence.

- *Missense mutations* result in a change in the amino acid sequence. For example, GAU in mRNA is translated as aspar-

tic acid (Asp), whereas a mutation that results in GUU is translated as valine (Val).

- *Nonsense mutations* result in a premature stop codon. For example, the codon UGG is translated as the amino acid tryptophan (Trp). A DNA point mutation could convert this to the stop codon UAG, which acts as a translation termination

APPLY THE CONCEPT

The genetic code in RNA is translated into the amino acid sequences of proteins

The double-stranded DNA sequence for the coding region of a short peptide is:

5'-A T G T T T T C G A C G T G C G A T T G A-3'
 3'-T A C A A A A G C T G C A C G C T A A C T-5'

1 5 10 15 20

1. Which strand of DNA (top or bottom) is transcribed into mRNA? Explain.

2. What is the amino acid sequence of the peptide coded for by the DNA?
3. A mutant strain has a C-G base pair at position #5 instead of the T-A pair shown above. What is the amino acid sequence of the peptide? Explain.
4. A mutation at base pair #15 results in a peptide that is not full length. What point mutation would cause this? Explain.

signal. If this occurred, the polypeptide chain would end at the amino acid translated just before the stop codon.

- *Frame-shift mutations* result from the insertion or deletion of one or more base pairs within the coding sequence. Since the genetic code is read as sequential, nonoverlapping triplets, this can cause new triplets to be read, and an altered sequence of amino acids in the resulting polypeptide.

Genetic Mutations

Do You Understand Concept 10.3?

- What are the characteristics of the genetic code?
- If the artificial mRNA UAUUAUAUA... is used in a test tube protein synthesis system, what would be the amino acid sequence of the resulting polypeptide chain? Note that in this system translation can begin anywhere on the mRNA.
- A deletion of two consecutive base pairs in the coding region of DNA causes a frame-shift mutation. But a deletion of three consecutive base pairs causes the deletion of only one amino acid, with the rest of the polypeptide chain intact. Explain.

The mRNA with its coding information is translated into an amino acid sequence at the ribosome. We will now consider this process.

concept 10.4 Translation of the Genetic Code Is Mediated by tRNA and Ribosomes

The translation of mRNA into proteins requires a molecule that links the information contained in each mRNA codon with a specific amino acid. That function is performed by a set of transfer RNAs (tRNAs). Two key events must take place to ensure that the protein made is the one specified by the mRNA:

- A tRNA must chemically read each mRNA codon correctly.
- The tRNA must deliver the amino acid that corresponds to the mRNA codon.

Once the tRNAs “decode” the mRNA and deliver the appropriate amino acids, components of the ribosome catalyze the formation of peptide bonds between the amino acids.

yourBioPortal.com

Protein Synthesis

Transfer RNAs carry specific amino acids and bind to specific codons

There is at least one specific tRNA molecule for each of the 20 amino acids. Each tRNA has three functions that are fulfilled by its structure and base sequence (FIGURE 10.13):

- *tRNAs bind to particular amino acids.* Each tRNA binds to a specific enzyme that attaches it to only 1 of the 20 amino acids. This covalent attachment is at the 3' end of the tRNA. We describe the details of this vital process in the next section.

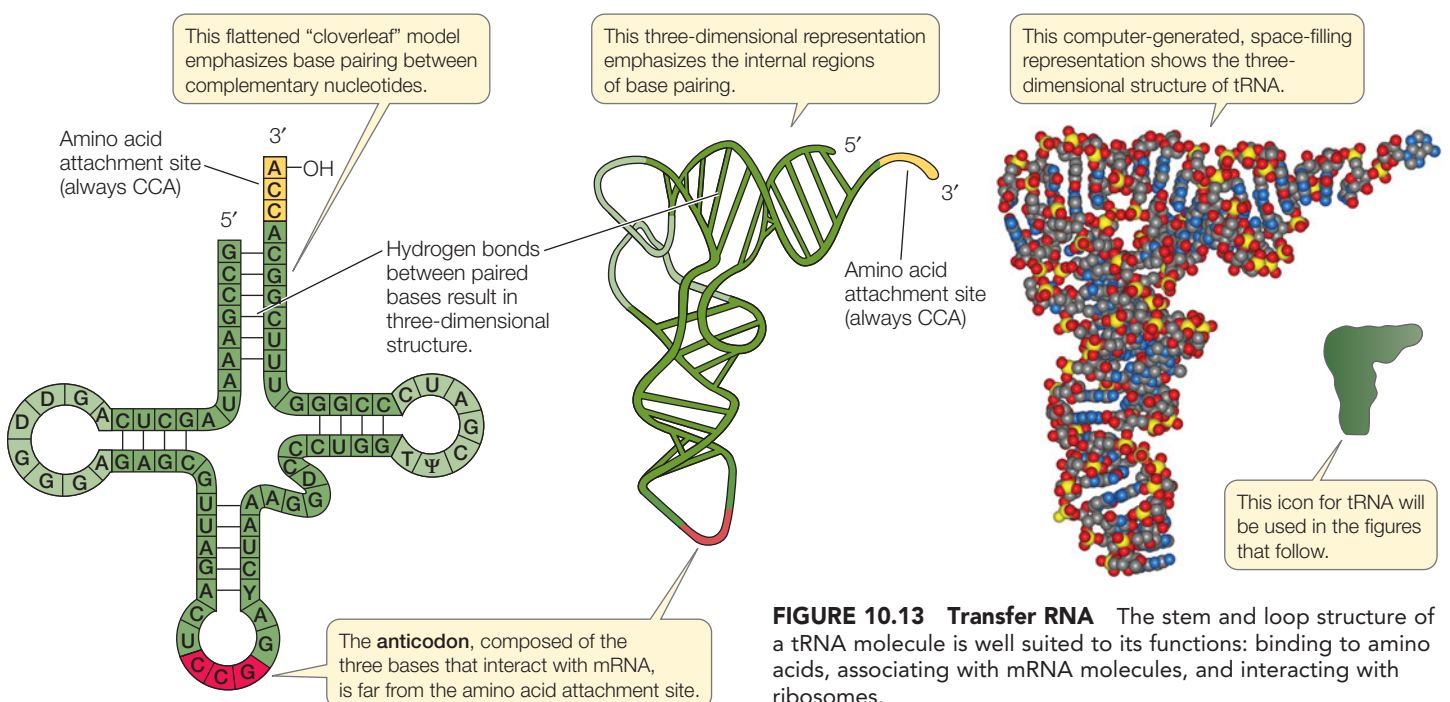

FIGURE 10.13 Transfer RNA The stem and loop structure of a tRNA molecule is well suited to its functions: binding to amino acids, associating with mRNA molecules, and interacting with ribosomes.

When it is carrying an amino acid, the tRNA is said to be “charged.”

- *tRNAs bind to mRNA.* At about the midpoint on the tRNA polynucleotide chain there is a triplet of bases called the **anticodon**, which is complementary to the mRNA codon for the particular amino acid that the tRNA carries. Like the two strands of DNA, the codon and anticodon bind together via noncovalent hydrogen bonds. For example, the mRNA codon for arginine is 5'-CGG-3', and the tRNA anticodon is 3'-GCC-5'.
- *tRNAs interact with ribosomes.* The ribosome has several sites on its surface that just fit the three-dimensional structure of a tRNA molecule. Interaction between the ribosome and the tRNA is noncovalent.

Recall that 61 different codons encode the 20 amino acids in proteins (see Figure 10.11). Does this mean that the cell must produce 61 different tRNA species, each with a different anticodon? No. The cell gets by with about two-thirds of that number of tRNA species because the specificity for the base at the 3' end of the codon (and the 5' end of the anticodon) is not always strictly observed. This phenomenon is called *wobble*, and it is possible because in some cases unusual or modified nucleotide bases occur in the 5' position of the anticodon. One such unusual base is inosine (I), which can pair with A, C, and U. For example, its presence allows three of the alanine codons GCA, GCC, and GCU to be recognized by the same tRNA (with the anticodon 3'-CGI-5'). Wobble occurs in some matches but not in others; of most importance, it does not allow the genetic code to be ambiguous. That is, *each mRNA codon binds to just one tRNA species, carrying a specific amino acid.*

Each tRNA is specifically attached to an amino acid

The charging of each tRNA with its correct amino acid is achieved by a family of enzymes known as *aminoacyl-tRNA synthetases*. Each enzyme is specific for one amino acid and for its corresponding tRNA. The reaction uses ATP, forming a high-energy bond between the amino acid and the tRNA:

The energy in this bond is later used in the formation of peptide bonds between amino acids in a growing polypeptide chain. Clearly, the specificity between the tRNA and its

corresponding amino acid is extremely important. These reactions, for example, are highly specific:

A clever experiment by Seymour Benzer and his colleagues at Purdue University demonstrated the importance of this specificity. They took the cys-tRNA molecule (see above) and chemically modified the cysteine, converting it into alanine. Which component—the amino acid or the tRNA—would be recognized when this hybrid charged tRNA was put into a protein-synthesizing system? The answer was the tRNA. Everywhere in the synthesized protein where cysteine was supposed to be, alanine appeared instead. The cysteine-specific tRNA had delivered its cargo (alanine) to every mRNA codon for cysteine. This experiment showed that the protein synthesis machinery recognizes the anticodon of the charged tRNA, not the amino acid attached to it.

Translation occurs at the ribosome

The ribosome is the molecular workbench where the translation of mRNA by tRNA is accomplished. All prokaryotic and eukaryotic ribosomes consist of two subunits (**FIGURE 10.14**). In eukaryotes, the large subunit consists of 3 different ribosomal RNA (rRNA) molecules and about 49 protein molecules arranged in a precise pattern. The small subunit consists of 1 rRNA molecule and about 33 proteins. These two subunits and several dozen other molecules interact noncovalently, fitting together like a jigsaw puzzle. If the hydrophobic interactions between the proteins and RNAs are disrupted, the ribosome falls apart, but it will reassemble perfectly when the disrupting agent is removed. When not active in the translation of mRNA, the ribosome exists as two separate subunits.

On the large subunit of the ribosome there are three sites to which a tRNA can bind, designated the A, P, and E sites (see Figure 10.14). The mRNA and ribosome move in relation to one another, and as they do so, a charged tRNA traverses these three sites in order:

- The *A (amino acid) site* is where the charged tRNA anticodon binds to the mRNA codon, thus lining up the correct amino acid to be added to the growing polypeptide chain.
- The *P (polypeptide) site* is where the tRNA adds its amino acid to the polypeptide chain.
- The *E (exit) site* is where the tRNA, having given up its amino acid, resides before being released from the ribosome and going back to the cytosol to pick up another amino acid and begin the process again.

The ribosome has a *fidelity function*, which ensures that a charged tRNA with the correct anticodon binds to the appropriate codon in the mRNA. When proper binding occurs, hydrogen bonds form between the three base pairs. The rRNA of the small ribosomal subunit plays a role in validating the

FIGURE 10.14 Ribosome Structure Each ribosome consists of a large and a small subunit. The subunits remain separate when they are not in use for protein synthesis.

three-base-pair match. Any tRNA that does *not* form hydrogen bonds with all three bases of the codon is ejected from the ribosome.

Translation takes place in three steps

Like transcription, translation occurs in three steps: initiation, elongation, and termination.

INITIATION The **initiation complex** consists of a charged tRNA and a small ribosomal subunit, both bound to the mRNA (**FIGURE 10.15**). After binding, the small subunit moves along the mRNA until it reaches the start codon. Recall that the mRNA start codon in the genetic code is AUG (see Figure 10.11). The anticodon of a methionine-charged tRNA binds to this start codon by complementary base pairing to complete the initiation complex. Thus the first amino acid in a new polypeptide chain is always methionine. (In bacteria, but not archaea, the first amino acid is a slightly modified form of methionine called formylmethionine.) However, not all mature proteins have methionine as their first amino acid. In many cases, the initiator methionine is removed by an enzyme after translation.

After the methionine-charged tRNA has bound to the mRNA, the large subunit of the ribosome joins the complex. The methionine-charged tRNA now lies in the P site of the ribosome, and the A site is aligned with the second mRNA codon. These ingredients—mRNA, two

FIGURE 10.15 The Initiation of Translation Translation begins with the formation of an initiation complex.

ribosomal subunits, and methionine-charged tRNA—are put together properly by a group of proteins called *initiation factors*.

ELONGATION A charged tRNA whose anticodon is complementary to the second codon of the mRNA now enters the open A site of the large ribosomal subunit (**FIGURE 10.16**). The large subunit then catalyzes two reactions:

- It breaks the bond between the methionine and its tRNA in the P site.
- It catalyzes the formation of a peptide bond between the methionine and the amino acid attached to the tRNA in the A site.

LINK You may review the structure of peptide linkages in Concept 3.2, especially Figure 3.6

Because the large ribosomal subunit performs these two actions, it is said to have **peptidyl transferase** activity. The component with this activity is actually one of the rRNAs in the ribosome, so the catalyst is an example of a *ribozyme* (from *ribonucleic acid* and *enzyme*).

Methionine thus becomes the amino (N) terminus of the new protein (recall that polypeptides grow in the amino to carboxyl direction; see Concept 3.2). The second amino acid is now bound to methionine but remains attached to its tRNA at the A site.

After the first tRNA releases its methionine, it moves to the E site and is then dissociated from the ribosome, returning to the cytosol to become charged with another methionine. The second tRNA, now bearing a dipeptide (a two-amino-acid chain), is shifted to the P site as the ribosome moves one codon along the mRNA in the 5'-to-3' direction (see Figure 10.16). These steps are repeated, and the polypeptide chain grows as each new amino acid is added.

TERMINATION The elongation cycle ends when a stop codon—UAA, UAG, or UGA—enters the A site (**FIGURE 10.17**). These codons bind a protein *release factor*, which allows hydrolysis of the bond between the polypeptide chain and the tRNA in the P site. The newly completed polypeptide thereupon separates from the ribosome.

TABLE 10.2 summarizes the nucleic acid signals for initiation and termination of transcription and translation.

Polysome formation increases the rate of protein synthesis

Several ribosomes can simultaneously translate a single mRNA molecule, producing multiple polypeptides at the same time. As soon as the first ribosome has moved far enough from the translation initiation site, a second initiation

FIGURE 10.16 The Elongation of Translation The polypeptide chain elongates as the mRNA is translated.

FIGURE 10.17 The Termination of Translation Translation terminates when the A site of the ribosome encounters a stop codon on the mRNA.

FIGURE 10.18 A Polysome

(A) A polysome consists of multiple ribosomes and their growing polypeptide chains moving along an mRNA molecule. (B) An electron micrograph of a polysome.

complex can form, then a third, and so on. An assemblage consisting of a strand of mRNA with its beadlike ribosomes and their growing polypeptide chains is called a **polyribosome**, or **polysome** (FIGURE 10.18). Cells that are actively synthesizing proteins contain large numbers of polysomes and few free ribosomes or ribosomal subunits.

Do You Understand Concept 10.4?

- Describe the sequence of events in translation that involve tRNA, from charging with an amino acid to initiation, elongation, and termination.
- Imagine a polypeptide whose second amino acid is tryptophan. Sketch a ribosome with the mRNA and the first two tRNAs for this polypeptide, noting their positions in the A, P, and E sites.
- What would happen if a valine tRNA synthetase lost its specificity and attached any of the 20 amino acids to the 3' end of the valine tRNA?

TABLE 10.2 Signals that Start and Stop Transcription and Translation

	TRANSCRIPTION	TRANSLATION
Initiation	Promoter DNA	AUG start codon in the mRNA
Termination	Terminator DNA	UAA, UAG, or UGA in the mRNA

Usually, the process of protein synthesis does not end with translation. Proteins can undergo covalent modifications both during and after translation—with chemical groups being

added or parts of the polypeptide chains removed. We will now turn to these modifications.

concept 10.5 Proteins Are Modified after Translation

The site of a polypeptide's function in the cell may be far away from its point of synthesis at the ribosome. This is especially true for eukaryotes, where a polypeptide may be moved into an organelle. Furthermore, polypeptides are often modified by the addition of new chemical groups that contribute to the function of the mature protein. In this section we examine these *posttranslational* aspects of protein synthesis.

Signal sequences in proteins direct them to their cellular destinations

Protein synthesis always begins on free ribosomes floating in the cytoplasm, and the “default” location for a protein is the cytosol. As the polypeptide chain emerges from the ribosome it may simply fold into its three-dimensional shape and perform its cellular role. However, a newly formed polypeptide may contain a **signal sequence** (or *signal peptide*)—a short stretch of amino acids that indicates where in the cell the polypeptide belongs. Proteins destined for different locations have different signals.

In the absence of a signal sequence, the protein will remain in the same cellular compartment where it was synthesized.

FIGURE 10.19
Destinations for Newly Translated Polypeptides in a Eukaryotic Cell

Signal sequences on newly synthesized polypeptides bind to specific receptor proteins on the outer membranes of the organelles to which they are directed. Once the protein has bound to it, the receptor forms a channel in the membrane, and the protein enters the organelle.

1 The polypeptide binds to a signal recognition particle, and then both bind to a receptor protein in the membrane of the ER. Translation proceeds.

2 The signal sequence is removed by an enzyme in the lumen of the ER.

3 The polypeptide continues to elongate until translation terminates.

4 The ribosome is released. The protein folds inside the ER.

Some proteins, however, contain signal sequences that “target” them to the nucleus, mitochondria, plastids, or peroxisomes (FIGURE 10.19, TOP). A signal sequence binds to a specific receptor protein at the surface of the organelle. Once it has bound, a channel forms in the organelle membrane, allowing the targeted protein to move into the organelle. For example, here is a nuclear localization signal:

-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-

The function of this peptide was established using experiments like the one illustrated in FIGURE 10.20. Proteins were made in the laboratory with or without the peptide, and then tested by injecting them into cells. Only proteins with the nuclear localization signal were found in the nucleus.

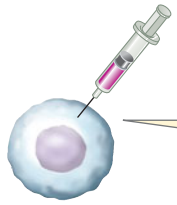

INVESTIGATION

FIGURE 10.20 Testing the Signal A series of experiments were used to test whether the nuclear localization signal (NLS) sequence is all that is needed to direct a protein to the nucleus.

HYPOTHESIS

A nuclear localization signal (NLS) is necessary for import of a protein into the nucleus.

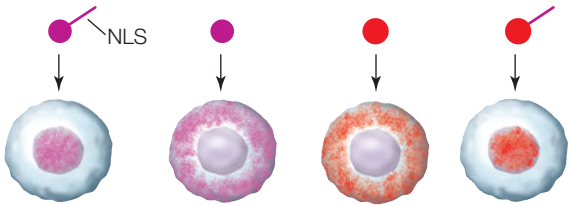

METHOD

1 A protein labeled with a fluorescent dye is injected into the cytoplasm.

RESULTS

Injected protein:			
Nucleoplasmin, a nuclear protein, with the NLS	Nucleoplasmin with the NLS removed	Pyruvate kinase, a cytoplasmic protein without the NLS	Pyruvate kinase, attached NLS

2 The distribution of the protein in the cell is observed with a fluorescence microscope.

CONCLUSION

The NLS is essential for nuclear protein import and will direct a normally cytoplasmic protein to the nucleus.

LINK For a description of how the proteins for this experiment were made, see Concept 13.3

If a polypeptide carries a particular signal sequence of 5–10 hydrophobic amino acids at its N terminus, it will be directed to the rough endoplasmic reticulum (RER) for further processing (FIGURE 10.19, BOTTOM). Translation will pause, and the ribosome will bind to a receptor at the RER membrane. Once the polypeptide–ribosome complex is bound, translation will resume, and as elongation continues, the protein will traverse the RER membrane. Such proteins may be retained in the lumen (the inside) or membrane of the RER, or they may move elsewhere within the endomembrane system (Golgi apparatus, lysosomes, and plasma membrane). If the proteins lack specific signals for destinations within the endomembrane system, they are usually secreted from the cell via vesicles that fuse with the plasma membrane.

Many proteins are modified after translation

Most mature proteins are not identical to the polypeptide chains that are translated from mRNA on the ribosomes. Instead, most polypeptides are modified in any of a number of ways after translation (FIGURE 10.21). These modifications are essential to the final functioning of the protein.

- **Proteolysis** is the cutting of a polypeptide chain. For example, the ER signal sequence is cut off from the growing polypeptide chain as it enters the ER. Some mature proteins are actually made from *polyproteins*—long polypeptides containing the primary sequences of multiple distinct proteins—that are cut into final products by enzymes called *proteases*. Proteases are essential to some viruses, including human immunodeficiency virus (HIV), because the large viral polypeptide cannot fold properly unless it is cut. Certain drugs used to treat acquired immune deficiency syndrome (AIDS) work by inhibiting the HIV protease, thereby preventing the formation of proteins needed for viral reproduction.
- **Glycosylation** is the addition of carbohydrates to proteins to form glycoproteins. In both the ER and the Golgi apparatus, resident enzymes catalyze the addition of various oligosaccharides (short chains of monosaccharides; see Concept 2.3) to certain amino acid R groups on proteins. One such type of “sugar coating” is essential for directing proteins to lysosomes. Other types are important for protein conformation and for recognition functions at the cell surface. In many cases the attached oligosaccharides help stabilize proteins, such as those in the extracellular matrix, and those in the storage vacuoles of plants.
- **Phosphorylation** is the addition of phosphate groups to proteins and is catalyzed by *protein kinases*. The charged phosphate groups change the conformation of the protein, often exposing the active site of an enzyme or the binding site for another protein. Phosphorylation is especially important in cell signaling (see Concepts 5.5 and 5.6).

FRONTIERS In some proteins, proline is converted to hydroxyproline after translation. This occurs in collagen, a protein that is secreted into the extracellular matrices of animal cells, and extensin, a protein secreted into the plant cell wall. Why is this modification a hallmark of extracellular matrix proteins? Examination of the role of hydroxyproline in the structures of these proteins may provide an answer.

Do You Understand Concept 10.5?

- Describe how signal sequences determine where a protein will go after it is made.
- What are some ways in which posttranslational modifications alter protein structure and function?
- Describe an experiment you would perform to test a proposed chloroplast-targeting signal sequence. Be specific about the type of cell and the proteins you would use.

How do antibiotics such as tetracycline target bacterial protein synthesis?

ANSWER Tetracyclines are widely used antibiotics that are effective against some strains of MRSA and many other bacterial infections. They derive their name from the four hydrocarbon rings that are common to this family of molecules. Tetracyclines kill bacteria by interrupting translation (Concept 10.1). They do this by binding noncovalently to the small subunit of bacterial ribosomes (Concept 10.4), where binding changes ribosome structure such that charged tRNAs can no longer bind to the A site on the ribosome (FIGURE 10.22). The specificity of antibiotics for bacterial ribosomes comes from the fact that bacterial and eukaryotic ribosomes have different proteins and RNAs.

Strains of MRSA with resistance to tetracyclines are emerging. The genes that confer resistance to this group of

antibiotics are carried on mobile genetic elements such as plasmids, which can move at high frequencies between bacteria, by bacterial conjugation. Some of the resistance genes encode proteins that transfer the tetracyclines out of the cell, while others encode proteins that protect the ribosomes from binding by the antibiotics. These resistance genes present a major challenge, because MRSA can be lethal. To overcome resistance, new antibiotics are being developed and tried. The evolutionary race between genetically caused drug resistance and new therapies continues. In the meantime, health-care providers and the general public are being advised to take precautions to prevent the spread of MRSA.

FIGURE 10.22 An Antibiotic at the Ribosome The antibiotic tetracycline binds to the small ribosomal subunit of bacteria. This causes a change in the structure of the A site, preventing tRNAs from binding, and protein synthesis stops.

Translation of the Genetic Code Is Mediated by tRNA and Ribosomes

Review ANIMATED TUTORIAL 10.4

- Transfer RNA (tRNA) mediates between mRNA and amino acids during translation at the ribosome.
- Each tRNA species has an amino acid attachment site and an **anticodon** that is complementary to a specific mRNA codon. **Review Figure 10.13**
- A specific synthetase enzyme charges each tRNA with its specific amino acid.
- Three sites on the large subunit of the ribosome interact with tRNA anticodons. The A site is where the charged tRNA anticodon binds to the mRNA codon. The P site is where the tRNA adds its amino acid to the growing polypeptide chain. The E site is where the tRNA is released. **Review Figure 10.14**
- Translation occurs in three steps: initiation, **elongation**, and **termination**. **Review Figures 10.15–10.17**
- In a **polyribosome**, or **polysome**, more than one ribosome moves along a strand of mRNA at one time. **Review Figure 10.18**

concept
10.5

Proteins Are Modified after Translation

- **Signal sequences** are short sequences of amino acids that direct polypeptides to their cellular destinations.
- These destinations include the nucleus and other organelles, which proteins enter after being recognized and bound by surface receptors.
- If a ribosome begins translating a polypeptide with an N-terminal RER signal sequence, it pauses and then resumes translation after attachment to a receptor in the RER membrane. **Review Figure 10.19**
- Posttranslational modifications of polypeptides include **proteolysis**, in which a polypeptide is cut into smaller fragments; **glycosylation**, in which sugars are added; and **phosphorylation**, in which phosphate groups are added. **Review Figure 10.21**

Regulation of Gene Expression

11

Many people drink alcoholic beverages, but relatively few of them become addicted (alcoholic). Alcoholism is characterized by a compulsion to consume alcohol, tolerance (increasing doses are needed for the same effect), and dependence (abrupt cessation of consumption leads to severe withdrawal symptoms). In most alcoholics, alcohol provides pleasant sensations (positive reinforcement) and alleviates unpleasant ones such as anxiety (negative reinforcement).

Alcoholism is a complex disease. Psychologists sometimes speak of “addictive personalities,” and genetic studies indicate there may be inherited factors that predispose people to the disease. One approach to describing the genes involved is to study animal models of alcoholism at the molecular level. James Murphy at Indiana University has bred a genetic strain of alcoholic rats, called P rats, that prefer alcohol when given the choice of alcohol-containing or alcohol-free water. These rats show many of the symptoms of addiction, including compulsive drinking, tolerance, and withdrawal. P rats also appear more anxious than wild-type rats, spending more time in a closed rather than an open environment. Drinking alcohol alters this behavior and seems to relieve their anxiety.

Scientists have found a link between a protein and the genetic mutation(s) leading to alcoholism in rats. CREB (cyclic AMP response element binding protein) is abundant in the brain and regulates the expression of hundreds of genes that are important in metabolism. CREB becomes activated when it is phosphorylated by the enzyme protein kinase A, which in turn is activated by the second messenger cyclic AMP. In an effort to understand the molecular basis of alcoholism and anxiety, neuroscientist Subhash Pandey and his colleagues at the University of Illinois compared CREB levels in the brains of P

rats and wild-type rats. They found that P rats have inherently lower levels of CREB in certain parts of the brain. When these rats consumed alcohol, the total levels of CREB did not increase, but the levels of phosphorylated CREB did. It is the phosphorylated version of CREB that regulates gene transcription.

The prospect that CREB, a molecule that regulates gene expression, is a key element in the genetic propensity for alcoholism is important because it begins to explain the molecular nature of a complex behavioral disease. Such understanding may permit more effective treatment of alcohol abuse, or even its prevention. And with reference to our purpose here, it underscores the importance of the regulation of gene expression in biological processes.

A rat drinks an alcoholic beverage. Some rats are genetically programmed to prefer alcohol over plain water.

How does CREB regulate the expression of many genes?

KEY CONCEPTS

- 11.1 Several Strategies Are Used to Regulate Gene Expression
- 11.2 Many Prokaryotic Genes Are Regulated in Operons

- 11.4 Eukaryotic Gene Expression Can Be Regulated after Transcription

concept 11.1 Several Strategies Are Used to Regulate Gene Expression

In Chapter 10 we introduce the concepts of gene expression. DNA is initially expressed as RNA. In many cases the RNA is then translated into protein at the ribosome. Throughout this book we describe instances where gene expression is altered so that the level of protein produced from a particular gene varies. Such variations are influenced by environmental conditions and the developmental stage of the cell or organism. Here are a few examples:

- In Chapter 5: When an extracellular signal binds to its receptor on a eukaryotic cell, it sets in motion a signal transduction pathway that may end with some genes being activated (their expression switched on) or others being repressed (their expression switched off).
- In Chapter 7: During the cell cycle, cyclins are synthesized only at specific points. The genes for cyclins are inactive at other points in the cycle.
- In Chapter 9: When a virus infects a host cell, it can “hijack” the host gene expression machinery and divert it to viral gene expression.

These and other examples indicate that *gene expression is precisely regulated*. In some cases, gene expression is modified to counteract changes in the cell’s environment, so that stable conditions are maintained within the cell. In other cases, gene expression changes so that the cell can perform specific functions. For example, all of our cells carry the genes encoding keratin (the protein in our hair and nails) and hemoglobin. Yet keratin is made only by epithelial cells such as skin cells, and hemoglobin is made only by developing red blood cells. In contrast, all human cells express the genes that encode enzymes needed for basic metabolic activities (such as glycolysis), and all cells must synthesize certain structural proteins such as actin (a component of the cytoskeleton). To generalize:

- **Constitutive genes** are actively expressed all the time.
- **Inducible genes** are expressed only when their proteins are needed by the cell.

Our discussion of the regulation of gene expression will focus on inducible genes.

Genes are subject to positive and negative regulation

At every step of the way from DNA to protein that we described in Chapter 10, gene expression can be regulated (FIGURE 11.1). As we proceed through this chapter, you will see examples of gene regulation at the transcriptional, posttranscriptional, translational, and posttranslational levels. An important form of gene regulation is at the level of *transcription*.

yourBioPortal.com

Go to WEB ACTIVITY 11.1
Eukaryotic Gene Expression Control Points

LINK You may wish to review the processes of transcription described in Concept 10.2

Gene expression begins at the *promoter*, where RNA polymerase binds to initiate transcription. As we mentioned above, not all genes are active (being transcribed) at a given time—there is *selective gene transcription*. Two types of regulatory proteins—also called **transcription factors**—control whether or not a gene is active: repressors and activators. These proteins bind to specific DNA sequences at or near the promoter (FIGURE 11.2):

- In negative regulation, a **repressor** binds near the promoter to prevent transcription.
- In positive regulation, the binding of an **activator** stimulates transcription.

FIGURE 11.1 Potential Points for the Regulation of Gene Expression Gene expression can be regulated before transcription, during transcription, after transcription but before translation, at translation, or after translation.

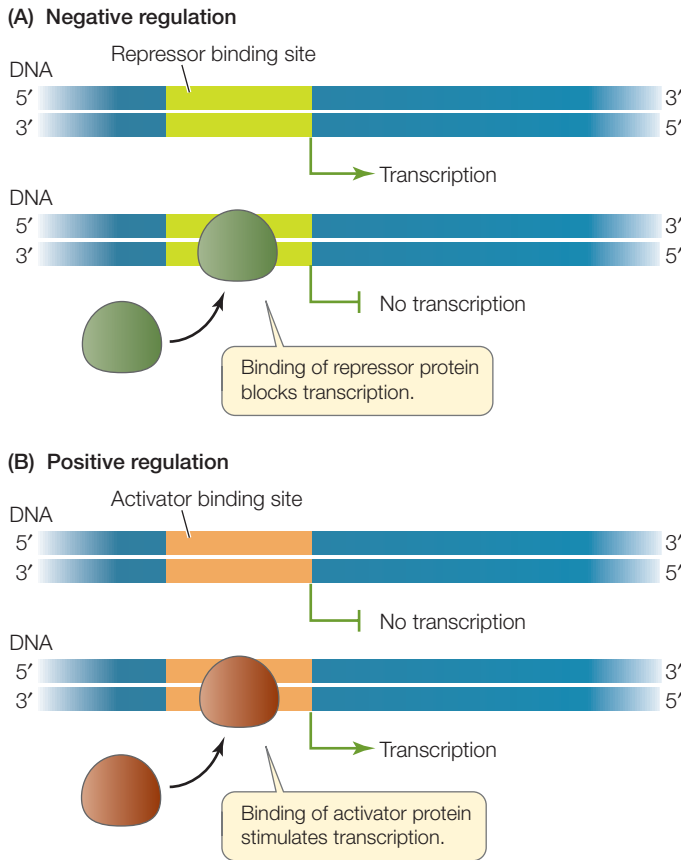

FIGURE 11.2 Positive and Negative Regulation Transcription factors regulate gene expression by binding to DNA and (A) repressing or (B) activating transcription by RNA polymerase.

You will see these mechanisms, or combinations of them, as we examine gene regulation in viruses, bacteria, and eukaryotes.

Viruses use gene regulation strategies to subvert host cells

The immunologist Sir Peter Medawar once described a virus as “a piece of bad news wrapped in protein.” As we describe in Concept 9.1, a **virus** injects its genetic material into a host cell, and in many cases it turns that cell into a virus factory (see Figure 9.2). This involves a radical change in gene expression for the host cell, and results in the death of the cell when new viral particles are released. Viral life cycles are very efficient—for example, the poliovirus completes its life cycle (from infection to release of new particles) in 4–6 hours, and each dying host cell can produce up to 10,000 new particles!

Unlike cellular organisms, viruses are *acellular*. They are not cells and do not carry out many of the processes characteristic of life, and they are dependent on living cells to reproduce. Not all viruses use double-stranded DNA as the genetic material that is contained within the viral particle and transmitted from one generation to the next. The viral genome may consist of double-stranded DNA, single-stranded DNA, or double- or single-stranded RNA. But whether the genetic material is DNA

or RNA, the viral genome takes over the host’s protein synthetic machinery within minutes of entering the cell.

Typically, the host cell immediately begins to produce new viral particles (*virions*), which are released as the cell breaks open, or *lyses*. This type of viral life cycle is called **lytic**. Some viral life cycles also include a **lysogenic** or dormant phase. In this case the viral genome becomes incorporated into the host cell genome and is replicated along with the host genome. The virus may survive in this way for many host cell generations. Sooner or later, an environmental signal can cause the host cell to begin producing virions—at which point the viral reproductive cycle enters the lytic phase.

By studying the relatively simple reproductive cycles of viruses, biologists have discovered principles of gene regulation that apply to much more complex cellular systems. We will discuss two examples of viruses here: one prokaryotic (a bacteriophage) and the other eukaryotic (the human immunodeficiency virus).

BACTERIOPHAGE Like other viruses, a *bacteriophage* (phage, or bacterial virus) may have a DNA or RNA genome, and its life cycle may or may not include a lysogenic phase. **FIGURE 11.3** illustrates the lytic life cycle of T4, a typical double-stranded DNA phage. At the molecular level, the lytic cycle has two stages, early and late:

- The viral genome contains a promoter that binds host RNA polymerase. In the *early stage*, viral genes that lie adjacent to this promoter are transcribed. These early genes encode proteins that shut down expression of host genes, stimulate viral genome replication, and activate the transcription of viral late genes. The host genes are shut down by a *postranscriptional* mechanism: a virus-encoded enzyme degrades the host RNA before it can be translated. Another viral nuclease digests the host’s chromosome, providing nucleotides for the synthesis of many copies of the viral genome. These processes can occur within a few minutes after the virus first infects the cell.
- In the *late stage*, viral late genes are transcribed; they encode the viral capsid proteins and enzymes that lyse the host cell to release the new virions.

Under ideal conditions, this entire process—from binding and infection to release of new phage—can take only half an hour. During this period, the sequence of transcriptional events is carefully controlled to produce complete, infective virions.

HIV Eukaryotes are susceptible to infections by various kinds of viruses that have various life cycle strategies. We focus here on **human immunodeficiency virus (HIV)**, the infective agent that causes acquired immunodeficiency syndrome (AIDS) in humans. HIV typically infects only cells of the immune system that express a surface receptor called CD4. The virion is enclosed within a phospholipid membrane derived from its previous host cell. Proteins in the membrane are involved in the infection of new host cells, which HIV enters by direct fusion of the viral envelope with the host plasma membrane (**FIGURE 11.4**).

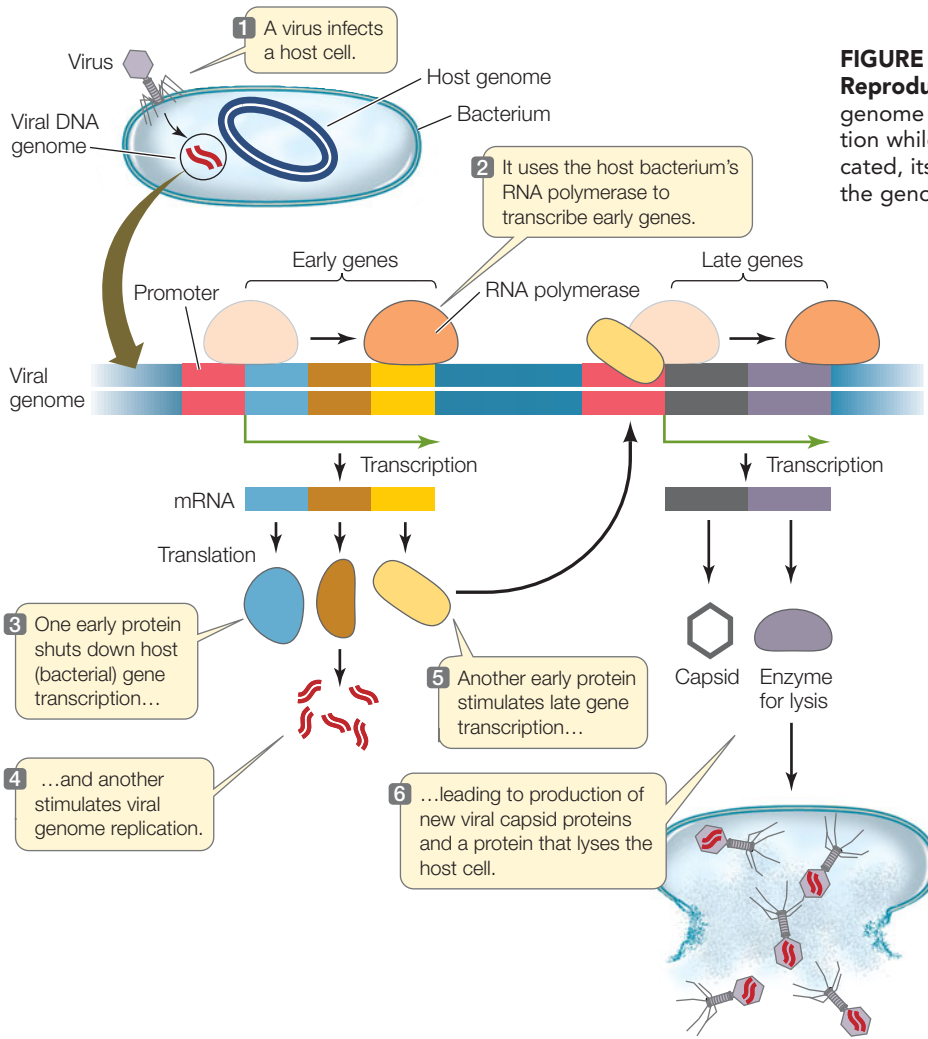

FIGURE 11.3 A Gene Regulation Strategy for Viral Reproduction In a host cell infected with a virus, the viral genome uses its early genes to shut down host transcription while it replicates itself. Once the viral genome is replicated, its late genes produce capsid proteins that package the genome, and other proteins that lyse the host cell.

HIV is a *retrovirus*: its genome is single-stranded RNA, and it carries within the virion an enzyme called reverse transcriptase. Shortly after infection, the **reverse transcriptase** makes a DNA strand that is complementary to the RNA, while at the same time degrading the RNA and making a second DNA strand that is complementary to the first. The resulting double-stranded DNA becomes integrated into the host's chromosome, where it resides as a *provirus*. The provirus may remain dormant in the host genome for years. However, certain cellular triggers can eventually stimulate transcription of the viral DNA, resulting in mRNAs that are translated into viral proteins, and in new copies of the viral genome (see Figure 11.4).

Under normal circumstances, host cells have negative regulatory systems that repress the expression of invading viral genes. These systems may have evolved as defense mechanisms against viruses. One such system involves transcription "terminator" proteins that bind to RNA polymerase and cause it to terminate transcription prematurely. However, HIV can counteract this negative regulation with a virus-encoded protein

FIGURE 11.4 The Reproductive Cycle of HIV This retrovirus enters a host cell via fusion of its envelope with the host's plasma membrane. Reverse transcription of retroviral RNA then produces a complementary DNA that becomes inserted into the host's genome. The inserted viral DNA directs the synthesis of new virus particles.

FIGURE 11.5 Regulation of Transcription by HIV The Tat protein acts as an antiterminator, allowing transcription of the HIV genome.

called Tat (*Transactivator of transcription*), which binds to the viral mRNA along with associated proteins that allow RNA polymerase to transcribe the viral genome (FIGURE 11.5).

FRONTIERS Because AIDS is a major challenge worldwide, biologists probably know more about HIV than any other virus. Major efforts are underway to develop drugs targeted at virtually every step in the virus's life cycle. Some of these stop viral transmission and replication without harming human cells.

Do You Understand Concept 11.1?

- What is the difference between positive and negative regulation of gene expression?
- Describe positive and negative regulation of gene expression in bacteriophage and HIV life cycles.
- What would be the effects of the following?
 - a. A mutation in the gene that encodes RNA polymerase so that it does not bind to the promoter for late genes in a bacteriophage.
 - b. The inhibition of reverse transcriptase in an HIV-infected cell.

We have seen how viruses co-opt the regulatory mechanisms of their host cells in order to express their own genes and reproduce. Now let's turn to a closer examination of gene regulation in prokaryotes.

concept 11.2 Many Prokaryotic Genes Are Regulated in Operons

Prokaryotes conserve energy and resources by making certain proteins only when they are needed. Because their environments can change abruptly, prokaryotes have evolved mechanisms to rapidly alter the expression levels of certain genes when conditions warrant. The most efficient means of regulating gene expression is at the level of transcription.

Regulating gene transcription conserves energy

As a normal inhabitant of the human intestine, *Escherichia coli* must be able to adjust to sudden changes in its chemical environment as the foods consumed by its host change (for example, from glucose at one time to lactose at another). In many cases, *E. coli* responds to such changes by changing the expression of its genes. To illustrate this, we will look at the regulation of the pathway for lactose catabolism in *E. coli*.

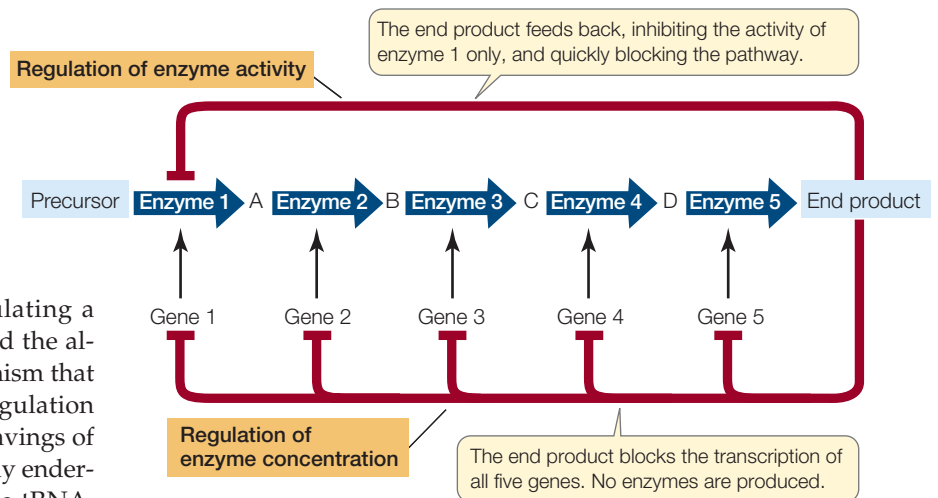

Lactose is a β -galactoside—a disaccharide containing galactose linked to glucose. Three proteins are involved in the initial uptake and metabolism of lactose by *E. coli*:

- β -galactoside permease is a carrier protein in the bacterial plasma membrane that moves the sugar into the cell.
- β -galactosidase is an enzyme that hydrolyzes lactose to glucose and galactose.
- β -galactoside transacetylase transfers acetyl groups from acetyl CoA to certain β -galactosides. Its role in the metabolism of lactose is not clear.

When *E. coli* is grown on a medium that contains glucose but no β -galactosides, the levels of these three proteins are extremely low—only a few molecules per cell. But if the cells are transferred to a medium with lactose as the predominant sugar, they promptly begin making all three enzymes, and within 10 minutes there are about 3,000 of each of these proteins per cell. Clearly, these are proteins encoded by inducible genes, and their expression is switched on by an **inducer**. In this case the inducer is allolactose, an isomer of lactose.

FIGURE 11.6 Two Ways to Regulate a Metabolic Pathway Feedback from the end product of a metabolic pathway can block enzyme activity (allosteric regulation), or it can stop the transcription of genes that code for the enzymes in the pathway (transcriptional regulation).

We have now seen two basic ways of regulating a metabolic pathway. In Concept 3.4 we described the allosteric regulation of enzyme activity—a mechanism that allows rapid fine-tuning of metabolism. The regulation of transcription is slower but results in greater savings of energy and resources. Protein synthesis is a highly endergonic process, since assembling mRNA, charging tRNA, and moving the ribosomes along mRNA all require large amounts of energy. **FIGURE 11.6** compares these two modes of regulation.

Operons are units of transcriptional regulation in prokaryotes

The genes that encode the three enzymes for processing lactose in *E. coli* are **structural genes**; they each specify the primary structure (the amino acid sequence) of a protein molecule that is not involved in regulation. The three genes lie adjacent to one another on the *E. coli* chromosome. This arrangement is no coincidence: the genes share a single promoter, and their DNA is transcribed into a single, continuous molecule of mRNA. Because this particular mRNA governs the synthesis of all three lactose-metabolizing enzymes, either all or none of these enzymes are made at any particular time.

A cluster of genes with a single promoter is called an **operon**, and the operon that encodes the three lactose-metabolizing enzymes in *E. coli* is called the *lac* operon. The *lac* operon promoter can be very efficient (the maximum rate of mRNA synthesis can be high), but mRNA synthesis can be shut down when the enzymes are not needed. This example of negative regulation was elegantly worked out by Nobel Prize winners François Jacob and Jacques Monod.

The *lac* operon has another DNA sequence called an **operator**, which is near the promoter and controls transcription of the structural genes (**FIGURE 11.7**). Operators can bind very tightly with repressor proteins, which play different roles in different operons:

- An *inducible operon* is turned *off* unless needed.
- A *repressible operon* is turned *on* unless *not* needed.

Operator–repressor interactions regulate transcription in the *lac* and *trp* operons

In the case of the inducible *lac* operon, a repressor protein prevents transcription until the *lac*-encoded proteins are needed. In contrast, the *trp* operon (described below) is a repressible operon that is turned off by a repressor only under particular circumstances.

***lac* OPERON** As we described above, the *lac* operon is not transcribed unless a β -galactoside (such as lactose) is the predominant sugar available in the cell's environment. A repressor protein is normally bound to the operator, preventing transcription. When lactose is present, the repressor detaches from the operator sequence, allowing RNA polymerase to bind to the promoter and start transcribing the structural genes (**FIGURE 11.8**).

The key to this regulatory system is the repressor protein. Expressed from a constitutive promoter (one that is always active), the repressor is always present in the cell in adequate amounts to occupy the operator and keep the operon turned off. The repressor has a recognition site for the DNA sequence in the operator, and it binds very tightly. However, it also has an allosteric binding site for the inducer. When the inducer (allolactose, an alternate form of lactose) binds to the repressor, the repressor changes shape so that it can no longer bind DNA.

FIGURE 11.7 The *lac* Operon of *E. coli* The *lac* operon of *E. coli* is a segment of DNA that includes a promoter, an operator, and the three structural genes that code for lactose-metabolizing enzymes. In reality, the structural genes are much longer than the short, regulatory sequences.

APPLY THE CONCEPT

Many prokaryotic genes are regulated in operons, which include regulatory DNA sequences

Genetic mutations are useful in analyzing the control of gene expression. In the *lac* operon of *E. coli* (see Figure 11.7), gene *i* codes for the repressor protein, P_{lac} is the promoter, *o* is the operator, and *z* is the first structural gene. (+) means wild type; (-) means mutant. Fill in the table, describing the level of transcription in different genetic and environmental conditions.

GENOTYPE	Z TRANSCRIPTION LEVEL	
	LACTOSE PRESENT	LACTOSE ABSENT
$i^- P_{lac}^+ o^+ z^+$		
$i^+ P_{lac}^+ o^+ z^-$		
$i^+ P_{lac}^- o^+ z^+$		
$i^+ P_{lac}^+ o^- z^+$

The *lac* Operon

trp OPERON Like an inducible operon, a repressible operon is switched off when its repressor is bound to its operator. However in this case, the repressor binds to the DNA only in the presence of a **co-repressor**. The co-repressor is a molecule that binds to the repressor, causing it to change shape and bind to the operator, thereby inhibiting transcription. An example is the operon whose structural genes catalyze the synthesis of the amino acid tryptophan (FIGURE 11.9). When tryptophan is present in the cell in adequate concentrations, it is energy efficient to stop making the enzymes for tryptophan synthesis. Therefore, tryptophan itself functions as a co-repressor that binds to the repressor of the *trp* operon, causing the repressor to bind to the *trp* operator to prevent transcription.

To summarize the differences between these two types of operons:

- In *inducible* systems, the substrate of a metabolic pathway (the inducer) interacts with a transcription factor (the repressor), rendering the repressor incapable of binding to the operator and thus allowing transcription.
- In *repressible* systems, the product of a metabolic pathway (the co-repressor) binds to the repressor protein, which is then able to bind to the operator and block transcription.

In general, inducible systems control catabolic pathways (which are turned on only when the substrate is available), whereas repressible systems control anabolic pathways (which are turned on until the concentration of the product becomes excessive).

FIGURE 11.8 The *lac* Operon: An Inducible System Allolactose (the inducer) leads to synthesis of the enzymes in the lactose-metabolizing pathway by binding to the repressor protein and preventing its binding to the operator.

FIGURE 11.9 The *trp* Operon: A Repressible System Because tryptophan activates an otherwise inactive repressor, it is called a co-repressor.

The *trp* Operon

LINK Review the descriptions of catabolic and anabolic reactions in Concept 2.5

In both of the systems described above, the regulatory protein is a repressor that functions by binding to the operator. Other operons are regulated by activator proteins that bind to DNA elements near the promoter and promote transcription. Like repressors, activators can regulate both inducible and repressible systems. We will discuss transcription factors in more detail in Concept 11.3.

RNA polymerase can be directed to a class of promoters

As noted above and in Chapter 10, RNA polymerase binds to specific DNA sequences at the promoter to initiate transcription. We have just described how repressor proteins can physically block RNA polymerase binding. However, there are other proteins in prokaryotes called **sigma factors** that can bind to RNA polymerase and direct the polymerase to specific promoters.

Genes that encode proteins with related functions may be at different locations in the genome but have the same promoter sequence. This allows them to be expressed at the same time and under the same physiological conditions. For example, some bacteria stop growing when nutrients in their environment are depleted. When this happens, they adopt an alternative lifestyle called *sporulation*—they reduce metabolism and form a tough spore coat. This process involves the sequential expression of specific classes of genes in a manner reminiscent of the early and late genes of bacteriophage infection (see Figure 11.3). Each member of a gene class has a common promoter sequence, and RNA polymerase is directed to the promoter in each case by a specific sigma factor. As we will see in Concept 11.3, this *global gene regulation* by proteins binding to RNA polymerase is also common in eukaryotes.

LINK For more on sporulation as a survival strategy, see Concept 19.2

Do You Understand Concept 11.2?

- Describe the molecular conditions at the *lac* operon promoter in the presence and absence of lactose.
- Describe the molecular events at the *trp* operon promoter in the presence and absence of tryptophan.
- If the *lac* repressor gene is mutated so that the allosteric site on the protein no longer binds allo-lactose, what would be the effect on transcription of the *lac* operon? What about a similar mutation in the *trp* repressor gene?

Studies of viruses and bacteria provide a basic understanding of the mechanisms that regulate gene expression and of the roles of regulatory proteins in both positive and negative regulation. We will now turn to the control of gene expression in eukaryotes. You will see both negative and positive control of transcription, as well as posttranscriptional mechanisms of regulation.

concept 11.3 Eukaryotic Genes Are Regulated by Transcription Factors and DNA Changes

As we mentioned in Concept 11.1, gene expression can be regulated at a number of different points in the process of transcribing a gene and translating the mRNA into a protein (see Figure 11.1). In this concept we will describe the mechanisms that result in the selective transcription of specific eukaryotic genes. The mechanisms for regulating transcription in eukaryotes have similar themes to those of prokaryotes. Both types of cells use DNA–protein interactions to mediate negative and positive control of gene expression. However, there are significant differences, which generally reflect the greater complexity of eukaryotic organisms (TABLE 11.1).

Transcription factors act at eukaryotic promoters

As in bacteria, a eukaryotic promoter is a region of DNA near the 5′-end of a gene where RNA polymerase binds and initiates transcription. Eukaryotic promoters are extremely diverse and difficult to characterize, but they each contain a core promoter sequence to which the RNA polymerase binds. The most common of these is the **TATA box**—so called because it is rich in A-T base pairs.

RNA polymerase II is the polymerase that transcribes the protein-coding genes in eukaryotes. It cannot bind to the promoter and initiate transcription by itself. Rather, it does so only after various **general transcription factors** have bound to the core promoter. General transcription factors bind to most promoters and are distinct from transcription factors that have specific regulatory effects only at certain promoters or classes of promoters. **FIGURE 11.10** illustrates the assembly of the resulting transcription complex at a promoter containing a TATA

box. First, the protein TFIID (“TF” stands for transcription factor) binds to the TATA box. Binding of TFIID changes both its own shape and that of the DNA, presenting a new surface that attracts the binding of other transcription factors. RNA polymerase II binds only after several other proteins have bound to the complex.

The core promoter sequence is bound by general transcription factors that are needed for the expression of all RNA polymerase II–transcribed genes. Other sequences that are (usually) found in or near promoter regions are specific to only a few genes and are recognized by specific transcription factors. These transcription factors may be positive regulators (*activators*) or negative regulators (*repressors*) of transcription:

Such transcription factors may be present only in certain cell types, or they may be present in all cells but activated by specific signals. DNA sequences that bind activators are called *enhancers*, and those that bind *repressors* are called *silencers*. Some enhancers and silencers occur near the core promoter, and others can be as far as 20,000 base pairs away. When the activators or repressors bind to these DNA sequences, they interact with the RNA polymerase complex, causing the DNA to bend. Often many such binding proteins are involved, and *the combination of factors present determines the initiation of transcription*. With about 2,000 different transcription factors in humans, there are many possibilities for regulation.

How do transcription factors recognize a specific nucleotide sequence in DNA? To answer this question, let's look at a specific example. NFATs (*nuclear factors of activated T cells*) are a group of transcription factors that control the expression

TABLE 11.1 Transcription in Bacteria and Eukaryotes

CHARACTERISTIC	BACTERIA	EUKARYOTES
Locations of functionally related genes	Often clustered in operons	Often distant from one another with separate promoters
RNA polymerases	One	Three: I: transcribes rRNA II: transcribes mRNA III: transcribes tRNA and small RNAs
Promoters and other regulatory sequences	Few	Many
Initiation of transcription	Binding of RNA polymerase	Binding of many proteins, including RNA polymerase, to promoter

FIGURE 11.10 The Initiation of Transcription in Eukaryotes Apart from TFIID, which binds to the TATA box, each transcription factor in this transcription complex has binding sites only for the other proteins in the complex, and does not bind directly to DNA. B, E, F, and H are general transcription factors.

Initiation of Transcription

of genes essential for the immune response (see Chapter 31). NFAT proteins bind to a 12-bp recognition sequence near the promoters of these genes, with the sequence CGAG-GAAAATTG (FIGURE 11.11). Recall that there are atoms in

the bases of DNA that are available for hydrogen bonding but are not involved in base pairing (see Figure 9.6). These atoms are important in the interactions between an NFAT and the DNA. In addition, there are hydrophobic interactions between the rings in the DNA bases and some amino acid R groups in the protein. As for an enzyme and its substrate (see Concept 3.3), there is an *induced fit* between the NFAT and the DNA, such that the protein undergoes a conformational change after binding begins.

FRONTIERS An important aspect of gene regulation is the specific binding of transcription factors to DNA. Major efforts are underway to understand this binding at the atomic level. The atoms of bases that are exposed within the major or minor grooves of DNA can interact by hydrogen or ionic bonding with the DNA binding domains of transcription factors. Biophysicists are determining the three-dimensional structures of transcription factors so that they can create computer models for how the proteins might interact with DNA.

The expression of sets of genes can be coordinately regulated by transcription factors

We have seen that prokaryotes can coordinate the regulation of several genes by arranging them in an operon. In addition, bacteria can coordinate the expression of groups of genes using sigma factors, which guide RNA polymerase to particular classes of promoters. This latter mechanism is also used in eukaryotes to coordinately regulate genes that may be far apart, even on different chromosomes. The expression of genes can be coordinated if they share regulatory sequences that *bind the same transcription factors*.

This type of coordination is used by organisms to respond to stress—for example, by plants in response to drought.

FIGURE 11.11 A Transcription Factor Protein Binds to DNA The transcription factor NFAT activates genes for the immune response by binding to a specific DNA sequence near the promoters of those genes.

FIGURE 11.12 Coordinating Gene Expression A single environmental signal, such as drought stress, activates a transcription factor that acts on many genes.

Under conditions of drought stress, a plant must simultaneously synthesize a number of proteins whose genes are scattered throughout the genome. The synthesis of these proteins comprises the stress response. To coordinate expression, each of these genes has a specific regulatory sequence near its promoter called the *dehydration response element* (DRE). In response to drought, a transcription factor changes so that it binds to this element and stimulates mRNA synthesis (FIGURE 11.12). The dehydration response proteins not only help the plant conserve water, but also protect the plant against freezing or excess salt in the soil. This finding has considerable importance for agriculture because crops are often grown under less than optimal conditions.

Epigenetic changes to DNA and chromatin can regulate transcription

So far we have focused on regulatory events that involve specific DNA sequences at or near a gene's promoter. Eukaryotic cells can also regulate the transcription of large stretches of DNA (containing many genes) by reversible, non-sequence-specific alterations to either the DNA or the chromosomal proteins that package the DNA in the nucleus. These alterations can be passed on to daughter cells after mitosis or meiosis. They are called **epigenetic** changes to distinguish them from mutations, which involve irreversible changes to the DNA's base sequence (see Concept 9.3).

DNA METHYLATION Depending on the organism, from 1 to 5 percent of cytosine residues in the DNA are chemically modified by the addition of a methyl group ($-\text{CH}_3$), to form 5-methylcytosine (FIGURE 11.13). This covalent addition is catalyzed by the enzyme **DNA methyltransferase** and, in mammals, usually occurs in C residues that are adjacent to G residues. DNA regions rich in these doublets are called **CpG islands**, and they are especially abundant in promoters.

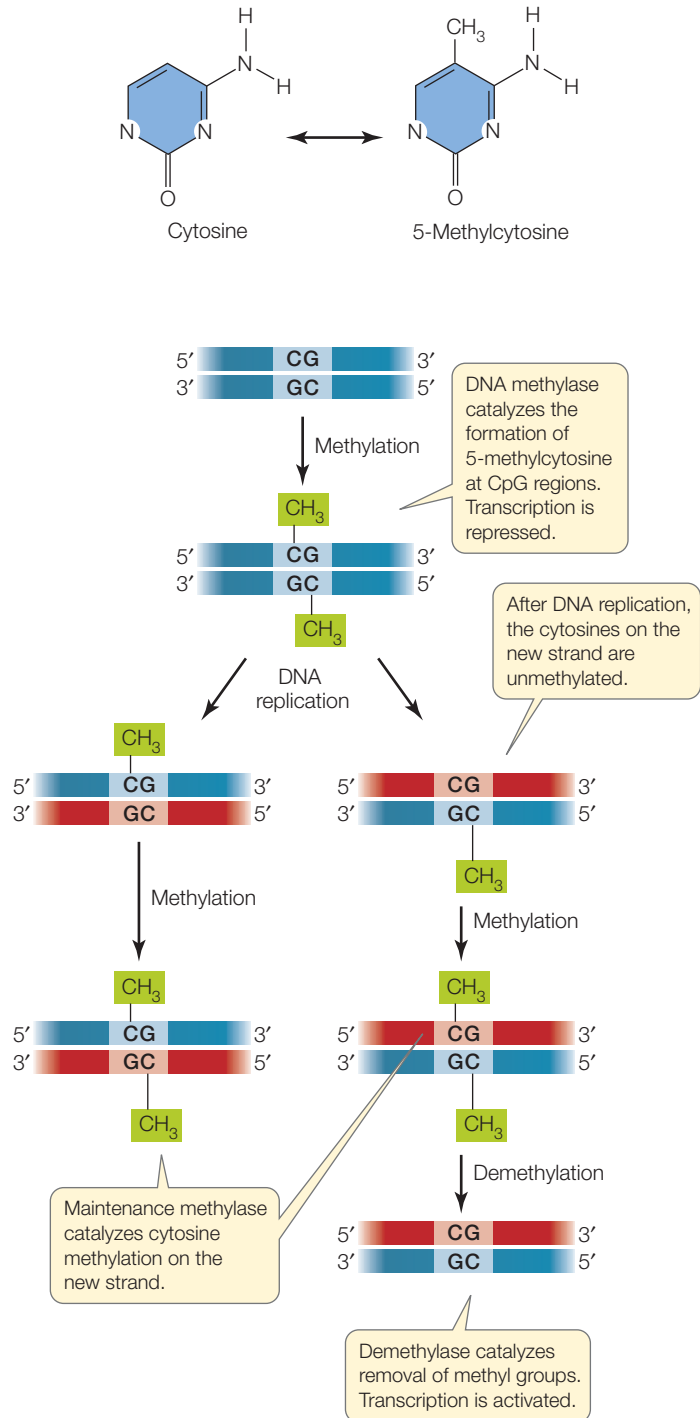

FIGURE 11.13 DNA Methylation: An Epigenetic Change The reversible formation of 5-methylcytosine in DNA can alter the rate of transcription.

This covalent change in DNA is *heritable*: when DNA is replicated, a **maintenance methylase** catalyzes the formation of 5-methylcytosine in the new DNA strand. However, the pattern of cytosine methylation can also be altered, because methylation is reversible: a third enzyme, appropriately called **demethylase**, catalyzes the removal of the methyl group from cytosine (see Figure 11.13).

Methylated DNA binds specific proteins that are involved in the repression of transcription; thus heavily methylated genes tend to be inactive (*silenced*). Sometimes, large stretches of DNA or almost whole chromosomes are methylated. Under a microscope, two kinds of chromatin can be distinguished in the stained interphase nucleus: *euchromatin* and *heterochromatin*. The euchromatin appears diffuse and stains lightly; it contains the DNA that is transcribed into mRNA. Heterochromatin is condensed and stains darkly; any genes it contains are generally not transcribed.

A dramatic example of heterochromatin is the X chromosome in female mammals. A normal female mammal has two X chromosomes, whereas a normal male has an X and a Y (see Concept 8.3). The Y chromosome is smaller and lacks most of the genes present on the X. As a result, females and males differ greatly in the “dosage” of X-linked genes. Because each female cell has two copies of each X chromosome gene, the female should have the potential to produce twice as much of each protein product as the male. Nevertheless, for 75 percent of the genes on the X chromosome, the total amount of mRNA produced is generally the same in males and in females. How does this happen?

In the early female embryo, one copy of X becomes heterochromatic and transcriptionally inactive in each cell, and the same X remains inactive in all of that cell’s descendants. In a given female embryo cell, the “choice” of which X to inactivate is random. Recall that one X in a female comes from her father and one from her mother. Thus, in one embryonic cell

FIGURE 11.14 X Chromosome Inactivation A Barr body in the nucleus of a human female cell is the transcriptionally inactive X chromosome.

the paternal X might be inactivated, but in a neighboring cell the maternal X might be inactive.

The inactive X is identifiable within the nucleus as a heterochromatic *Barr body* (named for its discoverer, Murray Barr) (**FIGURE 11.14**). This clump of heterochromatin consists of heavily methylated DNA. A female with the normal two X chromosomes will have one Barr body, whereas a rare female with three Xs will have two, and an XXXX female will have three. Males that are XXY will have one. These observations suggest that the interphase cells of each person, male or female, have a single active X chromosome, and thus a constant dosage of expressed X chromosome genes.

HISTONE PROTEIN MODIFICATION Another mechanism for epigenetic gene regulation is the alteration of chromatin structure, or **chromatin remodeling**. Large amounts of DNA (nearly 2 meters in humans!) is packed within the nucleus (a 5- μm -diameter organelle). The basic unit of DNA packaging in eukaryotes is the nucleosome, a core of positively charged **histone** proteins around which DNA is wound:

Nucleosomes can make DNA physically inaccessible to RNA polymerase and the rest of the transcription apparatus. Each histone protein has a “tail” of approximately 20 amino acids at its N terminus that sticks out of the compact structure and contains certain positively charged amino acids (notably lysine). Enzymes called **histone acetyltransferases** can add acetyl groups to these positively charged amino acids, thus neutralizing their charges:

Ordinarily, there is strong electrostatic attraction between the positively charged histone proteins and DNA, which is negatively charged because of its phosphate groups. Reducing the positive charges of the histone tails reduces the affinity

FIGURE 11.15 Epigenetic Remodeling of Chromatin for Transcription Initiation of transcription requires that nucleosomes change their structure, becoming less compact. This chromatin remodeling makes DNA accessible to the transcription complex (see Figure 11.10).

of the histones for DNA, loosening the compact nucleosome. Additional chromatin remodeling proteins can then bind to the nucleosome–DNA complex and open up the DNA for gene expression (**FIGURE 11.15**). Thus, histone acetyltransferases can *activate* transcription. Another kind of chromatin remodeling protein, **histone deacetylase**, can remove the acetyl groups from histones and thereby *repress* transcription.

Other types of histone modification can affect gene activation and repression. For example, histone methylation (not to be confused with the *cytosine* methylation we discussed above) is associated with gene inactivation. Histone phosphorylation also affects gene expression, the specific effect depending on which amino acid of the histone is modified. All of these effects are reversible, and so the transcriptional activity of a eukaryotic gene may be determined by varying patterns of histone modification.

Epigenetic changes can be induced by the environment

Despite the fact that they are reversible, many epigenetic changes such as DNA methylation and histone modification can permanently alter gene expression patterns in a cell. If the cell is a germline cell that forms gametes, the epigenetic changes can be passed on to the next generation. But what de-

termines these epigenetic changes? A clue comes from a recent study of human monozygotic (identical) twins.

Monozygotic twins come from a single fertilized egg that divides to produce two separate cells; each of these develops into a separate individual. Twin brothers or sisters thus have identical genomes. But are they identical in their *epigenomes*? A comparison of DNA in hundreds of such twin pairs shows that in tissues of three-year-olds, the DNA methylation patterns are virtually the same. But by age 50, when the twins have usually been living apart in different environments for decades, the patterns are quite different. This indicates that the *environment plays an important role in epigenetic modifications* and, therefore, in the regulation of genes that these modifications affect.

FRONTIERS Biologists are investigating the inheritance of epigenetic changes by characterizing the epigenetic tags on genes during embryonic development. Early in development, epigenetic tags are removed from almost all genes, so the “epigenome” begins with a largely blank slate. However, some genes escape this process and maintain the epigenetic changes they accumulated while they were in the parents. This is inheritance of an acquired characteristic, and its discovery was a major surprise to biologists—especially geneticists.

What factors in the environment lead to epigenetic changes? One might be stress: when mice are put in a stressful situation, genes that are involved in important brain pathways become heavily methylated (and transcriptionally inactive). Treatment of the stressed mice with an antidepressant drug reverses these changes. Transcription factors such as CREB that mediate addiction (see the opening story of this chapter) are involved in histone acetylation, which leads to subsequent gene activation.

Do You Understand Concept 11.3?

- How do transcription factors regulate gene expression?
- What is the difference between epigenetic regulation and gene regulation by transcription factors?
- How can a pattern of DNA methylation be inherited?
- In colorectal cancer, some tumor suppressor genes are inactive. This is an important factor resulting in uncontrolled cell division. Two of the possible explanations for the inactive genes are: (1) a mutation in the coding region, resulting in an inactive protein, and (2) epigenetic silencing at the promoter of the gene, resulting in reduced transcription. How would you investigate these two possibilities?

Thus far we have examined transcriptional gene regulation in viruses, prokaryotes, and eukaryotes. In the final concept we will focus on the posttranscriptional mechanisms for regulating gene expression in eukaryotes.

concept 11.4 Eukaryotic Gene Expression Can Be Regulated after Transcription

Gene expression involves transcription and then translation. So far we have described how eukaryotic gene expression is regulated at the transcriptional level. But as Figure 11.1 shows, there are many points at which regulation can occur after the initial gene transcript is made.

Different mRNAs can be made from the same gene by alternative splicing

Most primary mRNA transcripts in eukaryotes contain several introns (see Figure 10.6). We have seen how the splicing mechanism recognizes the boundaries between exons and introns. What would happen if the β -globin pre-mRNA, which has two introns, were spliced from the start of the first intron to the end of the second? The middle exon would be spliced out along with the two introns. An entirely new protein (certainly not a β -globin) would be made, and the functions of normal β -globin would be lost. Such **alternative splicing** can be a deliberate mechanism for generating a family of different proteins with different activities and functions from a single gene (FIGURE 11.16).

Two examples of this mechanism are found in HIV and in the fruit fly (*Drosophila*):

- The HIV genome (see Figure 11.4) encodes nine proteins but is transcribed as a single pre-mRNA. Most of the nine proteins are then generated by alternative splicing of this pre-mRNA.
- In *Drosophila*, sex is determined by the *Sxl* gene. This gene has four exons, which we will designate 1, 2, 3, and 4. In the female embryo, splicing generates two active forms of the *Sxl*

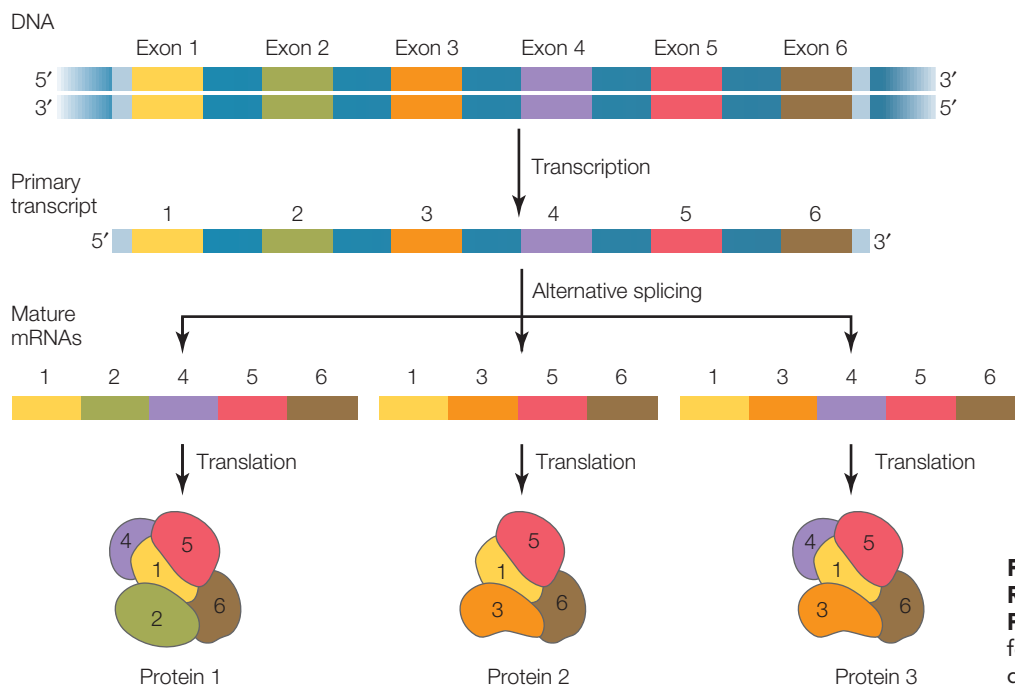

FIGURE 11.16 Alternative Splicing Results in Different Mature mRNAs and Proteins Pre-mRNA can be spliced differently in different tissues, resulting in different proteins.

protein, containing exons 1 and 2, and 1, 2, and 4. However, in the male embryo, the protein contains all four exons (1, 2, 3, and 4) and is inactive.

Before the human genome was sequenced, most scientists estimated that they would find between 80,000 and 150,000 protein-coding genes. You can imagine their surprise when the actual sequence revealed only about 24,000 genes! In fact, there are many more human mRNAs than there are human genes, and most of this variation comes from alternative splicing. Indeed, recent surveys show that more than 80 percent of all human genes are alternatively spliced.

Alternative splicing may be a key to the differences in levels of complexity among organisms. For example, although humans and chimpanzees have similar-sized genomes, there is more alternative splicing in the human brain than in the brain of a chimpanzee.

MicroRNAs are important regulators of gene expression

As we discuss in Concept 12.3, only a fraction of the genome in most plants and animals codes for proteins. Some of the genome encodes ribosomal RNA and transfer RNAs, but until recently biologists thought that the rest of the genome was not transcribed; some even called it “junk.” Recent investigations, however, have shown that some of these noncoding regions *are* transcribed. The noncoding RNAs are often very small and therefore difficult to detect. These tiny RNA molecules are called **microRNA (miRNA)**.

The first miRNA sequences were found in the worm *Caenorhabditis elegans*. This model organism, which has been studied extensively by developmental biologists, goes through several larval stages. Victor Ambros at the University of Massachusetts found mutations in two genes that had different effects on progress through these stages:

- *lin-14* mutations (named for abnormal cell *lineage*) cause the larvae to skip the first stage and go straight to the second stage. Thus the gene’s normal role is to facilitate events of the first larval stage.
- *lin-4* mutations cause certain cells in later larval stages to repeat a pattern of development normally observed in the first larval stage. It is as if the cells were stuck in that stage. So the normal role of this gene is to *negatively regulate lin-14*, turning off its expression so the cells can progress to the next stage.

Not surprisingly, further investigation showed that *lin-14* encodes a transcription factor that affects the transcription of genes involved in larval cell progression. It was originally expected that *lin-4*, the negative regulator, would encode a protein that downregulates genes activated by the *lin-14* protein. But this turned out to be incorrect. Instead, *lin-4* encodes a 22-base miRNA that inhibits *lin-14* expression *posttranscriptionally by binding to its mRNA*.

Hundreds of miRNAs, in a variety of eukaryotes, have now been described. Each one is about 22 nucleotides long and usually has dozens of mRNA targets. Each miRNA is transcribed

FIGURE 11.17 mRNA Degradation Caused by MicroRNAs

MicroRNAs inhibit the translation of specific mRNAs by causing their premature degradation.

as a longer precursor that is cleaved through a series of steps to double-stranded miRNAs. A protein complex guides the miRNA to its target mRNA, where translation is inhibited and the mRNA is degraded (**FIGURE 11.17**). The remarkable conservation of this gene-silencing mechanism in eukaryotes indicates that it is evolutionarily ancient and biologically important.

FRONTIERS The patterns of miRNA expression vary in different tissues and at different times. At an early stage of breast cancer, the cancer cells cause a distinctive pattern of miRNAs to appear in blood serum, and this is being investigated as a marker for cancer that might otherwise be undetectable. This may allow earlier detection of breast cancer, which would improve treatment outcomes.

Translation of mRNA can be regulated

The amount of a protein in a cell is not determined simply by the amount of its mRNA. For example, in yeast cells only about a third of the genes show clear correlations in the amounts of mRNA and protein; in these cases, more mRNA leads to more protein. For two-thirds of the genes there is no apparent relationship between the two—there may be lots of mRNA and little or no protein, or lots of protein and little mRNA. The concentrations of these proteins must therefore be determined

FIGURE 11.18 A Repressor of Translation Binding of a translational repressor to mRNA blocks the mRNA from associating with the ribosome. The repressor can be removed from the mRNA via allosteric regulation.

triphosphate (GTP) at its 5' end. An mRNA that is capped with an unmodified GTP molecule is not translated. For example, stored mRNAs in the egg cells of the tobacco hornworm moth are capped with unmodified GTP molecules and are not translated. After the egg is fertilized, however, the caps are modified, allowing the mRNA to be translated to produce the proteins needed for early embryonic development.

- *Translational repressor proteins.* Such proteins block translation by binding to mRNAs and preventing their attachment to the ribosome. For example, in mammalian cells the rate of translation of the protein ferritin increases rapidly when the level of free iron ions (Fe^{2+}) increases in the cell. Iron is an essential nutrient, but the free ions can be toxic to the cell; ferritin binds the ions and stores them in a safe but accessible form. The amount of ferritin mRNA in the cell remains constant, but when the iron level is low, a **translational repressor** binds to the ferritin mRNA and prevents its translation. When the iron level rises, some of the excess Fe^{2+} ions bind to the repressor and alter its three-dimensional structure, causing the repressor to detach from the mRNA, and allowing translation to proceed (FIGURE 11.18).

by factors acting after the mRNA is made. Cells do this in two major ways: by regulating the translation of mRNA or by altering how long proteins persist in the cell.

There are three known ways in which the translation of mRNA can be regulated:

- *Inhibition of translation with miRNAs.* This was discussed in the last section (see above).
- *Modification of the 5' cap.* As noted in Concept 10.2, an mRNA usually has a chemically modified molecule of guanosine

Protein stability can be regulated

The protein content of any cell at a given time is a function of both protein synthesis and protein degradation. Certain proteins can be targeted for destruction in a chain of events that begins when an enzyme attaches a 76-amino acid protein called **ubiquitin** (so named because it is ubiquitous, or widespread) to a lysine residue of the protein to be destroyed. Other ubiquitins then attach to the primary one, forming a polyubiquitin chain. The protein–polyubiquitin complex then binds to a huge protein complex called a **proteasome** (from *protease* and *soma*, “body”; FIGURE 11.19). Upon entering the proteasome, the polyubiquitin is removed and ATP energy is used to unfold the target protein. Three different proteases then digest the protein into small peptides and amino acids. You may recall from Chapter 7 that cyclins are proteins that regulate the activities of key enzymes at specific points in the cell cycle. Cyclins must be broken down at just the right time, and this is done by proteasomes.

FIGURE 11.19 A Proteasome Breaks Down Proteins Proteins targeted for degradation are bound by ubiquitin, which then directs the targeted protein to a proteasome. The proteasome is a complex structure where proteins are digested by several powerful proteases.

APPLY THE CONCEPT

Eukaryotic gene expression can be regulated transcriptionally and posttranscriptionally

The enzyme HMG CoA reductase (HR) catalyzes an initial step in the synthesis of cholesterol. The table shows the HR levels in liver cells following various treatments.

Explain the results of each treatment.

TREATMENT	AMOUNT OF HR PROTEIN
1. Actinomycin D, a drug that inhibits RNA polymerase II	Reduced
2. Suberoylanilide hydroxamic acid, a histone deacetylase inhibitor	Increased
3. Bortezomib, a proteasome inhibitor	Increased
4. High level of cholesterol	Reduced
5. Azacytidine, inhibitor of DNA methylation	Increased

Do You Understand Concept 11.4?

- How can a single gene transcribed into a single pre-mRNA code for several different proteins?
- Compare inhibition of translation by miRNA with inhibition by a repressor.
- You are studying the enzyme protease in germinating seeds. You find that protease activity increases tenfold after treatment of the seeds with a hormone, gibberellic acid. How would you show that this increase is due to:
 - a. release of a translational repressor by the hormone?
 - b. allosteric inhibition of a transcriptional repressor by the hormone?

How does CREB regulate the expression of many genes?

ANSWER CREB is a family of several closely related transcription factors that can either activate or repress gene expression (Concept 11.1). They bind to the *cAMP response element* (CRE), a short DNA sequence of GACGTCA that is found in the promoter regions of many genes (Concept 11.3). CREB proteins have a “leucine zipper” structure that consists of two parallel α helices rich in the amino acid leucine (**FIGURE 11.20**), and fingerlike extensions that fit into the major groove of the DNA double helix.

CREB binding and regulation of gene expression is essential for a number of processes in several organs, including the brain. In addition to its role in drug and alcohol addiction

(described in the opening story), CREB has been strongly implicated in long-term memory. Animals with mutations that result in a lack of active CREB can learn a maze test, but they don’t remember it later. Similar effects are seen if CREB activity is blocked right after a task is learned. When animals learn a task, imaging studies reveal CRE-containing genes becoming active in the hippocampus, a region of the brain that is involved in long-term memory (see Concept 34.5). Thus, CREB provides an insight into the molecular biology of memory, linking learning to the regulation of gene expression.

FIGURE 11.20 An Explanation for Alcoholism? The transcription factor CREB binds to DNA and activates the promoters of genes involved in addictive behaviors.

11

SUMMARY

concept 11.1 Several Strategies Are Used to Regulate Gene Expression

- Gene expression can be regulated at the levels of transcription, RNA processing, translation, or posttranslation. **Review Figure 11.1 and WEB ACTIVITY 11.1**
- Some genes are always expressed (**constitutive genes**), whereas others are expressed only at certain times and in certain cells (**inducible genes**).
- **Transcription factors** are regulatory proteins that bind DNA and regulate gene expression. **Activators** positively regulate gene expression. **Repressors** negatively regulate gene expression. **Review Figure 11.2**
- **Viruses** provide examples of gene regulation as they convert the host cell into a virus factory. **Review Figures 11.3 and 11.4**

concept 11.2 Many Prokaryotic Genes Are Regulated in Operons

- A metabolic pathway can be regulated either by allosteric regulation of an enzyme or by regulation of enzyme synthesis. **Review Figure 11.6**
- In prokaryotes, several genes can be part of a single transcriptional unit called an **operon**, which consists of a promoter, an **operator**, and two or more **structural genes**. **Review Figure 11.7**
- An inducible operon is turned off unless its expression is needed, whereas a repressible operon is turned on unless its expression is not needed. When an operon is turned off, it has a repressor protein bound to its operator, preventing transcription.
- The *lac* operon is an example of an inducible system, whereas the *trp* operon is an example of a repressible system. **Review Figures 11.8 and 11.9 and ANIMATED TUTORIALS 11.1 and 11.2**
- **Sigma factors** direct RNA polymerase to specific promoters in prokaryotes.

concept 11.3 Eukaryotic Genes Are Regulated by Transcription Factors and DNA Changes

- Eukaryotic gene expression is regulated both during and after transcription.
- **General transcription factors** bind to the core promoter sequences of protein-coding genes and direct RNA polymerase II to the promoter. **Review Figure 11.10 and ANIMATED TUTORIAL 11.3**
- Specific transcription factors (activators and repressors) bind to specific DNA elements near the promoter and affect the rate of transcription initiation. **Review Figures 11.11 and 11.12**
- The term **epigenetic** refers to changes in gene expression that do not involve changes in DNA sequences.
- Methylation of cytosine residues generally inhibits transcription. **Review Figure 11.13**
- **Chromatin remodeling** via the modification of **histone** proteins in nucleosomes also affects transcription. **Review Figure 11.15**
- Epigenetic changes can be induced by the environment and can be inherited.

concept 11.4 Eukaryotic Gene Expression Can Be Regulated after Transcription

- **Alternative splicing** of pre-mRNA can produce different proteins. **Review Figure 11.16**
- A **microRNA (miRNA)** is a small noncoding RNA that inhibits the translation of specific mRNAs by causing their premature degradation. **Review Figure 11.17**
- The translation of mRNA to proteins can be regulated by **translational repressors**. **Review Figure 11.18**
- A **proteasome** can break down proteins, thus affecting protein longevity. **Review Figure 11.19**

See **WEB ACTIVITY 11.2** for a concept review of this chapter.

Canis lupus familiaris, the dog, was domesticated by humans from the gray wolf thousands of years ago. There are several kinds of wolves, and they all look more or less the same. Not so with “man’s best friend.” The American Kennel Club recognizes about 155 different breeds. Dog breeds vary greatly in size, shape, coat color, hair length, and even behavior. For example, an adult Chihuahua weighs just 1.5 kg, whereas a Scottish deerhound weighs 70 kg. No other mammalian species shows such large phenotypic variation. Furthermore, there are hundreds of genetic diseases in dogs, and many of these diseases have counterparts in humans. Biologists are curious about the molecular basis of the phenotypic variation, and they view dogs as models for studying genetic diseases. For these reasons, the Dog Genome Project began in the late 1990s. Since then the sequences of several dog genomes have been published.

Two dogs—a boxer and a poodle—were the first of their species to have their entire genomes sequenced. The dog genome contains 2.8 billion base pairs of DNA in 39 pairs of chromosomes. There are 19,000 protein-coding genes, most of them with close counterparts in other mammals, including humans. The whole genome sequence made it easy to create a map of genetic markers—specific nucleotides or short sequences of DNA at particular locations on the genome that differ between individual dogs or breeds.

Genetic markers are used to map the locations of genes that control particular traits. To do this, scientists must extract

DNA from many individual dogs that vary in just one or a few characters. Taking samples of cells for DNA isolation is relatively easy: a cotton swab is swept over the inside of the dog’s cheek. As one scientist conducting genomic analyses of dogs said, the dogs “didn’t care, especially if they were going to get a treat or if there was a tennis ball in our other hand.”

The molecular methods used to analyze dogs have been applied to many other animals and plants of economic and social importance to humans. And of course, the human genome itself has been sequenced and is being studied intensively.

The Long-haired Chihuahua (left) and the Great Dane (right) are the same species, *Canis lupus familiaris*, and yet they show great variation in size. Genome sequencing has provided insights into how size is controlled by genes.

What does genome sequencing reveal about dogs and other animals?

12.1

There Are Powerful Methods for Sequencing Genomes and Analyzing Gene Products

A major goal in sequencing genomes is to understand genetics—that is, to identify mutations in DNA and relate them to phenotypes. While this had been done for individual genes, the notion of sequencing the entire genome of a complex organism was not contemplated until 1986. The Nobel laureate Renato Dulbecco and others proposed at that time that the world scientific community be mobilized to undertake the sequencing of the entire human genome. One motive was to detect DNA damage in people who had survived the atomic bomb attacks and been exposed to radiation in Japan during World War II. But in order to detect changes in the human genome, scientists first needed to know its normal sequence.

The result was the publicly funded **Human Genome Project**, an enormous undertaking that was successfully completed in 2003. This effort was aided and complemented by privately funded groups. The project benefited from the development of many new methods that were first used in the sequencing of smaller genomes—those of prokaryotes and simple eukaryotes, the model organisms you are familiar with from studies in genetics and cell biology. Many of these methods are still applied widely, and powerful new methods for sequencing genomes have emerged. These are complemented by new ways to examine phenotypic diversity in a cell's proteins and in the metabolic products of the cell's enzymes.

New methods have been developed to rapidly sequence DNA

Many prokaryotes have a single chromosome, whereas eukaryotes have many. Because of their differing sizes, chromosomes can be separated from one another, identified, and experimentally manipulated. It might seem that the most straightforward way to sequence a chromosome would be to start at one end and simply sequence the DNA molecule one nucleotide at a time. The task is somewhat simplified because only one of the two strands needs to be sequenced, the other being complementary. However, this large-polymer approach is not practical, since at most only several hundred base pairs (bp) can be sequenced at a time using current methods.

As you will see, a key to interpreting DNA sequences is to do several separate experiments simultaneously on a given chromosome, first breaking the DNA into *overlapping fragments*.

In the 1970s, the late Frederick Sanger invented a way to sequence DNA by using chemically modified nucleotides that were originally developed to stop cell division in cancer. This method, or a variation of it, was used to obtain the first human genome sequence as well as those of model organisms. However, it was relatively slow, expensive, and labor-intensive. The first decade of the new millennium saw the development of a faster and less-expensive method: **next-generation DNA sequencing** uses miniaturization techniques first developed

for the electronics industry, as well as the principles of DNA replication and the polymerase chain reaction (PCR).

LINK DNA replication and PCR can be reviewed in Concept 9.2

There are several variations in the next-generation sequencing techniques. One approach is outlined here and illustrated in **FIGURE 12.1**. First the DNA is prepared for sequencing:

1. A large molecule of DNA is cut into small fragments of about 100 bp each. This can be done by physically breaking up the DNA or by using enzymes that hydrolyze the phosphodiester bonds between nucleotides at intervals in the DNA backbone.
2. The DNA is denatured by heat, breaking hydrogen bonds holding the two strands together. Each single strand acts as a template for the synthesis of new, complementary DNA.
3. Each fragment is attached at each end to short adapter sequences, which are in turn attached to a solid support. The support can be a microbead or a flat surface.
4. Each DNA fragment is amplified by PCR to provide many (approximately 1,000) copies. The multiple copies at a single location allow for easy detection of added nucleotides during the sequencing steps.

Once the DNA has been attached to a solid substrate and amplified, it is ready for sequencing (see Figure 12.1B):

1. At the beginning of each sequencing cycle, the fragments are heated to denature them. A primer, DNA polymerase, and the four nucleotides (each tagged with a different fluorescent dye) are added. A universal primer that is complementary to one of the adaptor sequences is used in the sequencing reactions.
2. The replication process is set up so that DNA (complementary to the template strand) is added one nucleotide at a time. After each addition, the unincorporated nucleotides are removed.
3. The fluorescence of the new nucleotide at each location is detected with a camera. The color of the fluorescence indicates which of the four nucleotides was added.
4. The fluorescent tag is removed from the nucleotide that is already attached, and then the synthesis cycle is repeated. Images are captured after each nucleotide is added. The series of colors at each location indicate the sequence of nucleotides in the growing DNA strand at that location.

The power of this method derives from the fact that:

- It is fully automated and miniaturized.
- Millions of different fragments are sequenced at the same time. This is called *massively parallel sequencing*.
- It is an inexpensive way to sequence large genomes. For example, at the time of this writing, a complete human genome could be sequenced in a few days for several thousand dollars. In contrast, the Human Genome Project took 13 years and \$2.7 billion to sequence one genome!

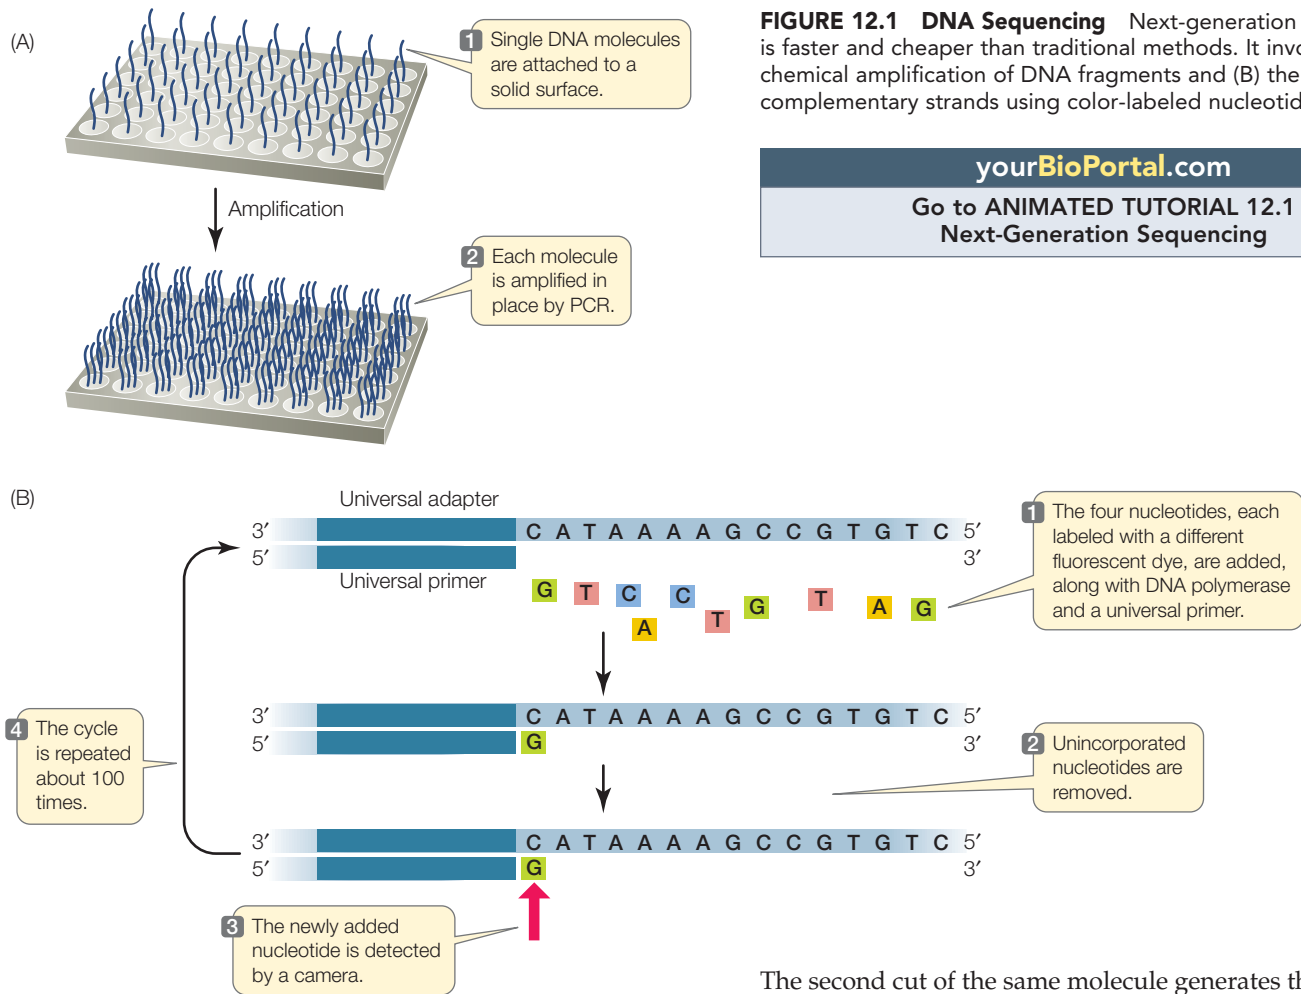

FIGURE 12.1 DNA Sequencing Next-generation sequencing is faster and cheaper than traditional methods. It involves (A) the chemical amplification of DNA fragments and (B) the synthesis of complementary strands using color-labeled nucleotides.

Go to ANIMATED TUTORIAL 12.1
Next-Generation Sequencing

FRONTIERS Rapid and relatively cheap DNA sequencing has led to the 1000 Genomes Project, in which the genomes of 2,500 people from many ethnic groups and locations are being sequenced. This provides a catalog of human genetic variation for further study. Scientists hope to discover the genetic bases of such human traits as aging and disease resistance, and to gain a better understanding of human migration patterns and evolution.

Once the sequences of millions of short fragments have been determined, the problem becomes how to put them together. In other words, how are they arranged in the chromosomes from which they came? Imagine if you cut out every word in this book (there are about 500,000 of them), put them on a table, and tried to arrange them in their original order! The enormous task of determining DNA sequences is possible because the original DNA fragments are *overlapping*.

Let's illustrate the process using a single 10-bp DNA molecule. (This is a double-stranded molecule, but for convenience we show only the sequence of the noncoding strand.) The molecule is cut three ways. The first cut generates the fragments:

TG, ATG, and CCTAC

The second cut of the same molecule generates the fragments:

AT, GCC, and TACTG

The third cut results in:

CTG, CTA, and ATGC

Can you put the fragments in the correct order? (The answer is ATGCCTACTG.) For genome sequencing, the fragments are called "reads" (FIGURE 12.2). Of course, the problem of ordering 2.5 million fragments of 100 bp from human chromosome 1 (246 million bp) is more challenging! The field of **bioinformatics** was developed to analyze DNA sequences using complex mathematics and computer programs.

Genome sequences yield several kinds of information

New genome sequences are being published at an accelerating pace, creating a torrent of biological information (FIGURE 12.3). This information is used in two related fields of research, both focused on studying genomes. In **functional genomics**, biologists use sequence information to identify the functions of various parts of genomes. These parts include:

- *Open reading frames*, which are the coding regions of genes. For protein-coding genes, these regions can be recognized by the start and stop codons for translation, and by intron

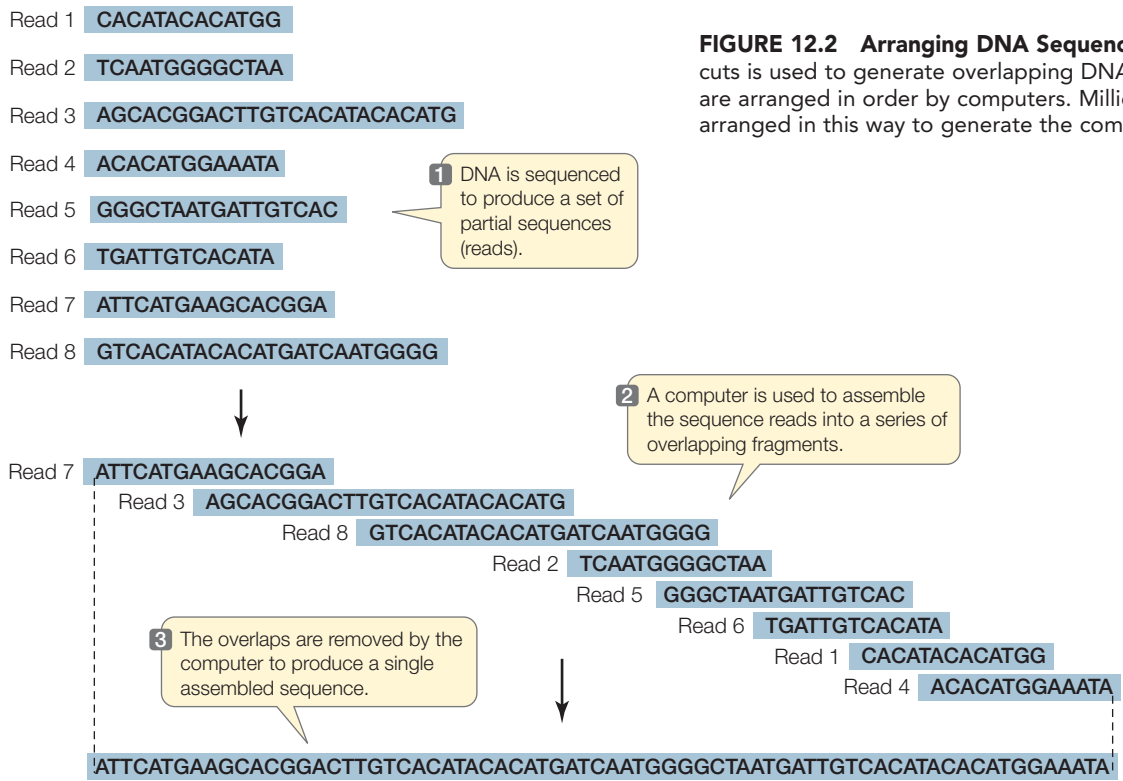

FIGURE 12.2 Arranging DNA Sequences A series of different cuts is used to generate overlapping DNA fragments. Their sequences are arranged in order by computers. Millions of short sequences are arranged in this way to generate the complete sequence of a genome.

A **chromosome** has a single DNA molecule with specialized DNA sequences for the initiation of DNA replication, for spindle interactions in mitosis (centromeres), and for maintaining the integrity of the ends (telomeres).

FIGURE 12.3 The Genomic Book of Life Genome sequences contain many features, some of which are summarized in this overview. Sifting through all the information contained in a genome sequence can help us understand how an organism functions and what its evolutionary history might be.

consensus sequences that indicate the locations of introns. A major goal of functional genomics is to understand the function of every open reading frame in each genome.

- *Amino acid sequences* of proteins, which can be deduced from the DNA sequences of open reading frames by applying the genetic code.
- *Regulatory sequences*, such as promoters and terminators for transcription.
- *RNA genes*, including rRNA, tRNA, small nuclear RNA, and microRNA genes.
- *Other noncoding sequences* that can be classified into various categories, including centromeric and telomeric regions, transposons, and repetitive sequences.

Sequence information is also used in **comparative genomics**: the comparison of a newly sequenced genome (or parts thereof) with sequences from other organisms. This can provide further information about the functions of sequences and can be used to trace evolutionary relationships among different organisms.

Phenotypes can be analyzed using proteomics and metabolomics

“The human genome is the book of life.” Statements like this were common when the human genome sequence was first revealed. They reflect the concept of *genetic determinism*—the idea that a person’s phenotype is determined solely by his or her genotype. But is an organism just a product of gene expression? We know that it is not. The proteins and small molecules present in any cell at a given point in time reflect not just gene

expression but changes in the proteins by the intracellular and extracellular environments. To take more complete snapshots of cells and organisms, two new fields have emerged to complement genomics: proteomics and metabolomics.

PROTEOMICS Many genes encode more than a single protein (**FIGURE 12.4A**). As we described in Concept 11.4, alternative splicing leads to different combinations of exons in the mature mRNAs transcribed from a single gene. Posttranslational modifications also increase the number and the structural and functional diversity of proteins derived from one gene (see Figures 12.4A and 10.21). The **proteome** is the sum total of the proteins produced by an organism, and it is more complex than its genome.

Two methods are commonly used to analyze proteins and the proteome:

- Because of their unique amino acid compositions (primary structures), most proteins have unique combinations of electric charge and size. On the basis of these two properties, they can be separated by two-dimensional gel electrophoresis. Thus isolated, individual proteins can be analyzed, sequenced, and studied (**FIGURE 12.4B**).
- Mass spectrometry uses electromagnets to identify molecules by the masses of their atoms, and it can also be used to determine the structures of molecules. The results are displayed as peaks on a graph.

While genomics seeks to describe the genome and its expression, **proteomics** seeks to identify and characterize all of the expressed proteins. Its ultimate aim is just as ambitious as that of genomics.

METABOLOMICS Studying genes and proteins gives a limited picture of what is going on in a cell. But as we have seen, both gene function and protein function are affected by a cell’s internal and external environments. Many proteins are enzymes, and their activities affect the concentrations of their substrates and products. So as the proteome changes, so do the abundances of these (often small) molecules, called metabolites. The **metabolome** is the quantitative description of all of the metabolites in a cell or organism. These include:

- *Primary metabolites* that are involved in normal processes, such as intermediates in pathways like glycolysis. This category also includes hormones and other signaling molecules.
- *Secondary metabolites*, which are often unique to particular organisms or groups of organisms. They are often involved in special responses to the environment. Examples are antibiotics made by microbes, and the many chemicals made by plants that are used in defense against pathogens and herbivores.

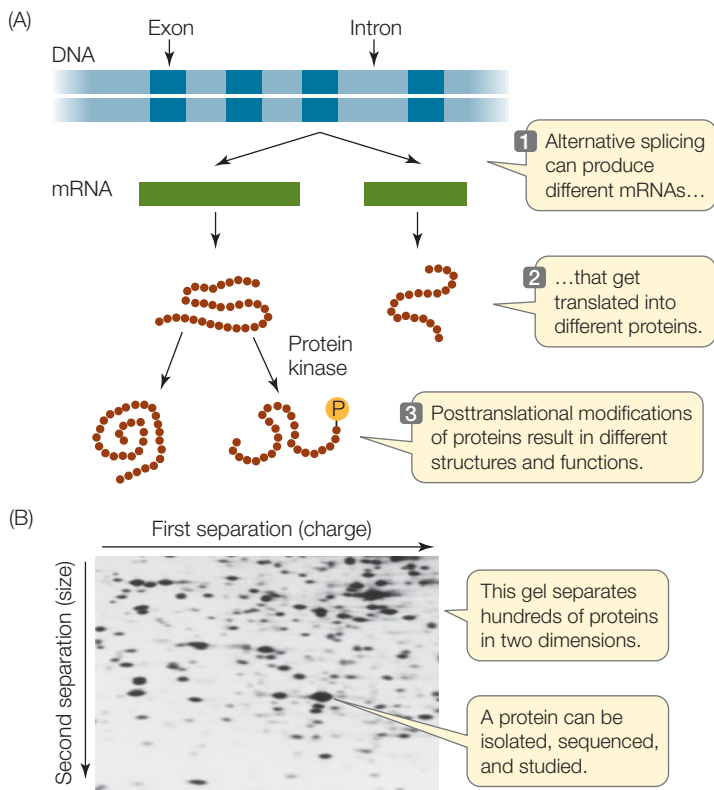

FIGURE 12.4 Proteomics (A) A single gene can code for multiple proteins. (B) A cell’s proteins can be separated on the basis of charge and size by two-dimensional gel electrophoresis. The two separations can distinguish most proteins from one another.

FIGURE 12.5 Genomics, Proteomics, and Metabolomics A combination of these approaches can give more comprehensive information about genotypes and phenotypes.

Metabolomics aims to describe the metabolome of a tissue or organism under particular environmental conditions. Measuring metabolites involves sophisticated analytical instruments. If you have studied organic or analytical chemistry, you may be familiar with gas chromatography and high-performance liquid chromatography which are used to separate molecules with different chemical properties. Mass spectrometry and nuclear magnetic resonance spectroscopy are used to identify molecules. These measurements result in “chemical snapshots” of cells or organisms, which can be related to physiological states.

Taken together, the genome, proteome, and metabolome can move biologists toward a more comprehensive picture of an organism’s genotype and phenotype (FIGURE 12.5).

Do You Understand Concept 12.1?

- Using a table, compare genomics, proteomics, and metabolomics with regard to the methods used and results obtained.
- A DNA molecule is cut into the following fragments that are sequenced: AGTTT, TAGG, CGAT, and CCT. The same molecule is cut in a different way to produce TTCGA, TCCT, AGT, GG, and TA. A third cut produces TTCGAT, CCTT, AGG, and AGT. What is the sequence of this DNA?
- If you were designing a computer program to recognize important sequences in DNA, what types of sequences would you include? What would you learn from finding these sequences in the DNA? Be as specific as you can.

The first cellular genomes to be fully sequenced were those of prokaryotes. In the next concept we will discuss these relatively small, compact genomes.

concept 12.2 Prokaryotic Genomes Are Relatively Small and Compact

When DNA sequencing became possible in the late 1970s, the first life forms to be sequenced were the simplest viruses. The sequences quickly provided new information on how viruses infect their hosts and reproduce. The next genomes to be fully sequenced were those of prokaryotes. We now have genome sequences for many microorganisms, to the great benefit of microbiology and medicine.

Prokaryotic genomes are compact

In 1995 a team led by Craig Venter and Hamilton Smith published the first complete genomic sequence of a free-living cellular organism, the bacterium *Haemophilus influenzae*. Many more prokaryotic sequences have followed, revealing not only how prokaryotic genes are organized to perform different cellular functions, but also how certain specialized functions of particular organisms are carried out.

There are several notable features of bacterial and archaeal genomes:

- They are relatively small. Prokaryotic genomes range in size from about 160,000 to 12 million bp and are usually organized into a single circular chromosome.
- They are compact. Typically, over 85 percent of the DNA consists of protein-coding regions or RNA genes, with only short sequences between genes.
- Their genes usually do not contain introns. An exception is the rRNA and tRNA genes of archaea, which are frequently interrupted by introns.
- In addition to the main chromosome, they often carry smaller, circular DNA molecules called plasmids, which may be transferred between cells (see Concept 8.4).

Beyond these broad similarities, there is great diversity among these single-celled organisms, reflecting their huge variety in the environments where they are found.

Let’s look in more detail at a few prokaryotic genomes in terms of functional and comparative genomics.

FUNCTIONAL GENOMICS As mentioned above, functional genomics is a biological discipline that assigns functions to the products of genes. This field is less than 20 years old but is now a major occupation of biologists. You can see the various functions encoded by the genomes of three prokaryotes (in this case, all bacteria) in TABLE 12.1.

H. influenzae lives in the upper respiratory tracts of humans and can cause ear infections and (more seriously) meningitis. Its single circular chromosome has 1,830,138 bp. In addition

TABLE 12.1 Gene Functions in Three Bacteria

CATEGORY	NUMBER OF GENES IN:		
	<i>E. COLI</i>	<i>H. INFLUENZAE</i>	<i>M. GENITALIUM</i>
Total protein-coding genes	4,288	1,727	482
Biosynthesis of amino acids	131	68	1

Translation	182	141	101
Uptake of molecules from the environment	427	123	34

to its origin of replication and the RNA genes, this bacterial chromosome has 1,727 open reading frames.

When this sequence was first announced, only 1,007 (58 percent) of the open reading frames encoded proteins with known functions. Since then scientists have identified the role of almost every protein encoded by the *H. influenzae* genome. All of the major biochemical pathways and molecular functions are represented. When the larger *Escherichia coli* genome (4.6 million bp) was determined, it was found that these functions are coded for by more genes (see Table 12.1), indicating that the pathways are more complex in *E. coli*.

COMPARATIVE GENOMICS Soon after the sequence of *E. coli* was announced, the genome of a smaller prokaryote, *Mycoplasma genitalium* (580,073 bp), was completed. Thus began the new era in biology of comparative genomics. Scientists can identify genes that are present in one bacterium and missing in another, allowing them to relate these genes to bacterial function.

For example, *M. genitalium* lacks most of the enzymes needed to synthesize amino acids, which *E. coli* and *H. influenzae* both possess (see Table 12.1). This finding reveals that *M. genitalium* must obtain its amino acids from its environment (usually the human urogenital tract). Furthermore, *E. coli* has dozens of genes for regulatory proteins that encode transcriptional activators or repressors; *M. genitalium* only has 7 such genes. This suggests that the biochemical flexibility of *M. genitalium* is limited by its relative lack of control over gene expression.

LINK For more on the role of activators and repressors in controlling gene expression in bacteria, see Concepts 11.1 and 11.2

FRONTIERS Some bacteria, such as *Methanococcus*, produce methane in the stomachs of cattle. Others, such as *Methylococcus*, remove methane from the air and use it as an energy source. The genomes of both of these bacteria have been sequenced. Researchers are analyzing the genes involved in methane production and oxidation to find ways to control atmospheric methane (a powerful greenhouse gas) and thereby slow the progress of global warming.

Some sequences of DNA can move about the genome

Genome sequencing allowed scientists to study more broadly a class of DNA sequences that had been discovered by geneticists decades earlier. Segments of DNA called **transposons** (or *transposable elements*) can move from place to place in the genome and can even move from one piece of DNA (such as a chromosome) to another (such as

a plasmid) in the same cell. A transposon might be at one location in the genome of one *E. coli* strain, and at a different location in another strain. The insertion of this movable DNA sequence from elsewhere in the genome into the middle of a protein-coding gene disrupts that gene (**FIGURE 12.6A**). Any mRNA expressed from the disrupted gene will have the extra sequence, and the protein will be abnormal. So transposons can produce significant phenotypic effects by inactivating genes.

Transposons are often short sequences of 1,000–2,000 bp and are found at many sites in prokaryotic genomes. The mechanisms that allow them to move vary. For example, the transposon may be replicated, and then the copy inserted into another site in the genome. Or it might splice out of one location and move to another location.

If a transposon becomes duplicated with two copies separated by one or a few genes, the result may be a single larger transposon (up to about 5,000 bp). In this case, the additional genes can be carried to different locations in the genome (**FIGURE 12.6B**). Some of these transposons carry genes for antibiotic resistance. We will discuss transposons again in Concept 12.3.

Metagenomics allows us to describe new organisms and ecosystems

If you take a microbiology laboratory course, you will learn how to identify various prokaryotes on the basis of their growth in lab cultures. Microorganisms can be identified by their nutritional requirements or the conditions under which they will grow (e.g., aerobic versus anaerobic). For example, staphylococci are a group of bacteria that inhabit skin and nasal passages. Unlike many bacteria, staphylococci can use the sugar alcohol mannitol as an energy source and thus can

FIGURE 12.6 DNA Sequences That Move Transposons (or transposable elements) are DNA sequences that move from one location to another. (A) In one method of transposition, the DNA sequence is replicated and the copy inserts elsewhere in the genome. (B) Transposons can evolve to carry additional genomic sequences.

grow on a special medium containing mannitol. Often a dye is included in the medium, which changes color if the bacteria are pathogenic (disease-causing). Such culture methods have been the mainstay of microbial identification for over a century and are still useful and important. However, scientists can now use PCR and modern DNA analysis techniques to analyze microbes *without* culturing them in the laboratory.

In 1985, Norman Pace, then at Indiana University, came up with the idea of isolating DNA directly from environmental samples. He used PCR to amplify specific sequences from the samples to determine whether particular microbes were present. The PCR products were sequenced to explore their diversity. The term **metagenomics** was coined to describe this approach of analyzing genes without isolating the intact organism. It is now possible to do DNA sequencing with samples from almost any environment. The DNA can be cloned to make “libraries” of sequences (FIGURE 12.7), or it can be amplified and sequenced directly, using next-generation sequencing methods. The sequences can be used to detect the presence of previously unidentified organisms as well as known microbes. For example:

- Sequencing of DNA from 200 liters of seawater indicated that it contained 5,000 different viruses and 2,000 different bacteria, many of which had not been described previously.
- One kilogram of marine sediment contained a million different viruses, most of them new.

- Water runoff from a mine contaminated with toxic chemicals contained many new species of prokaryotes thriving in this apparently inhospitable environment. Some of these organisms exhibited metabolic pathways that were previously unknown to biologists. These organisms and their capabilities may be useful in cleaning up pollutants from the water.
- Gut samples from 124 Europeans revealed that each person harbored at least 160 species of bacteria (constituting their “gut microflora”). Many of these species were found in all of the individuals, but the presence of other bacteria varied from person to person. Such variations in gut microflora may be associated with obesity or bowel diseases.

LINK For more on the complex ecosystem inside the human gut, see Figure 42.2

These and other discoveries are truly extraordinary and potentially very important. It is estimated that 90 percent of the microbial world has been invisible to biologists and is only now being revealed by metagenomics. Entirely new ecosystems of bacteria and viruses are being discovered in which, for example, one species produces a molecule that another metabolizes. It is hard to overemphasize the importance of such an increase in our knowledge of the hidden world of microbes. This new knowledge underscores the remarkable diversity among prokaryotic organisms, and will further our understanding of natural ecological processes. Furthermore, it has the potential to help us find better ways to manage environmental catastro-

FIGURE 12.7 Metagenomics Microbial DNA extracted from the environment can be amplified and analyzed. This has led to the description of many new genes and species.

INVESTIGATION

FIGURE 12.8 Using Transposon Mutagenesis to Determine the Minimal Genome *Mycoplasma genitalium* has one of the smallest genomes of any prokaryote. But are all of its genes essential to life? By inactivating the genes one by one, scientists determined which of them are essential for the cell's survival. This research may lead to the construction of artificial cells with customized genomes, designed to perform functions such as degrading oil and making plastics.

HYPOTHESIS

Only some of the genes in a bacterial genome are essential for cell survival.

METHOD

M. genitalium has 482 genes; only two are shown here.

A transposon inserts randomly into one gene, inactivating it.

Inactive gene A

Experiment 1

Experiment 2

Inactive gene B

Each mutant is put into growth medium.

RESULTS

Growth means that gene A is not essential.

No growth means that gene B is essential.

CONCLUSION

If each gene is inactivated in turn, a "minimal essential genome" can be determined.

ANALYZE THE DATA

The growth of *M. genitalium* strains with insertions in genes (intragenic regions) was compared with the growth of strains with insertions in noncoding (intergenic) regions of the genome:

Type of insertion	Number of different genes/regions	Number that grew
Intragenic	482	100
Intergenic	199	184

- A. Explain these data in terms of genes essential for growth and survival. Are all of the genes in *M. genitalium* essential for growth? If not, how many are essential? Why did some of the insertions in intergenic regions prevent growth?
- B. If a transposon inserts into the following regions of genes, there might be no effect on phenotype. Explain in each case:
- near the 3' end of the coding region
 - within a gene coding for rRNA

How does this affect your answer to the first question?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

phes such as oil spills, or to remove toxic heavy metals from soil and water.

Will defining the genes required for cellular life lead to artificial life?

When the genomes of prokaryotes and eukaryotes are compared, a striking conclusion arises: certain genes are present in all organisms (universal genes). There are also some (nearly) universal gene segments that are present in many genes in many organisms. One example is a sequence encoding an ATP binding site, which is a domain found in many proteins. These findings suggest that there is some ancient, minimal set of DNA sequences common to all cells. One way to identify these sequences is to look for them in computer analyses of sequenced genomes.

Another way to define the minimal genome is to take an organism with a simple genome and deliberately mutate one gene at a time to see what happens. *M. genitalium* has one of the smallest known genomes—only 482 genes. Even so, some of its genes are dispensable under some circumstances. For example, it has genes for metabolizing both glucose and fructose, but it can survive in the laboratory on a medium containing only one of these sugars.

What about other genes? Researchers addressed this question using transposons as mutagens. When transposons in the bacterium were activated, they inserted themselves into genes at random, mutating and inactivating them (FIGURE 12.8). The mutated bacteria were tested for growth and survival, and DNA from interesting mutants was sequenced to find out which genes were mutated. The astonishing result of these studies was that *M. genitalium* could survive in the laboratory with a minimal genome of only 382 functional genes!

Is this really all it takes to make a viable organism? As described in the opening story of Chapter 4, scientists made a synthetic genome based on that of the bacterium *Mycoplasma discoides* and inserted it into an empty cell, creating the first organism with a synthetic genome. This research has promise for making organisms with novel functions, such as the synthesis of plastics polymers or the ability to break down environmental pollutants.

Do You Understand Concept 12.2?

- What are the characteristics of most prokaryotic genomes?
- Examine Table 12.1 and Figure 12.8. What gene functions would you predict are nonessential for *M. genitalium* as determined by transposon-mediated inactivation?
- You want to isolate a prokaryote that can live on discarded Styrofoam cups. Such an organism might live in a landfill where ground-up cups are discarded. How would you use metagenomics to identify such a bacterium? How would you show that its ability to live on Styrofoam is essential, and that it cannot live in another environment?

The methods used to sequence and analyze prokaryotic genomes have also been applied to eukaryotic genomes, which we will examine next.

concept 12.3 Eukaryotic Genomes Are Large and Complex

As genomes have been sequenced and described, a number of major differences have emerged between eukaryotic and prokaryotic genomes:

- *Eukaryotic genomes are larger than those of prokaryotes*, and they have more protein-coding genes. This difference is not surprising given that multicellular organisms have many cell types with specific functions that require specialized proteins. A typical virus contains enough DNA (about 10,000 bp) to encode only a few proteins. As we saw above, one of the simplest prokaryotes, *Mycoplasma*, has several hundred protein-coding genes in a genome of about 0.5 million bp. A rice plant, in contrast, has 37,544 genes.
- *Eukaryotic genomes have more regulatory sequences*—and many more regulatory proteins—than prokaryotic genomes. The greater complexity of eukaryotes requires much more regulation, which is evident in the many points of control associated with the expression of eukaryotic genes (see Concepts 11.3 and 11.4).
- *Much of eukaryotic DNA is noncoding*. Distributed throughout many eukaryotic genomes are various kinds of DNA sequences that are not transcribed into functional RNAs (such

as rRNA and tRNA) or mRNA. Some of these sequences are introns or regulatory sequences. In addition, eukaryotic genomes contain various kinds of repeated sequences.

Model organisms reveal many characteristics of eukaryotic genomes

Most of the lessons learned from eukaryotic genomes have come from several model organisms that have been studied extensively: the yeast *Saccharomyces cerevisiae*, the nematode (roundworm) *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and the plant *Arabidopsis thaliana* (thale cress). Model organisms have been chosen because they are relatively easy to grow and study in a laboratory, their genetics are well studied, and they exhibit characteristics that represent a larger group of organisms. **TABLE 12.2** shows some characteristics of the genomes of these organisms.

YEAST: THE BASIC EUKARYOTIC MODEL Yeasts are single-celled eukaryotes. Like other eukaryotes, they have membrane-enclosed organelles. They can live as either haploid or diploid organisms, and this is usually determined by environmental conditions: under adverse conditions the diploid cells will undergo meiosis and sporulation. While the prokaryote *E. coli* has a single circular chromosome and 4,290 genes, *Saccharomyces cerevisiae* has 16 linear chromosomes and 5,770 genes. The most striking difference between the yeast genome and that of *E. coli* is in the number of genes for targeting proteins to organelles. Both of these single-celled organisms appear to use about the same number of genes to perform the basic functions of cell survival. It is the compartmentalization of the eukaryotic yeast cell into organelles that requires it to have many more genes.

TABLE 12.2 Representative Sequenced Genomes

ORGANISM	HAPLOID GENOME SIZE (Mb)	NUMBER OF GENES	PROTEIN-CODING SEQUENCE	NOTABLE GENES
Bacteria				
<i>M. genitalium</i>	0.58	482	88%	Minimal genome
<i>H. influenzae</i>	1.8	1,738	89%	
<i>E. coli</i>	4.6	4,377	88%	
Yeasts				
<i>S. cerevisiae</i>	12.1	5,770	70%	Targeting; cell organelles
<i>S. pombe</i>	12.1	4,929	60%	
Plants				
<i>A. thaliana</i>	157	28,000	25%	Photosynthesis; cell walls
Rice	394	37,544	12%	
Soybean	1,115	46,000	7%	
Animals				
<i>C. elegans</i>	100	19,427	25%	Tissue formation
<i>D. melanogaster</i>	130	13,379	13%	Embryonic development
Human	3,200	24,000	1.2%	

Mb = millions of base pairs

This finding is direct, quantitative confirmation of something we have known for a century: the eukaryotic cell is structurally and functionally more complex than the prokaryotic cell.

THE NEMATODE: UNDERSTANDING CELL DIFFERENTIATION The 1-mm-long nematode *Caenorhabditis elegans* normally lives in the soil. It can also live in the laboratory, where it has become a favorite model organism of developmental biologists (see Chapter 14). The nematode has a transparent body that develops over 3 days from a fertilized egg to an adult worm that has a nervous system, digests food, and reproduces sexually. Its genome is 8 times larger than that of yeast and has 3.5 times as many protein-coding genes. Gene inactivation studies show that the worm can survive in laboratory cultures with only 10 percent of these genes. But this “minimum genome” is still five times the size of the minimum genome for *Mycoplasma*. The extra genes in the nematode minimal genome encode proteins needed for cell differentiation, for intercellular communication, and for holding cells together to form tissues.

DROSOPHILA MELANOGASTER: UNDERSTANDING GENETICS AND DEVELOPMENT The fruit fly *Drosophila melanogaster* is a famous model organism. Studies of fruit fly genetics resulted in the formulation of many basic principles of genetics (see Concept 8.3). The fruit fly is a much larger organism than *C. elegans* (it has ten times as many cells), and it is much more complex: it undergoes complicated developmental transformations from egg to larva to pupa to adult. These differences are reflected in the fruit fly genome, which has many genes encoding transcription factors needed for complex embryonic development (you will study some of these in Chapter 14). In general, the fruit fly genome has a distribution of coding sequence functions quite similar to those of many other complex eukaryotes (FIGURE 12.9).

ARABIDOPSIS: STUDYING THE GENOMES OF PLANTS About 250,000 species of flowering plants dominate the land and fresh water.

FIGURE 12.9 Functions of the Eukaryotic Genome The distribution of gene functions in *Drosophila melanogaster* shows a pattern that is typical of many complex organisms.

Although there is generally more interest in the plants we use for food and fiber, scientists first sequenced the genome of a simpler flowering plant with a relatively small genome. *Arabidopsis thaliana*, thale cress, is a member of the mustard family and has long been a favorite model organism of plant biologists. It is small (hundreds could grow and reproduce in the space occupied by this page) and easy to manipulate. Its genome has about 28,000 protein-coding genes, but many of these are duplicates and probably originated by chromosomal rearrangements. When these duplicate genes are subtracted from the total, about 15,000 unique genes are left—similar to the gene numbers found in fruit flies and nematodes. Indeed, many of the genes found in these animals have **orthologs**—genes with very similar sequences—in *Arabidopsis* and other plants, suggesting that plants and animals have a common ancestor.

FRONTIERS The genome sequences of corn and soybean reveal that many protein-coding genes in these important crop plants are duplicated as a result of chromosome rearrangements. This makes “gene counts” somewhat misleading, since many genes are redundant. More importantly, this redundancy presents a challenge to plant breeders trying to improve the characteristics of these plants: instead of one simple cross to transfer a single allele into a new strain, the breeders may have to do multiple crosses to transfer multiple copies of that allele.

Arabidopsis has some genes, however, that are unique to plants. These include genes involved in photosynthesis, in the transport of water throughout the plant, in the assembly of the cell wall, in the uptake and metabolism of inorganic substances from the environment, and in the synthesis of specific molecules used for defense against microbes and herbivores. These plant defense molecules may be a major reason why the numbers of protein-coding genes in some plants are higher than in many animals. Plants cannot escape their enemies or other adverse conditions as animals can, and they must cope with situations where they are. So they make tens of thousands of molecules to help them fight their enemies and adapt to their changing environments (see Chapter 28).

These plant-specific genes are also found in the genomes of other plants, including rice (*Oryza sativa*), which was the first major crop plant to be fully sequenced. Rice is the world’s most important crop—it is a staple in the diets of 3 billion people. The larger genome of rice has a set of genes remarkably similar to that of *Arabidopsis*. The genome of the poplar tree (*Populus trichocarpa*) was also sequenced, to gain insight into the potential for this rapidly growing tree to be used as a source of fuel. A comparison of the three genomes shows many genes in common, which may comprise the *basic plant genome* (FIGURE 12.10).

Gene families exist within individual eukaryotic organisms

About half of all eukaryotic protein-coding genes exist as only one copy in the haploid genome (with two alleles in somatic

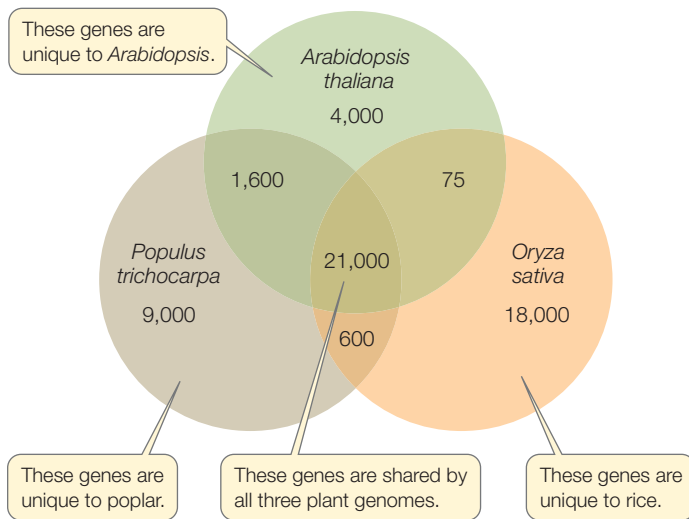

FIGURE 12.10 Plant Genomes Three plant genomes share a common set of approximately 21,000 genes that appear to comprise the “minimal” plant genome.

cells). The rest are present in multiple copies that arose from gene duplications. Over evolutionary time, different copies of the genes have undergone separate mutations, giving rise to groups of closely related genes called **gene families**. Some gene families, such as those encoding the globin proteins that make up hemoglobin, contain only a few members in a single organism. Other families, such as the genes encoding the immunoglobulins that make up antibodies, have hundreds of members.

LINK Gene duplication is a key mechanism for the evolution of new functions; see Concept 15.6

Within a single organism, the genes in a family are usually slightly different from one another. As long as at least one member encodes a functional protein, the other members may mutate in ways that change the functions of the proteins they encode. For evolution, the availability of multiple copies of a gene allows for selection of mutations that provide advantages under certain circumstances. If a mutated gene is useful, it may be selected for in succeeding generations. If the mutated gene is a total loss, the functional copy is still there to carry out its role.

As an example, let’s look at the gene family encoding the globins in vertebrates. These proteins are found in hemoglobin and myoglobin (an oxygen-binding protein present in muscle). The globin genes all arose long ago from a single common ancestral gene (see Figure 15.22). In humans there are three functional members of the α -globin cluster and five in the β -globin cluster (**FIGURE 12.11**). Each hemoglobin molecule in an adult human is a tetramer containing two identical α -globin subunits, two identical β -globin subunits, and four heme pigments (see Chapter 3, p. 44).

During human development, different members of the globin gene cluster are expressed at different times and in different tissues. This differential gene expression has great physiological significance. For example, the hemoglobin in the human

FIGURE 12.11 The Globin Gene Family The α -globin and β -globin clusters of the human globin gene family are located on different chromosomes. The genes of each cluster are separated by noncoding “spacer” DNA. The nonfunctional pseudogenes are indicated by the Greek letter psi (ψ). The γ gene has two variants, A_γ and G_γ .

fetus contains γ -globin, which binds O_2 more tightly than adult hemoglobin. This specialized form of hemoglobin ensures that in the placenta, O_2 will be transferred from the mother’s blood to the developing fetus’s blood. Just before birth the liver stops synthesizing fetal hemoglobin and the bone marrow cells take over, making the adult forms (two α and two β). Thus hemoglobins with different binding affinities for O_2 are provided at different stages of human development.

In addition to genes that encode functional proteins, many gene families include nonfunctional **pseudogenes**, which are designated with the Greek letter psi (ψ ; see Figure 12.11). These pseudogenes result from mutations that cause a loss of function rather than an enhanced or new function. The DNA sequence of a pseudogene may not differ greatly from that of other family members. It may simply lack a promoter, for example, and thus fail to be transcribed. Or it may lack a recognition site needed for the removal of an intron, so that the transcript it makes is not correctly processed into a useful mature mRNA. In some gene families pseudogenes outnumber functional genes. Because some members of the family are functional, there appears to be little selection pressure to preserve the functions of redundant genes.

Eukaryotic genomes contain many repetitive sequences

Eukaryotic genomes contain numerous repetitive DNA sequences that do not code for polypeptides. There are highly repetitive sequences and moderately repetitive sequences, which include rRNA genes, tRNA genes, and transposons (**TABLE 12.3**).

Highly repetitive sequences are short (less than 100 bp) sequences that are repeated thousands of times in tandem (side-by-side) arrangements in the genome. They are not transcribed. Their proportion in eukaryotic genomes varies, from 10 percent in humans to about half the genome in some species of fruit flies. Often they are associated with heterochromatin, the densely packed, transcriptionally inactive part of the genome.

Other highly repetitive sequences are scattered around the genome. For example, **short tandem repeats (STRs)** of 1–5 bp can be repeated up to 100 times at a particular chromosomal location. The copy number of an STR at a particular location varies between individuals and is inherited.

Moderately repetitive sequences are repeated 10–1,000 times in the eukaryotic genome. These sequences include the genes that are transcribed to produce tRNAs and rRNAs, which are used in protein synthesis. The cell makes tRNAs and rRNAs constantly, but even at the maximum rate of transcription, single copies of the tRNA and rRNA genes would be inadequate to supply the large amounts of these molecules needed by most cells. Thus the genome has multiple copies of these genes, in clusters containing transcribed regions (with introns) and nontranscribed “spacers” between the genes.

TABLE 12.3 Types of Sequences in Eukaryotic Genomes

CATEGORY	TRANSCRIBED	TRANSLATED
Single-copy genes		
Promoters and expression control sequences	No	No
Introns	Yes	No
Exons	Yes	Yes
Moderately repetitive sequences		
rRNA and tRNA genes	Yes	No
Transposons		
I. Retrotransposons		
LTR retrotransposons	Yes	No
SINEs	Yes	No
LINEs	Yes	Yes
II. DNA transposons		
Highly repetitive short sequences	No	No

Most moderately repetitive sequences are not stably integrated into the genome but instead are transposons (see Figure 12.6). Transposons make up over 40 percent of the human genome. There are two main types of transposons in eukaryotes: retrotransposons (Class I transposons) and DNA transposons (Class II; see Table 12.3). **Retrotransposons** make RNA copies of themselves, which are then copied back into DNA before insertion at new locations in the genome. They are divided into two categories:

1. *LTR retrotransposons* have long terminal repeats (LTRs) of DNA sequence (100–5,000 bp) at each end. LTR retrotransposons constitute about 8 percent of the human genome.
2. *Non-LTR retrotransposons* do not have LTR sequences at their ends. They are further divided into two subcategories: SINEs and LINEs. *SINEs* (short interspersed elements) are up to 500 bp long and are transcribed but not translated. There are about 1.5 million of them scattered over the human genome, making up about 15 percent of the total DNA content. A single type, the 300-bp *Alu* element, accounts for 11 percent of the human genome; it is present in a million copies. *LINEs* (long interspersed elements) are up to 7,000 bp long, and some are transcribed and translated into proteins. They constitute about 17 percent of the human genome.

DNA transposons do not use RNA intermediates. Like some prokaryotic transposons, they are excised from the original location and become inserted at a new location without being replicated.

APPLY THE CONCEPT

Eukaryotic genomes are large and complex

Repetitive DNA sequences can be classified by nucleic acid hybridization (see Figure 10.7). A genome is initially cut into 300-bp fragments, and these are heated to denature the DNA. If the solution is cooled, the DNA strands will form hydrogen bonds and reassociate into double-stranded structures. If there are many copies of a DNA sequence in the solution (repetitive DNA), it will find its complementary sequence and reassociate faster than if there are only a few copies. The table shows results from equal amounts of DNA from three species.

1. Why do yeast and mouse DNAs reassociate faster than *E. coli* DNA?

REASSOCIATION TIME (MIN)	PERCENTAGE OF DNA REASSOCIATED		
	<i>E. COLI</i>	YEAST	MOUSE
1	0	3	10
10	0	17	35
100	100	100	100

2. Would you expect human DNA to reassociate faster or slower than yeast DNA?

Do You Understand Concept 12.3?

- Compare the general properties of the genomes of prokaryotes and eukaryotes.
- Does the size of a genome determine how much information it contains? Explain in terms of repetitive sequences and protein-coding genes.
- What is the evolutionary role of eukaryotic gene families?
- During transposition, an adjacent gene is sometimes replicated along with a retrotransposon. What would be the consequence of making a new copy of this gene at a new location in the genome?

The analysis of eukaryotic genomes has resulted in an enormous amount of useful information, as we have seen. In the next concept we look more closely at the human genome.

concept 12.4 The Human Genome Sequence Has Many Applications

During the first decade of this millennium the haploid genomes of more than ten individuals were sequenced and published. With the rapid development of new sequencing technologies, the time is approaching when a human genome can be sequenced for less than \$1,000.

The human genome sequence held some surprises

The following are just some of the interesting facts we have learned about the human genome:

- Among the 3.2 billion bp in the haploid human genome, there are about 24,000 protein-coding genes. This was a surprise. Before sequencing began, the diversity of human proteins suggested there would be 80,000–150,000 genes. The actual number—not many more than in a fruit fly—means that posttranscriptional mechanisms (such as alternative splicing; see Concept 11.4) must account for the observed number of proteins in humans. It turns out that most human genes encode multiple proteins.
- The average gene spans 27,000 bp. Gene sizes vary greatly, from about 1,000 to 2.4 million bp. Variation in gene size is to be expected given that human proteins vary in size, from about 100 to 5,000 amino acids per polypeptide chain.
- Virtually all human genes have many introns.
- At least 3.5 percent of the genome is functional but noncoding. These sequences have roles in gene regulation (e.g., are transcribed to microRNAs) or in chromosome structure (e.g., telomere DNA).
- Over 50 percent of the genome is made up of transposons and other repetitive sequences.

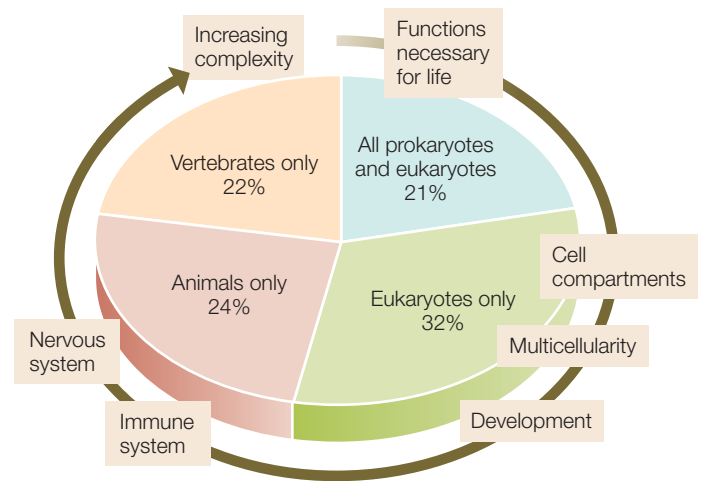

FIGURE 12.12 Evolution of the Genome A comparison of the human and other genomes has revealed how genes with new functions have been added over the course of evolution. Each percentage number refers to genes in the human genome. Thus, 21 percent of human genes have homologs in prokaryotes and other eukaryotes, 32 percent of human genes occur only in other eukaryotes, and so on.

- Most of the genome (at least 97 percent) is the same in all people. Despite this apparent homogeneity, there are, of course, many individual differences. Scientists have mapped over 7 million single nucleotide polymorphisms (SNPs; see below) in humans, and more will be found as more human genomes are sequenced.

Comparisons between sequenced genomes from prokaryotes and eukaryotes have revealed some of the evolutionary relationships between genes. Some genes are present in both prokaryotes and eukaryotes; others are only in eukaryotes; still others are only in animals, or only in vertebrates (FIGURE 12.12).

More comparative genomics is possible now that the genomes of two other primates, the chimpanzee and the rhesus macaque, have been sequenced. The chimpanzee is evolutionarily close to humans and shares 95 percent of the human genome sequence. The more distantly related rhesus macaque shares 91 percent of the human sequence. The search is on for a set of human genes that differ from the other primates and “make humans human.”

Human genomics has potential benefits in medicine

Complex phenotypes are determined not by single genes but by multiple genes interacting with the environment. The single-allele models of phenylketonuria and sickle-cell anemia (see Concept 9.3) do not apply to such common disorders as diabetes, heart disease, and Alzheimer’s disease. To understand the genetic bases of these diseases, biologists are now using rapid genotyping technologies to create “haplotype maps,” which are used to identify genes involved in disease.

Haplotype maps are based on **single nucleotide polymorphisms (SNPs)**—DNA sequence variations that involve single nucleotides. SNPs (pronounced “snips”) arise as point mutations (see Concept 9.3). Because of these mutations, a single

FIGURE 12.13 SNP Genotyping and Disease

Scanning the genomes of people with and without particular diseases reveals correlations between SNPs and complex diseases.

nucleotide in a homologous DNA sequence may vary between individuals or between alleles in a single organism. Biologists use SNPs to create genetic maps of organisms, to classify organisms and species, and to identify individual organisms carrying specific alleles.

HAPLOTYPE MAPPING The SNPs that differ between individuals are not all inherited as independent alleles. Rather, *a set of SNPs that are close together on a chromosome are inherited as a unit* (they are tightly linked). A piece of chromosome with a set of linked SNPs is called a **haplotype**. You can think of the haplotype as a sentence and the SNP as a word in the sentence. Analyses of haplotypes in humans from all over the world have thus far identified 500,000 common variations.

GENOTYPING TECHNOLOGY AND PERSONAL GENOMICS New technologies are continually being developed to analyze thousands or millions of SNPs in the genomes of individuals. Such technologies include next-generation sequencing methods and DNA microarrays, which depend on hybridization to identify specific SNPs.

A **DNA microarray** is a grid of microscopic spots of oligonucleotides arrayed on a solid surface. It can be “probed” with a complex mixture of DNA or RNA; if the mixture contains a sequence that is complementary to one of the oligonucleotides, the sequence will hybridize to that spot. Colored fluorescent dyes are used to detect hybridizing spots. For example, a microarray of 500,000 SNP-containing oligonucleotides has been used to analyze DNA from thousands of people to find out which SNPs are associated with specific diseases. The aim is to identify particular alleles that contribute (along with particular alleles of other genes) to each complex disease (**FIGURE 12.13**). The amount of data from 500,000 SNPs and thousands of people with thousands of medical records is prodigious. With so much natural variation, statistical measures of association between a haplotype and a disease need to be very rigorous.

These association tests have revealed haplotypes or alleles that are associated with modestly increased risks for such complex diseases as breast cancer, diabetes, arthritis, obesity, and coronary heart disease. For example, 12 sequence variants are associated with increased incidence of heart attacks, and if considered together, the variants can be used to identify individuals who are at increased risk. Indeed, the predictive value of such a genetic test is greater than the widely used test for elevated blood cholesterol level. Private companies will now scan a human genome for SNP alleles, and the price for this service keeps getting lower. However, at this point it is unclear what a person without symptoms should do with the information, since multiple genes, environmental influences, and epigenetic effects all contribute to the development of these diseases.

FRONTIERS Perhaps the most remarkable human genome sequenced thus far is that of an ancient human who lived 4,000 years ago in Greenland. Using a hair sample unearthed from permafrost, scientists extracted the entire genome. Surprisingly, initial SNP analyses show that “Inuk” had blood type A, brown eyes, and dark skin—characteristics shared with modern natives of Siberia. Additional human genome sequences, especially of Arctic peoples, will help researchers reconstruct the human migration that brought Inuk to Greenland.

PHARMACOGENOMICS Genetic variation can affect how an individual responds to a particular drug. For example, consider an enzyme in the liver that catalyzes the following reaction:

A mutation in the gene that encodes this enzyme may make the enzyme less active and reduce the rate at which the active drug is modified to a less active form. For a given dose of the drug, a person with the mutation would have more active drug in his or her bloodstream than a person without the mutation. So the effective dose of the drug would be lower for this person.

Now consider a different case, in which a liver enzyme is needed to make the drug active:

A person carrying a mutation in the gene encoding this enzyme would not be affected by the drug, since the activating enzyme is not present.

The study of how an individual’s genome affects his or her response to drugs or other agents is called **pharmacogenomics**. This type of analysis makes it possible to predict whether or not a drug will be effective. The objective is to *personalize drug treatment* so that a physician can know in advance whether an individual will benefit from a particular drug (**FIGURE 12.14**). This approach might also be used to reduce the incidence of adverse drug reactions in individuals who metabolize particular drugs slowly.

PROTEOMICS Comparisons of the proteomes of humans and other eukaryotic organisms have revealed a common set of

All patients with the same diagnosis

These patients either do not respond to the drug or suffer side effects. They need an alternative drug or dose.

These patients have the genes for an effective response to the drug.

FIGURE 12.14 Pharmacogenomics Correlations between genotypes and responses to drugs will help physicians develop more personalized medical care.

proteins that can be categorized into groups (families) with similar amino acid sequences and similar functions. Forty-six percent of the yeast proteome, 43 percent of the worm proteome, and 61 percent of the fruit fly proteome are shared by the human proteome. Functional analyses indicate that this set of 1,300 proteins provides the basic metabolic functions of a eukaryotic cell—including glycolysis, the citric acid cycle, membrane transport, protein synthesis and targeting, and DNA replication.

Of course, these are not the only human proteins. There are many more, which presumably distinguish us as *human* eukaryotic organisms. As we describe elsewhere, proteins have different functional regions called domains—for example, a protein may have a ligand-binding domain and a membrane-spanning domain. While a particular organism may have many unique proteins, those proteins are often just unique combinations of domains that exist in other organisms. For example, a ligand-gated channel might have its ligand-binding domain

swapped for another with a different specificity, thereby changing the signal that opens the channel. *This reshuffling of the genetic deck is a key to evolution.*

There is considerable interest in using proteomics in the diagnosis of diseases. For diseases caused by a single gene, examining the single protein involved is possible (e.g., the hemoglobins; see Figure 10.2). But for more complex diseases such as diabetes or cancer, many genes and proteins may be involved, and the *pattern* of proteins made in a particular tissue at a certain time might indicate the presence or likelihood of the disease. Proteomic analyses of tissues (including blood) are being developed to provide early warnings of the presence of particular diseases before symptoms occur.

METABOLOMICS There has been some progress in defining the human metabolome. A database created by David Wishart and colleagues at the University of Alberta contains over 6,500 metabolite entries. The challenge now is to relate the levels of these substances to physiology. For example, high levels of glucose in the blood are associated with diabetes, and there may be patterns of metabolites that are diagnostic of other diseases. This could aid in early diagnosis and treatment.

DNA fingerprinting uses short tandem repeats

As noted in Concept 12.3, short tandem repeats (STRs) are blocks of 1–5 bp that can be repeated up to 100 times at particular locations on chromosomes. Since the number of repeats can vary widely, there are usually numerous alleles for a particular STR. For example, at a particular location on human chromosome 15 there might be an STR of “AGG.” An individual might inherit an allele with six copies of the repeat (AGGAGGAGGAGGAGG) from her mother and an allele with two copies (AGGAGG) from her father (**FIGURE 12.15A**). PCR can be used to amplify DNA fragments containing these repeat sequences, and the number of copies of the repeat can be determined by sizing the DNA fragments.

DNA fingerprinting refers to a group of techniques used to identify particular individuals by their DNA; the most common of these techniques involves STR analysis. When several different STR loci are analyzed, an individual’s unique pattern becomes apparent. The U.S. Federal Bureau of Investigation

APPLY THE CONCEPT

The human genome sequence has many applications

It is the year 2025. You are taking care of a patient who is worried that he may have an early stage of kidney cancer. His mother died from this disease.

1. Assume that the SNPs linked to genes involved in the development of this type of cancer have been identified. How would you determine if this man has a genetic predisposition for developing kidney cancer? Explain how you would do the analysis.
2. How might you develop a metabolomic profile for kidney cancer and then use it to determine whether your patient has kidney cancer?
3. If the patient is diagnosed with the cancer, how would you use pharmacogenomics to choose the right medications to treat his tumor?

uses 13 STR loci in its Combined DNA Index System (CODIS) database.

DNA fingerprinting is used to resolve questions of paternity, and in forensics (crime investigations) to identify criminals. It also has other uses—for example, it can help in analyses of historical events. In 1918 the Russian tsar Nicholas II and his wife and five children were killed during the Communist revolution. A report that the bodies had been burned was not questioned until 1991, when a shallow grave with several skeletons was discovered a few miles from the presumed execution site. The remains were from a man, a woman, and three female children, and STR analysis indicated that they were all related to one another (FIGURE 12.15B). These STR patterns were also related to living descendants of the tsar. The accuracy and specificity of this method gave historical and cultural closure to a major event of the twentieth century.

Do You Understand Concept 12.4?

- The average human gene spans 27,000 bp. The average human polypeptide has 300 amino acids. Explain.
- What is a haplotype with regard to an STR? How can haplotypes be used to relate DNA to a phenotype?
- A person has a rare allele for an STR (STR-1) that has a frequency in the population of 1 percent (0.01). The same person has allele frequencies for other STRs as follows: STR-2, 0.005; STR-3, 0.01; STR-4, 0.05; STR-5, 0.01. What is the probability that an individual will have all of these alleles? What does this mean in terms of identifying an individual with this genotype?

What does genome sequencing reveal about dogs and other animals?

ANSWER In the opening story of this chapter we described how genome sequencing is being applied to breeds of dogs. For example, next-generation sequencing methods (Concept 12.1) have allowed biologists to collect data on genes that control body size. This has led to the identification

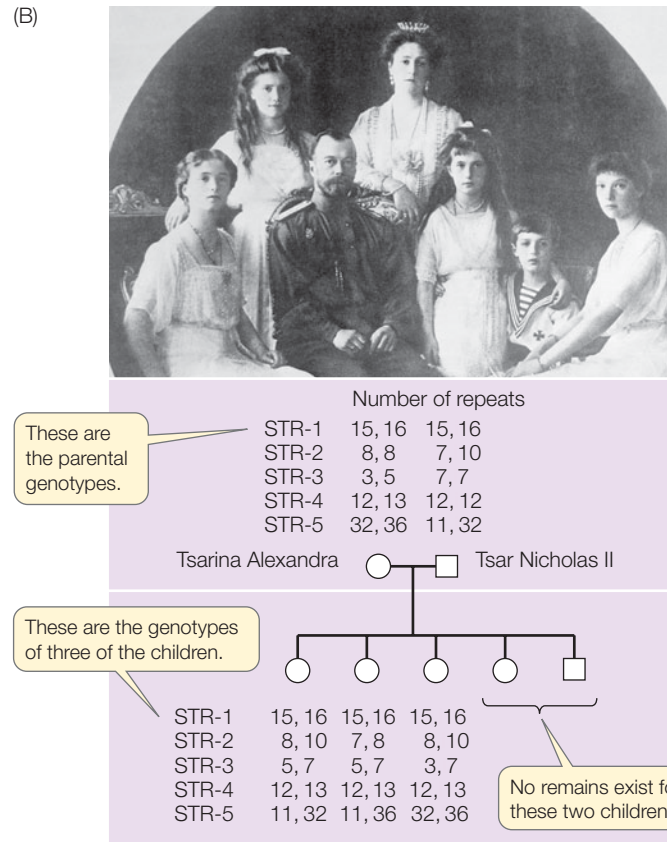

FIGURE 12.15 DNA Fingerprinting (A) A short tandem repeat (STR) can occur in a specific, inherited pattern. (B) STR analyses were used to determine that bony remains were from one family, and other evidence pointed to the Russian tsar and his family.

of a SNP (Concept 12.4) in the gene for insulin-like growth factor 1 (IGF-1) that is important in determining size. Large breeds have an allele that encodes an active IGF-1, and small breeds have a different allele that encodes a less active version of the protein. In humans, IGF-1 mediates the overall effects of growth hormone, and people with a mutation in the IGF-1 gene have short stature.

Another gene important to phenotypic variation is found in whippets, sleek dogs that run fast and are often raced. A mutation in the gene for myostatin, a protein that inhibits the overdevelopment of muscles, results in a whippet that is more muscular and runs faster (FIGURE 12.16A). Comparative genomics shows that this gene is important in other animals as well. In Belgian Blue cattle, individuals homozygous for a particular myostatin SNP have huge muscles (FIGURE 12.16B). There is interest in applying this knowledge to humans. For example, in muscular dystrophy the skeletal muscles waste away, and blocking myostatin could be useful in keeping muscles robust. Athletes anxious to have bulkier muscles have also been focusing on this gene and its protein product.

Inevitably, some scientists have set up companies to test dogs for genetic variations using DNA supplied by anxious owners and breeders. The black dog rescued from the pound that looks like a Labrador retriever may turn out to be a German pointer. Some traditional breeders frown on this practice, but others say it will bring more joy (and prestige) to owners.

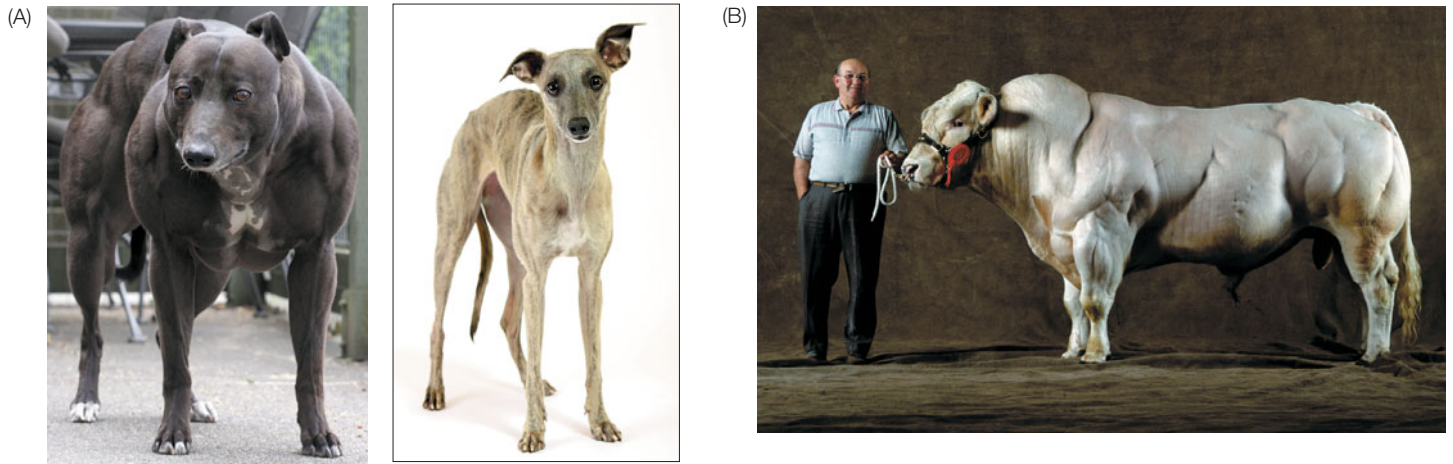

FIGURE 12.16 Muscular Gene (A) These dogs are both whippets, but the muscle-bound dog (left) has a mutation in a gene that

normally limits muscle buildup. (B) A similar mutation in Belgian Blue cattle also leads to overgrown muscles.

12

SUMMARY

concept 12.1 There Are Powerful Methods for Sequencing Genomes and Analyzing Gene Products

- To sequence a genome, the chromosomes are cut into overlapping fragments, which are sequenced. Then the fragment sequences are lined up to assemble the DNA sequence of the chromosome.
- Next-generation sequencing** involves attaching short, single-stranded DNA fragments to a solid surface. A primer and DNA polymerase are added, and tagged nucleotides are detected by a camera as they are added to the complementary DNA strand. Many sequences can be done in parallel. **Review Figure 12.1 and ANIMATED TUTORIAL 12.1**
- The analysis of DNA sequences is done by computer. Genomic sequences include protein-coding genes, RNA genes, transcription control elements, and repeated sequences. **Review Figure 12.3**
- The **proteome** is the total protein content of an organism. It can be analyzed using chemical methods that separate and identify proteins. These include two-dimensional electrophoresis and mass spectrometry. **Review Figure 12.4**
- The **metabolome** is the total content of small molecules in a tissue under particular conditions. These molecules include intermediates in metabolism, hormones and other signaling molecules, and secondary metabolites. **Review Figure 12.5**

concept 12.2 Prokaryotic Genomes Are Relatively Small and Compact

- Prokaryotic genomes have been studied using **functional genomics** to determine the roles of various parts of the genome, including the protein-coding genes. **Comparative genomics** is used to compare sequences among organisms. **Review Table 12.1**
- Transposons** are sequences of DNA that can move about the genome. **Review Figure 12.6**
- Metagenomics** is the identification of DNA sequences in environmental samples without first isolating, growing, and identifying the organisms. **Review Figure 12.7**

- Transposon mutagenesis can be used to inactivate genes one by one. Then the organism can be tested for survival. In this way, a minimal genome can be identified. **Review Figure 12.8**

concept 12.3 Eukaryotic Genomes Are Large and Complex

- Sequences from model organisms have highlighted some common features of eukaryotic genomes. In addition, there are specialized genes such as those for cellular compartmentalization, development, and features unique to plants. **Review Figures 12.9 and 12.10 and Table 12.2**
- Some genes exist as members of **gene families**. Proteins may be made from these closely related genes at different times and in different tissues. **Review Figure 12.11**
- Eukaryotic genomes contain various kinds of repeated sequences. **Review Table 12.3**

concept 12.4 The Human Genome Sequence Has Many Applications

- The haploid human genome has 3.2 billion bp.
- Only 1.5 percent of the genome codes for proteins; much of the rest consists of repeated sequences.
- Virtually all human genes have introns, and alternative splicing leads to the production of more than one protein per gene.
- Genotyping using **single nucleotide polymorphisms (SNPs)** can be used to correlate variations in the genome with diseases or drug sensitivity. It may lead to personalized medicine. **Review Figure 12.13**
- Pharmacogenomics** is the analysis of how a person's genetic make-up affects his or her drug metabolism. **Review Figure 12.14**
- Short tandem repeats (STRs)** are DNA sequences that are variable in length. They can be used to identify individuals. **Review Figure 12.15**

See **WEB ACTIVITY 12.1** for a concept review of this chapter.

Biotechnology

13

The United Nations defines **biotechnology** as “any technological application that uses biological systems, living organisms, or derivatives thereof to make or modify products or processes.” This broad definition includes major human activities such as brewing beer (see Chapter 6) and the domestication of animals and plants (see Chapter 12). More recently, biotechnology has become associated with the genetic modification of microorganisms for the production of particular substances, and of a variety of plants and animals used in agriculture.

Industrial biotechnology began in a lab in England in 1917 during World War I. The production of cordite, an explosive used to propel a bullet or shell to its target, required the solvent acetone, $(\text{CH}_3)_2\text{CO}$. But acetone was mostly manufactured by England’s enemy, Germany. A microbiologist of the University of Manchester, Chaim Weizmann, found that if the bacterium *Clostridium acetylbutylicum* was grown using starch as an energy source, it produced abundant quantities of acetone. The British government set up a factory to grow large vats of these bacteria, and the cordite shortage was solved.

The contemporary era of biotechnology as a major industry dates from June 16, 1980, on the steps of the U.S. Supreme Court. In this case, scientists were studying bacteria not for their ability to make something, but to break it down. Many bacteria have genes that code for unusual enzymes and biochemical pathways, and they can use all sorts of substances as nutrients, including pollutants. Scientists have discovered these organisms simply by mixing polluted soil with water and seeing what grows. In 1971, Ananda Chakrabarty at the General Electric Research Center in New York used genetic crosses to develop a single strain of the bacterium *Pseudomonas* that carried genes for the

breakdown of various hydrocarbons in oil. He and his company applied for a patent to legally protect their discovery and profit from it. In a landmark case, the U.S. Supreme Court ruled in 1980 that “a live, human-made microorganism is patentable” under the U.S. Constitution.

The Supreme Court ruling came at a time when new laboratory methods were being developed to insert specific DNA sequences into organisms by recombinant DNA technology. Since then, an entirely new biotechnology industry has sprung up. The resulting flood of patents for DNA sequences and genetically modified organisms, some of them developed to improve the environment, continues to this day.

Ananda Chakrabarty received the first patent for a genetically modified organism, a bacterium that breaks down crude oil.

How is biotechnology used to alleviate environmental problems?

KEY CONCEPTS

- 13.1 Recombinant DNA Can Be Made in the Laboratory
- 13.2 DNA Can Genetically Transform Cells and Organisms
- 13.3 Genes and Gene Expression Can Be Manipulated
- 13.4 Biotechnology Has Wide Applications

concept 13.1 Recombinant DNA Can Be Made in the Laboratory

Biotechnology began with the use of organisms with genetic capabilities that occur in nature. For example, existing biochemical pathways in yeast are used to make alcohol, and as noted in the opening story, bacteria can be grown in large quantities to make acetone and other industrial chemicals. More recently, it has become possible to genetically modify organisms with genes from other, distantly related organisms, to create new combinations of genes that would not otherwise occur in the same cell. This technology involves the use of **recombinant DNA**: single molecules containing DNA sequences from two or more organisms. Biologists have relied on manipulating natural molecules and processes to develop the techniques for making recombinant DNA. Three key tools are widely used:

- Restriction enzymes for cutting DNA into pieces (fragments) that can be manipulated
- Gel electrophoresis for the analysis and purification of DNA fragments
- DNA ligase for joining DNA fragments together in novel combinations

Restriction enzymes cleave DNA at specific sequences

All organisms, including bacteria, must have ways of dealing with their enemies. As we described in Concept 9.1, bacteria are attacked by viruses called bacteriophage (or phage, for short). These viruses inject their genetic material into the host cells and turn them into virus-producing factories, eventually killing the cells. Some bacteria defend themselves against such invasions by producing **restriction enzymes** (also known as restriction endonucleases), which cut double-stranded DNA molecules—such as those injected by bacteriophage—into smaller, noninfectious fragments (FIGURE 13.1). These enzymes break the bonds of the DNA backbone between the 3' hydroxyl group of one nucleotide and the 5' phosphate group of the next nucleotide.

There are many different restriction enzymes, each of which cleaves DNA at a specific sequence of bases called a **recognition sequence** or a **restriction site**. Most recognition sequences are 4–6 base pairs (bp) long. As examples, here are three enzymes that each recognize a different 6-bp sequence and cleave the DNA as indicated by the red arrows:

Note that each of these sequences forms a *palindrome*: the opposite strands have the same sequences when they are read

FIGURE 13.1 Bacteria Fight Invading Viruses by Making Restriction Enzymes

from their 5' ends. This is similar to a palindromic word such as “racecar,” which is the same when read in either direction. Restriction enzymes have two identical active sites on two subunits, which cleave the two strands simultaneously. The names of these enzymes reflect their origins; for example *Eco*RI was found in *E. coli*, and *Bam*HI in the bacterium *Bacillus amyloliquifaciens*.

Note also that these enzymes cut the two DNA strands in such a way that there will be a short sequence of single-stranded DNA at each cut end. Many restriction enzymes create these single-stranded overhangs, which are referred to as “sticky ends” because they are able to form hydrogen bonds with complementary sequences on other DNA molecules. Other restriction enzymes make cuts directly opposite one another on the two DNA strands, creating “blunt ends.”

The bacterial cell protects itself from its own restriction enzymes by modifying the restriction sites in its own DNA. Specific modifying enzymes called *methylases* add methyl ($-\text{CH}_3$) groups to certain bases at the restriction sites after the chromosome has been replicated (see Figure 11.13). The restriction enzymes do not recognize or cut the methylated restriction sites in the host’s DNA. But unmethylated phage DNA is efficiently recognized and cleaved.

The *Eco*RI recognition sequence occurs, on average, about once in every 4,000 bp in a typical prokaryotic genome, or about once per four prokaryotic genes. So *Eco*RI can chop a large piece of DNA into smaller pieces containing, on average, just a few genes. When *Eco*RI is used in the laboratory to cut a small genome such as that of a virus with, say, 50,000 bp, only a few fragments are obtained. For a huge eukaryotic chromosome with tens of millions of bp, a very large number of fragments is created.

Of course, “on average” does not mean that the enzyme cuts all stretches of DNA at regular intervals. For example, the *Eco*RI recognition sequence does not occur even once in the 40,000 bp of the T7 phage genome—a fact that is crucial to the survival of this virus, since its host is *E. coli*. Fortunately for *E.*

coli, the *EcoRI* recognition sequence does appear in the DNA of other bacteriophage.

Hundreds of restriction enzymes (all with unique recognition sequences) have been purified from various microorganisms. In the laboratory, different restriction enzymes can be used to cut samples of DNA from the same source. The procedure of using restriction enzymes in the lab is called setting up a *restriction digest*. Thus restriction enzymes can be used to cut a sample of DNA in many different, specific places. When analyzed by gel electrophoresis (see below), the fragments formed can be used to create a physical map of the intact DNA molecule. Before DNA sequencing technology became automated and widely available, this was a way to physically map base sequences on DNA.

Gel electrophoresis separates DNA fragments

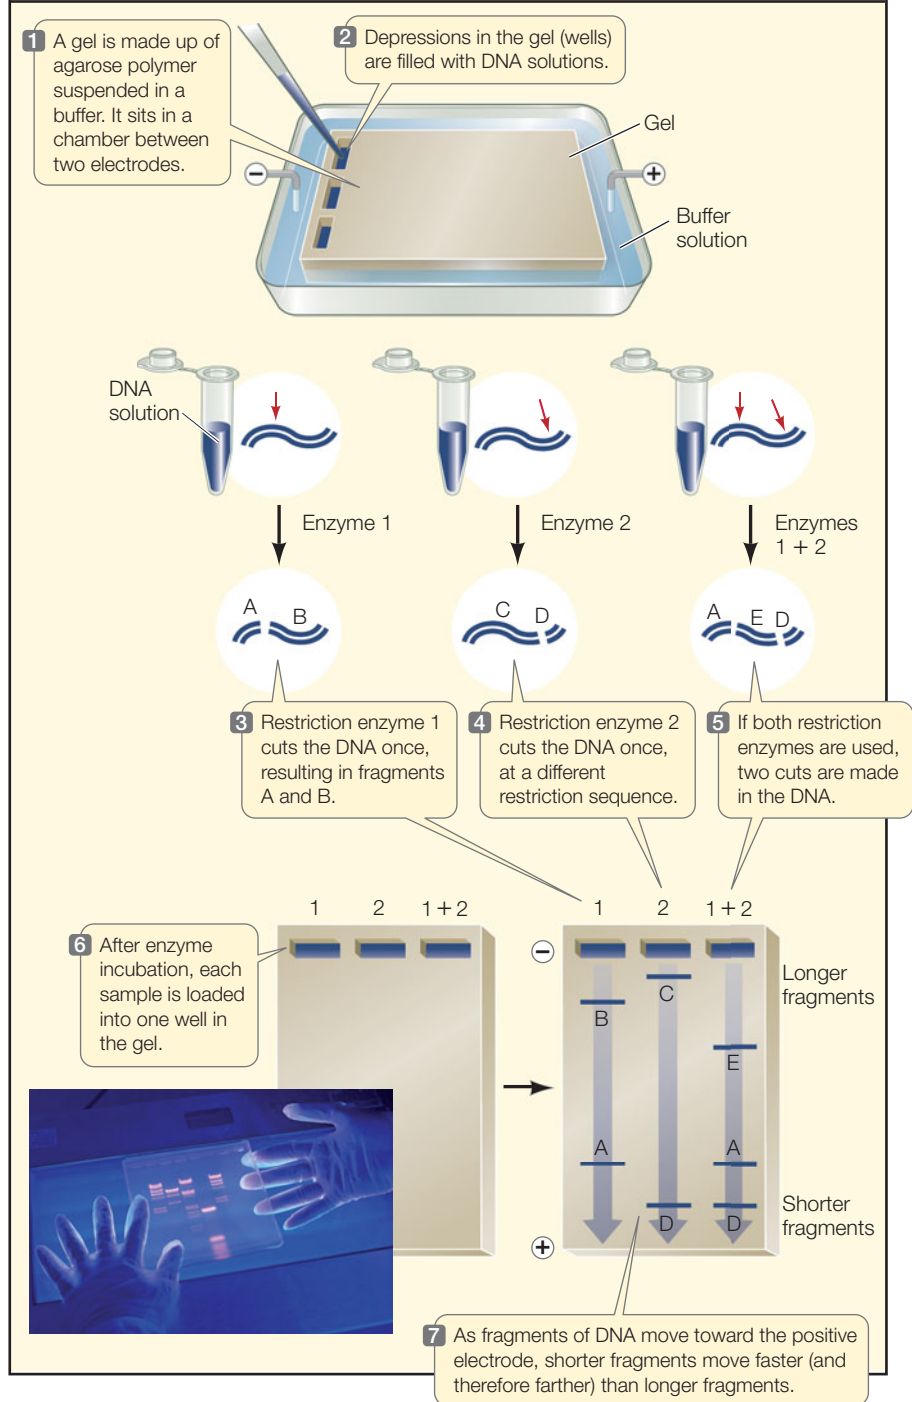

After a sample of DNA has been cut with a restriction enzyme, the fragments must be separated from each other to determine the number of fragments and the size (in bp) of each fragment. In this way an individual fragment can be identified, and it can then be purified for further analysis or for use in an experiment.

A convenient way to separate or purify DNA fragments is by **gel electrophoresis**. Samples containing the fragments are placed in wells at one end of a semisolid gel (usually made of agarose or polyacrylamide polymers), and an electric field is applied to the gel (FIGURE 13.2). Because of its phosphate groups, DNA is negatively charged at neutral pH; therefore, because opposite charges attract, the DNA fragments move through the gel toward the positive end of the field. Because the spaces between the polymers of the gel are small, small DNA molecules can move through the gel faster than larger ones. Thus, DNA fragments of different sizes separate from one another and can be detected with a dye. This gives us three types of information about a DNA sample:

- *The number of fragments.* The number of fragments produced by digestion of a DNA sample with a given restriction enzyme depends on how many times that enzyme's recognition sequence occurs in the sample. Thus gel electrophoresis can provide some information about the presence of specific DNA sequences in the DNA sample.

RESEARCH TOOLS

FIGURE 13.2 Separating Fragments of DNA by Gel Electrophoresis
A mixture of DNA fragments is placed in a gel and an electric field is applied across the gel. The negatively charged DNA moves toward the positive end of the field, with smaller molecules moving faster than larger ones. After minutes to hours for separation, the electric power is shut off and the separated fragments can be analyzed.

Go to ANIMATED TUTORIAL 13.1
Separating Fragments of DNA by Gel Electrophoresis

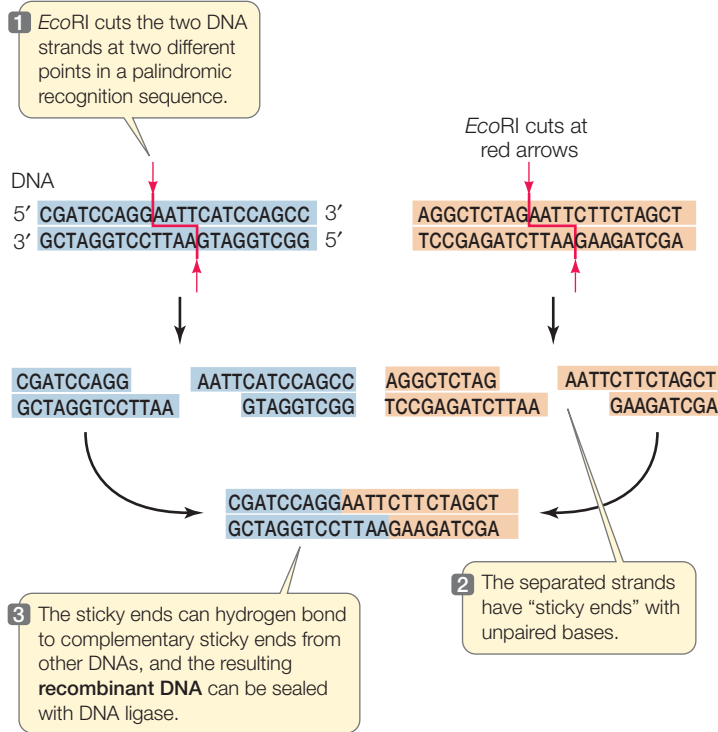

FIGURE 13.3 Cutting, Splicing, and Joining DNA Many restriction enzymes (*EcoRI* is shown here) make staggered cuts in DNA. *EcoRI* can be used to cut two different DNA molecules (blue and orange). The exposed bases can hydrogen bond with complementary exposed bases on other DNA fragments, forming recombinant DNA. DNA ligase stabilizes the recombinant molecule by forming covalent phosphodiester bonds in the DNA backbone.

After separation on the gel, a slice of gel containing the desired DNA fragment (identified by its size) can be cut out and then be purified by one of a variety of methods. This fragment can then be analyzed to determine its sequence or used to make recombinant DNA.

Recombinant DNA can be made from DNA fragments

Another enzyme that is involved in DNA metabolism in cells is **DNA ligase**, which catalyzes the joining of DNA fragments by making phosphodiester bonds between them. This is the enzyme that joins Okazaki fragments during DNA replication (see Concept 9.2). With restriction enzymes (which *break* bonds) and DNA ligase (which *makes* bonds), scientists can cut DNA into fragments and then splice them together in new combinations as recombinant DNA. As shown in **FIGURE 13.3**, two fragments with complementary sticky ends first join by hydrogen bonding, and then the DNA ligase forms a phosphodiester bond in each strand, making a single intact DNA molecule.

In the early 1970s, Stanley Cohen and Herbert Boyer wondered whether recombinant DNA could be a functional carrier of genetic information. They used restriction enzymes to cut sequences from two *E. coli* plasmids (small circular DNAs; see Concept 8.4) containing different antibiotic resistance genes. Then they used DNA ligase to join the fragments together. The resulting plasmid, when inserted into new *E. coli* cells, gave those cells resistance to both antibiotics (**FIGURE 13.4**). A new era of biotechnology was born.

- *The sizes of the fragments.* DNA fragments of known size are often placed in one well of the gel to provide a standard for comparison. This tells us how large the DNA fragments in the other wells are. By comparing the fragment sizes obtained with two or more restriction enzymes, the locations of their recognition sites relative to one another can be worked out (mapped).
- *The relative abundance of a fragment.* In many experiments, the investigator is interested in how much DNA is present. The relative *intensity* of a band produced by a specific fragment can indicate the amount of that fragment.

APPLY THE CONCEPT

Recombinant DNA can be made in the laboratory

The specificity of restriction enzyme recognition can be used to detect mutations. For example, the enzyme *MstII* cuts DNA at CCTNAGG, where N is any base. Around the sixth codon in the β -globin gene is the sequence CCTGAGGAG. In addition to this *MstII* site, there are additional sites on each side of the sequence, such that when *MstII* is used to cut human DNA in this region, two fragments of 1.15 and 0.20 kilobase (one kilobase = 1,000 bp) are obtained. The sickle allele of the β -globin gene causes sickle-cell anemia when it occurs in the homozygous state. In this allele, the sequence around the sixth codon is mutated to CCTGTGGAG.

1. Identify the point mutation that led to the sickle allele.
2. What fragment(s) would result when *MstII* is used to cut DNA with the sickle allele?
3. Sketch the patterns of cuts with normal and sickle alleles on a gel.
4. Could an individual have both patterns? Explain.
5. How can this information be used to make a DNA test for these alleles?

INVESTIGATION

FIGURE 13.4 Recombinant DNA With the discovery of restriction enzymes and DNA ligase, it became possible to combine DNA fragments from different sources in the laboratory. But would such “recombinant DNA” be functional when inserted into a living cell? The results of this experiment completely changed the scope of genetic research, increasing our knowledge of gene structure and function, and ushering in the new field of biotechnology.

HYPOTHESIS

Biologically functional recombinant chromosomes can be made in the laboratory.

METHOD *E. coli* plasmids carrying a gene for resistance to either the antibiotic kanamycin (*kan^r*) or tetracycline (*tet^r*) are cut with a restriction enzyme.

RESULTS Some *E. coli* are resistant to both antibiotics. No *E. coli* are doubly resistant.

CONCLUSION

Two DNA fragments with different genes can be joined to make a recombinant DNA molecule, and the resulting DNA is functional.

ANALYZE THE DATA

Two plasmids were used in this study: pSC101 had a gene for resistance to tetracycline and pSC102 had a gene for resistance to kanamycin. Equal quantities of the plasmids—either intact, cut with *EcoRI*, or cut with *EcoRI* and then sealed with DNA ligase—were mixed and incubated with antibiotic-sensitive *E. coli*. The *E. coli* were then grown on various combinations of the antibiotics. Here are the results:

DNA treatment	Number of resistant colonies		
	Tetracycline only	Kanamycin only	Both antibiotics
None	200,000	100,000	200
<i>EcoRI</i> cut	10,000	1,100	70
<i>EcoRI</i> , then ligase	12,000	1,300	570

- Did treatment with *EcoRI* affect the transformation efficiency? Explain.
- Did treatment with DNA ligase affect the transformation efficiency of each cut plasmid? Which quantitative data support your answer?
- How did doubly antibiotic-resistant bacteria arise in the “none” treatment? (Hint: see Concept 9.3.)
- Did the *EcoRI* followed by ligase treatment increase the appearance of doubly antibiotic-resistant bacteria? What data support your answer?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

Do You Understand Concept 13.1?

- Using diagrams of the chemical structure of DNA (see Concepts 3.1 and 9.2), compare the actions of a restriction enzyme and DNA ligase.
- How is recombinant DNA technology different from genetic recombination that occurs in meiosis?
- A DNA molecule of 12,000 bp (12 kilobase, or kb) is cut by restriction enzymes as follows:

CONDITION	SIZES OF FRAGMENTS (KB)
Enzyme A	2, 10
Enzyme B	2, 10
Enzymes A + B	2, 8

- Sketch the results of the three cuts on an electrophoresis gel.
- Indicate on a linear map where each enzyme cuts the DNA.

With the tools described in this concept—restriction enzymes, gel electrophoresis, and DNA ligase—scientists can cut and rejoin different DNA molecules from any and all sources, including artificially synthesized DNA sequences. In the next concept we will examine some of the ways these recombinant DNA molecules are used.

concept 13.2 DNA Can Genetically Transform Cells and Organisms

One goal of recombinant DNA technology is to **clone**—produce many identical copies of—a particular DNA sequence. Cloning might be done for sequence analysis, to produce a protein product in quantity, or as a step toward creating an organism with a new phenotype. Recombinant DNA can be cloned by inserting it into host cells in a process known as **transformation** (or **transfection** if the host cells are derived from an animal). A host cell or organism that contains recombinant DNA is referred to as a **transgenic** cell or organism. Later in this chapter we will encounter many examples of transgenic cells and organisms, including yeast, mice, rice plants, and even cattle.

Various methods are used to create transgenic cells. Generally, *only a few* of the cells that are exposed to the recombinant DNA actually become transformed with it. In order to grow only the transgenic cells, **selectable marker** genes, such as genes that confer resistance to antibiotics, are often included as part of the recombinant DNA molecule. Antibiotic resistance genes were the markers used in Cohen and Boyer’s experiment (see Figure 13.4).

Genes can be inserted into prokaryotic or eukaryotic cells

In theory, any cell or organism can act as a host for the introduction of recombinant DNA. Most research has been done using model organisms:

- *Bacteria* are easily grown and manipulated in the laboratory. Much of their molecular biology is known, especially for well-studied bacteria such as *E. coli*. Furthermore, bacteria contain plasmids, which are easily manipulated to carry recombinant DNA into the cell. Because the processes of transcription and translation proceed differently in prokaryotes than they do in eukaryotes, however, bacteria might not be suitable as hosts to express eukaryotic genes.
- *Yeasts* such as *Saccharomyces* are commonly used as eukaryotic hosts for recombinant DNA studies. The advantages of using yeasts include rapid cell division (a life cycle completed in 2–8 hours), ease of growth in the laboratory, and a relatively small genome size. In addition, yeasts have most of the characteristics of other eukaryotes, except for those characteristics involved in multicellularity.
- *Plant cells* are good hosts because of their ability to make stem cells (unspecialized, totipotent cells) from mature plant tissues. The unspecialized cells can be transformed with recombinant DNA and then studied in culture, or grown into new plants. There are also methods for making whole transgenic plants without going through the cell culture step. These methods result in plants that carry the recombinant DNA in all their cells, including the germline cells.
- *Cultured animal cells* can be used to study expression of human or animal genes, for example for medical purposes. Whole transgenic animals can also be created.

Recombinant DNA enters host cells in a variety of ways

Methods for inserting DNA into host cells vary. The cells may be chemically treated to make their outer membranes more permeable, and then mixed with the DNA so it can diffuse into the cells. Another approach is called *electroporation*: a short electric shock is used to create temporary pores in the membranes through which the DNA can enter. Viruses and bacteria can be altered so that they carry or insert recombinant DNA into cells. Transgenic animals can be produced by injecting recombinant DNA into the nuclei of fertilized eggs. There are even “gene guns,” which “shoot” the host cells with tiny particles carrying the DNA.

The challenge of inserting new DNA into a cell lies not just in getting it into the host cell, but in getting it to replicate as the host cell divides. DNA polymerase does not bind to just any sequence. If the new DNA is to be replicated, it must become part of a segment of DNA that contains an origin of replication (see Concept 9.2). Such a DNA molecule is called a **replicon**, or replication unit.

There are two general ways in which the newly introduced DNA can become part of a replicon within the host cell:

- It may be inserted into a host chromosome. Although the site of insertion is usually random, this is nevertheless a common method of integrating new genes into host cells.
- It can enter the host cell as part of a carrier DNA sequence, called a **vector**, and can either integrate into the host chromosome or have its own origin of DNA replication.

Several types of vectors are used to get DNA into cells.

PLASMIDS AS VECTORS As we described in Concept 8.4, plasmids are small, circular DNA molecules that replicate autonomously in many prokaryotic cells. A number of characteristics make plasmids useful as transformation vectors:

- They are relatively small (an *E. coli* plasmid usually has 2,000–6,000 bp) and therefore easy to manipulate in the laboratory.
- A plasmid will usually have one or more restriction enzyme recognition sequences that each occur only once in the plasmid sequence. These sites make it easy to insert additional DNA into the plasmid before it is used to transform host cells.
- Many plasmids contain genes that confer resistance to antibiotics, and thus can serve as selectable markers.
- Plasmids have a bacterial origin of replication (*ori*) and can replicate independently of the host chromosome. It is not uncommon for a bacterial cell to contain hundreds of copies of a recombinant plasmid. For this reason, the power of bacterial transformation to amplify a gene is extraordinary. A 1-liter culture of bacteria harboring the human β -globin gene in a typical plasmid has as many copies of that gene as there are cells in a typical adult human (10^{14}).

The plasmids used as vectors in the laboratory have been extensively altered to include convenient features: multiple cloning sites with 20 or more unique restriction enzyme sites for cloning purposes; origins of replication for a variety of host cells; and various kinds of reporter genes (see below) and selectable marker genes:

PLASMID VECTORS FOR PLANTS An important vector for carrying new DNA into many types of plants is a plasmid found in the bacterium *Agrobacterium tumefaciens*. This bacterium lives in the soil, infects plants, and causes a disease called crown gall,

which is characterized by the presence of growths (or tumors) on the plant. *A. tumefaciens* contains a plasmid called Ti (for tumor-inducing):

Ti plasmid
Hosts: *Agrobacterium tumefaciens* (plasmid) and infected plants (T DNA)

The Ti plasmid carries genes that allow the bacterium to infect plant cells and then insert a region of its DNA called the T DNA into the chromosomes of infected cells. The T DNA contains genes that cause the growth of tumors and the production of specific sugars that the bacterium uses as sources of energy. Scientists have exploited this remarkable natural “genetic engineer” to insert foreign DNA into the genomes of plants.

When used as a vector for plant transformation, the tumor-inducing and sugar-producing genes on the T DNA are removed and replaced with foreign DNA. The altered Ti plasmids are first used to transform *Agrobacterium* cells from which the original Ti plasmids have been removed. Then the *Agrobacterium* cells are used to infect plant cells.

VIRUSES AS VECTORS Constraints on plasmid replication limit the size of the new DNA that can be inserted into a plasmid

to about 10,000 bp. Although many prokaryotic genes may be smaller than this, most eukaryotic genes—with their introns and extensive flanking sequences—are bigger. A vector that accommodates larger DNA inserts is needed for these genes.

Both prokaryotic and eukaryotic viruses are often used as vectors for eukaryotic DNA. Bacteriophage λ, which infects *E. coli*, has a DNA genome of about 45,000 bp. If the genes that cause the host cell to die and lyse—about 20,000 bp—are eliminated, the virus can still attach to a host cell and inject its DNA. The deleted 20,000 bp can be replaced with DNA from another organism. Because viruses infect cells naturally, they offer a great advantage over plasmids, which often require artificial means to coax them to enter host cells.

FRONTIERS Some human diseases, for example certain cancers and genetic diseases, are caused by deficiencies in the expression of a specific gene. Such diseases could theoretically be treated by gene therapy—the insertion of functional copies of the affected gene into the patient’s cells. Viral vectors that infect human cells are being developed for gene therapy. Success has been limited so far, but the research continues.

Reporter genes are used to identify host cells containing recombinant DNA

Even when a population of host cells interacts with an appropriate vector, only a small proportion of the cells actually take up the vector. Furthermore, the process of making recombinant DNA is far from perfect. After a ligation reaction, not all the

RESEARCH TOOLS

FIGURE 13.5 Marking Recombinant DNA by Inactivating a Gene Selectable marker (reporter) genes are used by scientists to select for bacteria that have taken up a plasmid. A second reporter gene allows for the identification of bacteria

harboring the recombinant plasmid. The host bacteria in this experiment could display any of the three phenotypes indicated in the table.

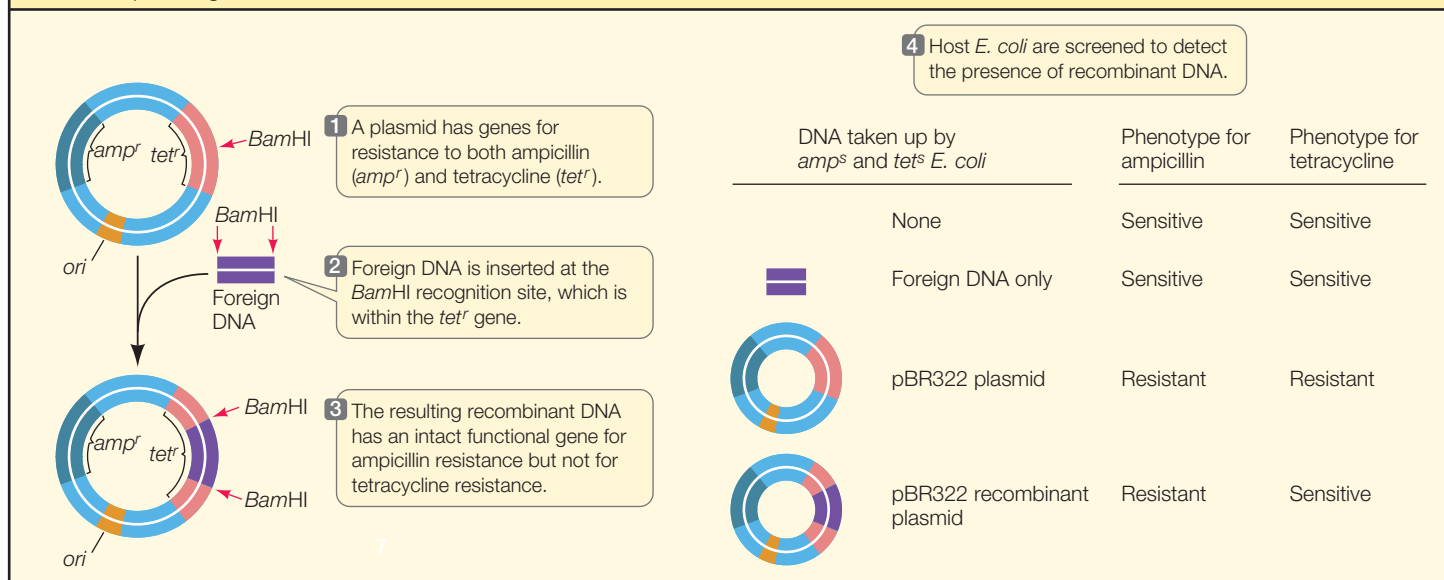

FIGURE 13.6 Green Fluorescent Protein as a Reporter The presence of a plasmid with the gene for green fluorescent protein is readily apparent in transgenic cells because they glow under ultraviolet light.

vector copies contain the foreign DNA. How can we identify or select the host cells that contain the vector with foreign DNA?

As we described above, selectable markers such as antibiotic resistance genes can be used to select cells containing those genes. Only cells carrying the antibiotic resistance gene can grow in the presence of that antibiotic. During the process of making recombinant DNA, a second antibiotic resistance gene can be used to identify cells that carry the vector *with the desired insert*. If the second antibiotic resistance gene is inactivated by the insertion of additional DNA, then cells carrying copies of the vector with the inserted DNA can be identified by their sensitivity to that antibiotic (FIGURE 13.5). Since the uptake of recombinant DNA is a rare event (only about 1 cell in 10,000 takes up a plasmid in such experiments), it is vital to be able to select the small number of cells harboring the recombinant DNA.

Selectable markers are one type of **reporter gene**, which is any gene whose expression is easily assayed. Other reporter genes code for proteins that can be detected visually. For example, green fluorescent protein, which normally occurs in the jellyfish *Aequorea victoria*, emits green light when exposed to ultraviolet light. The gene for this protein has been isolated and incorporated into vectors and is now widely used as a reporter gene (FIGURE 13.6).

Such reporters are not just used to select and identify cells carrying recombinant DNA. They can be attached to promoters in order to study how the promoters function under different conditions or in different tissues of a transgenic multicellular organism. They can also be attached to other proteins, to study how and where those proteins become localized within eukaryotic cells.

Do You Understand Concept 13.2?

- Outline the steps used to create recombinant DNA, transform host cells, and detect cells carrying the recombinant DNA.
- Shuttle vectors have the ability to transform both prokaryotic and eukaryotic cells. What sequences would you expect these vectors to have?
- What are the advantages of green fluorescent protein over antibiotic resistance as a marker on a plasmid for genetic transformation?

We have described how DNA can be cut, inserted into a vector, and introduced into host cells. We have also seen how host cells carrying recombinant DNA can be identified. Now let's consider the sources of DNA used for cloning, as well as some molecular methods for manipulating gene expression.

APPLY THE CONCEPT

DNA can genetically transform cells and organisms

The β -galactosidase (*lacZ*) gene in the *E. coli lac* operon (see Concept 11.2) encodes an enzyme that can convert the colorless substrate X-gal into a bright blue product. This product is clearly visible in a colony of bacteria carrying the *lacZ* gene. Colonies that do not have a functional *lacZ* gene are white when exposed to X-gal. A plasmid vector contains the *lacZ* gene with a restriction site for *EcoR*1 within its coding sequence, and a gene for resistance (*r*) to the antibiotic ampicillin. In cloning experiments involving this vector, a strain of *E. coli* is used that carries no other functional *lacZ* gene and that is sensitive (*s*) to ampicillin. A biologist performs three transformations in a procedure designed to

DNA TAKEN UP BY <i>E. COLI</i>	PHENOTYPE FOR AMPICILLIN	PHENOTYPE FOR X-GAL (BLUE OR WHITE)
None		
Plasmid only		
Recombinant plasmid		

clone a gene from a wheat plant into this vector. The *EcoR*1 site in the *lacZ* gene is used for inserting the wheat DNA. Fill in the table with the results you would expect from each transformation.

concept 13.3 Genes and Gene Expression Can Be Manipulated

Cloning and the formation of recombinant DNA are applications of the concepts of DNA as a double-stranded, base-paired molecule, and as the genetic material in model organisms such as bacteria and viruses. In this section, you can see these same concepts applied to other aspects of DNA manipulation, such as the selection or creation of DNAs for amplification, the detection of expressed genes, and the artificial regulation of gene expression.

DNA fragments for cloning can come from several sources

The goal of cloning by recombinant DNA techniques is often to elucidate the functions of specific DNA sequences, including regulatory and coding regions, and the proteins they encode. The DNA fragments used in cloning procedures are obtained from a

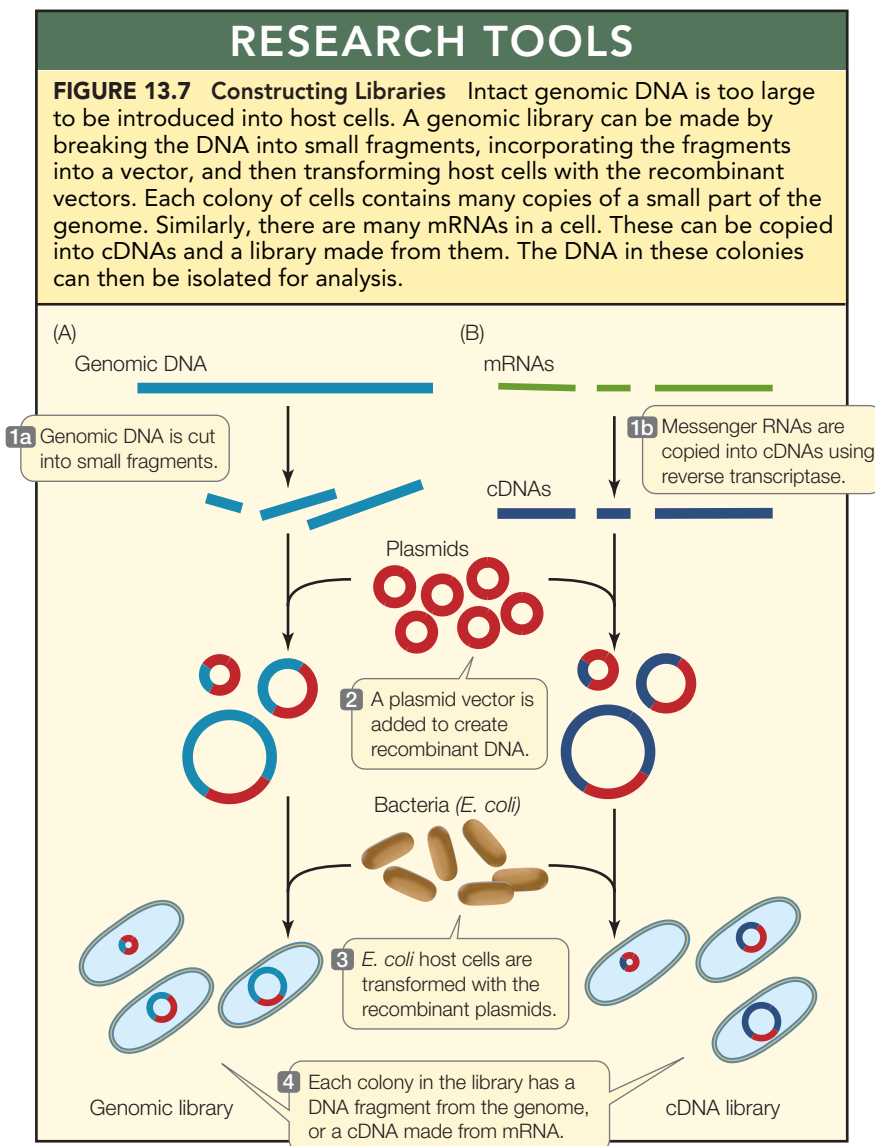

number of sources. In many cases the first step is to create a *library* of DNA fragments: a collection of clones that can be searched for the gene or genes of interest, or analyzed in other ways to learn more about the original source of the DNA fragments.

GENOMIC LIBRARIES A **genomic library** is a collection of DNA fragments that together comprise the genome of an organism. This is the starting point for some methods of genome sequencing. Restriction enzymes or other means, such as mechanical shearing, can be used to break chromosomes into smaller pieces (**FIGURE 13.7A**). Each fragment is inserted into a vector, which is then taken up by a host cell. Proliferation of a single transformed cell in a selective medium (such as for antibiotic resistance) produces a colony of recombinant cells, each of which harbors many copies of the same fragment of DNA. The colonies are grown by spreading the transformed cells over a solid culture medium in petri dishes (small circular plates), which are incubated at a suitable temperature for the host cells to grow.

A single petri dish can hold thousands of bacterial colonies and is easily screened for the presence of a particular DNA sequence. Colonies containing that sequence are identified by DNA hybridization using a probe labeled with complementary fluorescent or radioactive nucleotides. To do this, the petri dish with its bacterial colonies is duplicated, and then the bacteria on one of the plates are treated to expose the DNA for hybridization (see Figure 10.7).

cDNA LIBRARIES A much smaller DNA library—one that includes only the genes transcribed in a particular tissue—can be made from **complementary DNA**, or **cDNA** (**FIGURE 13.7B**). This involves isolating mRNA from cells and making cDNA copies of that mRNA by complementary base pairing. The enzyme *reverse transcriptase* catalyzes this reaction. This collection of cDNAs from a particular tissue at a particular time in the life cycle of an organism is called a **cDNA library**, which is a “snapshot” of the transcription pattern of the cell. cDNA libraries have been invaluable for comparing gene expression in different tissues at different stages of development. For example, if cDNAs derived from developing red blood cells are examined, the globin sequences (encoding the subunits of hemoglobin) are prominent. But a cDNA library derived from hair follicles does not contain those sequences.

SYNTHETIC DNA In Concept 9.2 (see Figure 9.15) we described the polymerase chain reaction (PCR), a method of amplifying DNA in a test tube. PCR can begin with as little as 10^{-12} g (a picogram) of DNA. Any fragment of DNA can be amplified as long as appropriate primers are available. This amplified DNA can then be inserted into a plasmid to create recombinant DNA, and cloned in host cells. The *artificial synthesis* of DNA by organic chemistry

is now fully automated. Synthetic oligonucleotides (single-stranded DNA fragments of 20 to 40 bp) are used as primers in PCR reactions. These primers can be designed to create short new sequences at the ends of the PCR products. This might be done to create a mutation in a recombinant gene, or to add restriction enzyme sites at the ends of the PCR product to aid in ligation reactions. Longer synthetic sequences can be pieced together to construct an *artificial gene* (or even an entire artificial genome; see the opening story of Chapter 4). If the amino acid sequence of a desired protein product is known, the genetic code can be used to determine the corresponding DNA sequence, which can be synthesized in the laboratory.

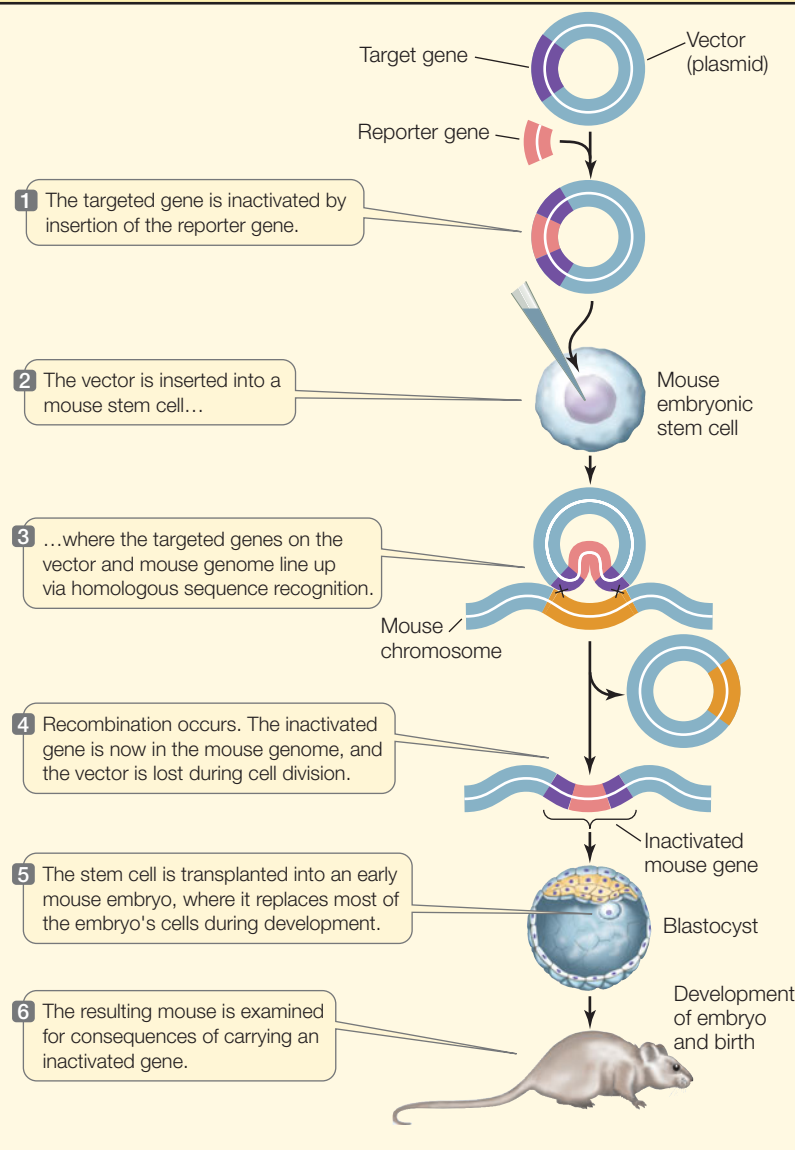

DNA mutations can be made in the laboratory

Mutations that occur in nature have been important in demonstrating cause-and-effect relationships in biology. However, mutations in nature are rare events. Recombinant DNA technology allows us to ask “what if” questions by creating mutations artificially. Because synthetic DNA can be made with any desired sequence, it can be manipulated to create specific mutations, the consequences of which can be observed when the mutant DNA is expressed in host cells. These mutagenesis techniques have revealed many cause-and-effect relationships.

For example, consider the experiment illustrated in Figure 10.20. Researchers hypothesized that a nuclear localization signal (NLS)—a short sequence of amino acids—is necessary for targeting a protein to the nucleus after it is made at the ribosome. The researchers used recombinant DNA technology to synthesize genes encoding proteins with and without the sequence, which were then used to transform cells. Without the NLS, newly synthesized proteins did not enter the nucleus. Knowing this, the researchers then asked, “Are certain amino acids more functionally important to the NLS than others?” In follow-up experiments, they made a series of mutated genes to test whether certain amino acids were needed at certain locations in the NLS. They found that changing the amino acids at the very beginning or very end of the NLS, but not the middle, abolished its function. This led to a fuller description of the binding of the NLS to its nuclear receptor. Without the ability to generate specific mutations, these experiments would not have been possible.

RESEARCH TOOLS

FIGURE 13.8 Making a Knockout Mouse Animals carrying mutations are rare. Homologous recombination is used to replace a normal mouse gene with an inactivated copy of that gene, thus “knocking out” the gene. Discovering what happens to a mouse with an inactive gene tells us much about the normal role of that gene.

Genes can be inactivated by homologous recombination

Another way to understand a gene's function is to inactivate it so it is not transcribed and translated into a protein. An example of this approach is the use of transposon mutagenesis in experiments designed to describe the minimal genome (see Figure 12.8). In animals, such manipulation is called a **knockout** experiment. Techniques have been developed for knocking out genes in mice, fruit flies, and the nematode *Caenorhabditis elegans*, all of which are model organisms. We will focus here on the technique used for mice.

In mice, a process called **homologous recombination** is used to target a specific gene (FIGURE 13.8). The normal allele of the mouse gene to be tested is inserted into a plasmid. Restriction enzymes are then used to insert a fragment containing a reporter gene or selectable marker into the middle of the normal gene. This addition of extra DNA disrupts the gene's coding region so that it no longer encodes a functional protein product.

Once the recombinant plasmid has been made, it is used to transfect mouse embryonic stem cells. A **stem cell** is an unspecialized cell that divides and differentiates into specialized cells. The sequences of the targeted gene in the plasmid tend to line up with their

homologous sequences in the mouse chromosome. If recombination occurs, the disrupted, inactive allele is “swapped” with the functional allele in the host cell.

The knockout technique has been important in assessing the roles of many genes, and is especially valuable in studying human genetic diseases. Many such diseases (including phenylketonuria; see Concept 10.1) have *knockout mouse models*: mouse strains with similar diseases that were produced by homologous recombination. These models can be used to study the diseases and to test potential treatments. Mario Capecchi, Martin Evans, and Oliver Smithies shared a Nobel Prize for developing the knockout mouse technique.

Complementary RNA can prevent the expression of specific genes

Another way to study the expression of a specific gene is to block the translation of its mRNA. This is yet another example of scientists imitating nature. As described in Concept 11.4, gene expression is sometimes controlled in nature by the production of short, single-stranded RNA molecules (*microRNAs*) that are complementary to specific mRNA sequences. Such a complementary molecule is called **antisense RNA** because it binds by base pairing to the “sense” bases on the mRNA. The resulting partially double-stranded RNA hybrid inhibits translation of the mRNA. Although the gene continues to be transcribed, translation does not take place. After determining the sequence of a gene in the laboratory, scientists can make a specific, single-stranded antisense RNA and add it to a cell to prevent translation of that gene’s mRNA (**FIGURE 13.9A**).

Several drugs use antisense RNA to reduce the expression of genes involved with cancer. For example, the gene *BCL2* codes for a protein that blocks apoptosis, and in some forms of cancer *BCL2* expression is activated inappropriately through mutation. These cells fail to undergo apoptosis, continue to divide, and form tumors. The drug oblimersen is an antisense RNA that binds to *BCL2* mRNA. It prevents production of the protein and leads to apoptosis of the tumor cells and shrinkage of the tumor.

A related technique takes advantage of **RNA interference (RNAi)**, a natural mechanism for inhibiting mRNA translation. RNAi occurs via the action of *small interfering RNAs* (siRNAs), which are formed in a process similar to the processing of microRNAs. An siRNA is a short (21–25 bp) double-stranded RNA which is unwound to single strands by a protein complex that guides one strand to a complementary region on an mRNA

molecule. The protein complex then catalyzes the breakdown of the targeted mRNA. RNAi was not discovered until the late 1990s, but since then scientists have synthesized double-stranded siRNAs to inhibit the expression of known genes (**FIGURE 13.9B**). This technique has been used extensively to block expression of specific genes in the model animal *C. elegans*.

Because these double-stranded siRNA molecules are more stable than antisense RNA, the use of siRNA is now the preferred approach for blocking translation in both research and medicine. Macular degeneration is an eye disease that results in near blindness when blood vessels proliferate in the eye. The signaling molecule that stimulates vessel proliferation is a growth factor. An RNAi-based therapy is being developed to target this growth factor’s mRNA, and the therapy shows promise for stopping and even reversing the progress of the disease.

FRONTIERS RNAi is now the major tool used by biologists to experimentally reduce gene expression. The technique is called “gene knockdown” (as opposed to “knockout”), and it is important in establishing cause-and-effect relationships. For example, a particular membrane protein was suspected of pumping cancer-fighting drugs out of cells, making them resistant to the drugs. Treating these cells with RNAi that was directed against expression of the pump gene essentially reversed this drug resistance.

DNA microarrays reveal RNA expression patterns

The emerging science of genomics has to face two major quantitative realities. First, there are very large numbers of genes in eukaryotic genomes. Second, the pattern of gene expression in different tissues at different times is quite distinctive. For example, the cells of a skin cancer at its early stage may have a unique mRNA “fingerprint” that differs from those of normal skin cells and cells from a more advanced skin cancer.

To find such patterns, scientists could isolate mRNA from a cell and test it by hybridization with each gene in the genome to determine, by the amount of hybridization, the amount of expression of each gene. But that would involve many steps and take a long time. It is far simpler to do these hybridizations all in one step. This is possible with *DNA microarray* technology, which provides large arrays of sequences for hybridization experiments.

DNA arrays (“gene chips”) were inspired by the semiconductor industry. A silicon microchip consists of an array of

FIGURE 13.9 Using Antisense RNA and siRNA to Block the Translation of mRNA

Once a gene’s sequence is known, the synthesis of its protein can be prevented by making either an antisense RNA (A) or a small interfering RNA (B) that is complementary to its mRNA.

microscopic electric circuits etched onto a tiny silicon base, called a chip. In the same way, a series of DNA sequences can be attached to a glass slide in a precise order. The slide is divided into a grid of microscopic spots, or “wells.” Each spot contains thousands of copies of a particular oligonucleotide of 20 or more bases that corresponds to a unique sequence from the genome of an organism. A computer controls the addition of these oligonucleotide sequences in a predetermined pattern. Each oligonucleotide can hybridize with only one DNA or RNA sequence, and thus is a unique identifier of a gene. Many thousands of different oligonucleotides can be placed on a single microarray.

Microarrays can be used to examine patterns of gene expression in different tissues and under different conditions, and they can be used to identify individual organisms with particular mutations (see Concept 12.4). You can see the concept of microarray analysis by following the example illustrated in **FIGURE 13.10**. Most women with breast cancer are treated with surgery to remove the tumor, and then treated with radiation soon afterward to kill cancer cells that the surgery may have missed. But a few cancer cells may still survive in some patients, and these eventually form tumors in the breast or elsewhere in the body. The challenge for physicians is to develop

criteria to identify patients with surviving cancer cells so they can be treated aggressively with tumor-killing chemotherapy. Scientists at the Netherlands Cancer Institute used medical records to identify patients whose cancer recurred or did not recur. Then they extracted mRNA from the patients’ tumors, which had been stored after surgery, and made cDNA from the samples. The cDNAs were hybridized to microarrays containing sequences derived from 1,000 human genes. The scientists found 70 genes whose expression differed dramatically between tumors from patients whose cancers recurred and tumors from patients whose cancers did not recur. From this information the Dutch group identified *gene expression signatures* that are useful in clinical decision-making: patients with a good prognosis can avoid unnecessary chemotherapy, while those with a poor prognosis can receive more aggressive treatment.

Do You Understand Concept 13.3?

- Outline the steps involved in “knocking out” a gene in a bacterium and in an animal. What are the uses for these methods?
- What are the differences between a genomic library and a cDNA library? Between antisense RNA and siRNA?
- You hypothesize that when a corn plant is infected with a fungus, a set of genes is turned on that fights the infection. How would you investigate this using microarray technology?

FIGURE 13.10 Using DNA Microarrays for Clinical Decision-Making The pattern of expression of 70 genes in tumor tissues (the pattern of colored spots) indicates whether breast cancer is likely to recur. Actual arrays have more dots than shown here.

We have now seen how recombinant DNA is made, how cells and organisms are transformed, and how gene expression can be manipulated. In the final concept we will look at some of the many applications of biotechnology.

concept 13.4 Biotechnology Has Wide Applications

In the opening story of this chapter we defined biotechnology as the use of cells or whole living organisms to make or modify materials or processes that are useful to people, such as foods, medicines, and chemicals. Bacteria and yeast cells can be transformed with almost any gene, and they can be induced to express that gene at high levels and to export the protein product out of their cells. This technology has turned these microbes into versatile factories for many important products. Today there is interest in producing nutritional supplements and pharmaceuticals in whole transgenic animals and plants and harvesting the products in large quantities—for example, from cow’s milk or rice grains. Another goal is to produce animals and plants with improved characteristics, such as increased nutritional value or better tolerance of harsh environments. Key to this boom in biotechnology has been the development of specialized vectors that not only carry genes into animal and plant cells, but also make those cells express the genes at high levels.

DNA Chip Technology

Expression vectors can turn cells into protein factories

Many potentially useful proteins come from eukaryotes. But if a eukaryotic gene is inserted into a typical plasmid and used to transform *E. coli*, none of the gene product will be made. Other key prokaryotic DNA sequences must be included with the gene. A bacterial promoter, a signal for transcription termination, and a special sequence that is necessary for ribosome binding on the mRNA must all be included in the transformation vector if the gene is to be expressed in the bacterial cell.

To solve this kind of problem, scientists make **expression vectors** that have all the characteristics of typical vectors, as well as the extra sequences needed for the foreign gene (also called a *transgene*) to be expressed in the host cell. For bacterial hosts, these additional sequences include the elements named above (**FIGURE 13.11**); for eukaryotes, they include the poly A-addition sequence, transcription factor binding sites, and enhancers. An expression vector can include various types of promoters and other features:

FIGURE 13.11 A Transgenic Cell Can Produce Large Amounts of the Transgene's Protein Product To be expressed in *E. coli*, a gene derived from a eukaryote requires bacterial sequences for transcription initiation (promoter), transcription termination, and ribosome binding. Expression vectors contain these additional sequences, enabling the eukaryotic protein to be synthesized in the prokaryotic cell.

yourBioPortal.com

Go to WEB ACTIVITY 13.1
Expression Vectors

- An *inducible promoter*, which responds to a specific signal, can be included. For example, a promoter that responds to hormonal stimulation can be used so that the transgene will be expressed at high levels when the hormone is added.
- A *tissue-specific promoter*, which is expressed only in a certain tissue at a certain time, can be used if localized expression is desired. For example, many seed proteins are expressed only in the plant embryo. Coupling a transgene to a seed-specific promoter will allow it to be expressed only in seeds and not, for example, in leaves.
- *Signal sequences* can be added so that the gene product is directed to an appropriate destination. For example, when a protein is made by yeast or bacterial cells in a liquid medium, it is economical to include a signal directing the protein to be secreted into the extracellular medium for easier recovery.

LINK You may wish to review the mechanisms of transcription, described in Concept 10.2

FRONTIERS Tobacco mosaic virus infects but does not kill tobacco plants. Using the virus as vector, tobacco leaves can become factories for the synthesis of valuable proteins. For example, the gene for an anticancer vaccine has been inserted into the virus, and infected tobacco plants make a great deal of the vaccine protein, which is being tested on patients. An important challenge with this technique is purification of the desired protein, separating it completely from plant proteins.

Medically useful proteins can be made by biotechnology

Some medically useful products are being made by biotechnology (**TABLE 13.1**), and more are in various stages of development. The manufacture of human insulin provides a good illustration of a medical application of biotechnology. Insulin is essential for glucose uptake into cells. People with type I diabetes mellitus cannot make this hormone and must receive insulin injections. Until recently, the insulin used for this purpose came from cattle and pigs.

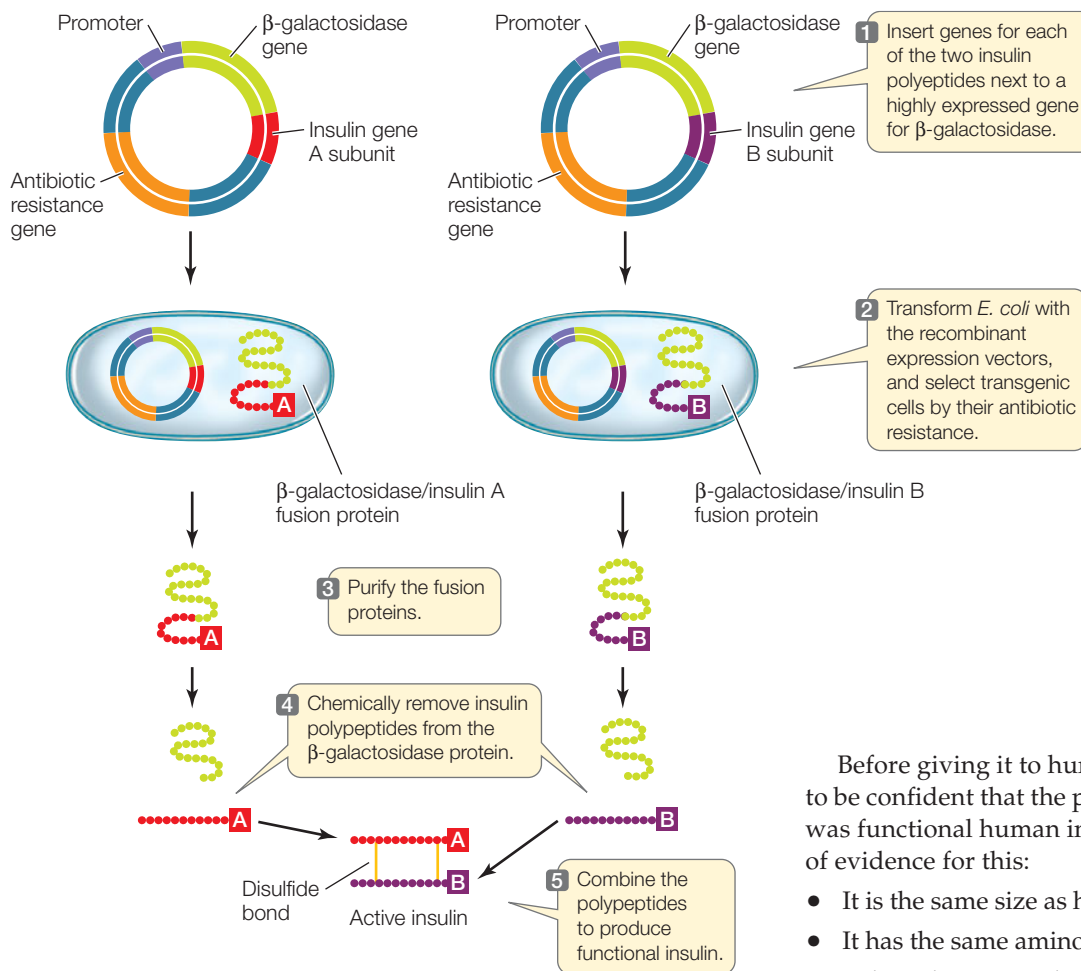

LINK The role of insulin in regulating glucose metabolism is detailed in Concept 39.4

Insulin is a protein of 51 amino acids and is made up of two polypeptide chains. The amino acid sequence of insulin from cattle differs from the human sequence by three amino acids, and the pig sequence differs from that of humans by just one amino acid. These differences are enough to cause an immune reaction in some patients who are diabetic, and these patients need to be treated with the human protein. Since the hormone is made in tiny amounts, harvesting enough from deceased persons is not practical. Recombinant DNA biotechnology has solved this problem.

FIGURE 13.12 illustrates the strategy used to make human insulin. The two insulin polypeptides are synthesized

TABLE 13.1 Some Medically Useful Products of Biotechnology

PRODUCT	USE
Erythropoietin	Prevents anemia in patients undergoing kidney dialysis and cancer therapy
Colony-stimulating factor	Stimulates production of white blood cells in patients with cancer and AIDS
Bovine/porcine somatotropin	Stimulates growth and milk production in animals
Tissue plasminogen activator	Dissolves blood clots after heart attacks and strokes
Human growth hormone	Replaces missing hormone in people of short stature
Human insulin	Stimulates glucose uptake from blood in patients with type I diabetes mellitus
Factor VIII	Replaces clotting factor missing in patients with hemophilia A
Platelet-derived growth factor	Stimulates wound healing

**FIGURE 13.12 Human Insulin: From Gene to Drug** Human insulin chains are made by recombinant DNA technology and then combined to produce the widely used drug.

Before giving it to human patients, the scientists had to be confident that the product made by biotechnology was functional human insulin. There were several lines of evidence for this:

- It is the same size as human insulin.
- It has the same amino acid sequence.
- It has the same shape, as measured by physical techniques.
- It binds to the insulin receptor on cells and stimulates glucose uptake.

Another way of making medically useful products in large amounts is **pharming**: the production of pharmaceuticals in farm animals or plants. For example, a gene encoding a useful protein might be placed next to the promoter of the gene that encodes lactoglobulin, an abundant milk protein. Transgenic animals carrying this recombinant DNA will secrete large amounts of the foreign protein into their milk. These natural “bioreactors” can produce abundant supplies of the protein,

separately using an expression vector containing the gene for β -galactosidase, which is part of the inducible *lac* operon (see Concept 11.2). Each insulin gene is inserted into the vector in such a way that it is induced, transcribed, and translated along with the β -galactosidase gene. After extraction and purification of the β -galactosidase-insulin fusion proteins, the insulin polypeptides are cleaved off by chemical treatment. The two insulin polypeptides are then combined to make a complete, functional human insulin molecule.

FIGURE 13.13 Pharming An expression vector carrying a desired gene can be put into an animal egg, which is implanted into a surrogate mother. The transgenic offspring produce the new protein in their milk. The milk is easily harvested and the protein isolated, purified, and made clinically available for patients.

which can be separated easily from the other components of the milk (FIGURE 13.13).

Human growth hormone, a protein made in the pituitary gland, has many effects, especially in growing children (see Concept 30.3). People with growth hormone deficiencies have short stature as well as other abnormalities. In the past they were treated with protein isolated from the pituitary glands of dead people, but the supply was too limited to meet demand. Recombinant DNA technology was used to coax bacteria into making the protein, but the cost of treatment was high (\$30,000 a year). In 2004, a team led by Daniel Salamone at the University of Buenos Aires made a transgenic cow that secretes

human growth hormone in her milk. The yield is prodigious: only 15 such cows are needed to meet the worldwide demand of children suffering from this type of dwarfism.

DNA manipulation is changing agriculture

The cultivation of plants and the husbanding of animals provide the world's oldest examples of biotechnology, dating back more than 10,000 years. Over the centuries, people have adapted crops and farm animals to their needs. Through selective breeding of these organisms, desirable characteristics such as large seeds, high fat content in milk, or resistance to disease have been selected for and improved.

The traditional way to improve crop plants and farm animals was to identify individuals with desirable phenotypes that existed as a result of natural variation. Through deliberate crosses, the genes responsible for the desirable traits could be introduced into widely used varieties or breeds. Despite some spectacular successes, such as the breeding of high-yielding varieties of wheat, rice, and hybrid corn, such deliberate crossing has been a hit-or-miss affair. Many desirable traits are controlled by multiple genes, and it is hard to predict the results of a cross or to maintain a prized combination in a true-breeding variety. In sexual reproduction, combinations of desirable genes are quickly separated by meiosis. Furthermore, traditional breeding takes a long time: many plants and animals take years to reach maturity and then can reproduce only once or twice a year.

Recombinant DNA technology has several advantages over traditional methods of breeding (FIGURE 13.14):

- *The ability to identify specific genes.* The development of genetic markers allows breeders to select for specific desirable genes, making the breeding process more precise and rapid.
- *The ability to introduce any gene from any organism into a plant or animal species.* This ability, combined with mutagenesis techniques, vastly expands the range of possible new traits.
- *The ability to generate new organisms quickly.* Manipulating cells in the laboratory and regenerating a whole plant by cloning is much faster than traditional breeding.

Consequently, recombinant DNA technology has found many applications in agriculture (TABLE 13.2). We will describe a

TABLE 13.2 Potential Agricultural Applications of Biotechnology

PROBLEM	TECHNOLOGY/GENES
Improving the environmental adaptations of plants	Genes for drought tolerance, salt tolerance
Improving nutritional traits	High-lysine seeds; β -carotene in rice
Improving crops after harvest	Delay of fruit ripening; sweeter vegetables
Using plants as bioreactors	Plastics, oils, and drugs produced in plants

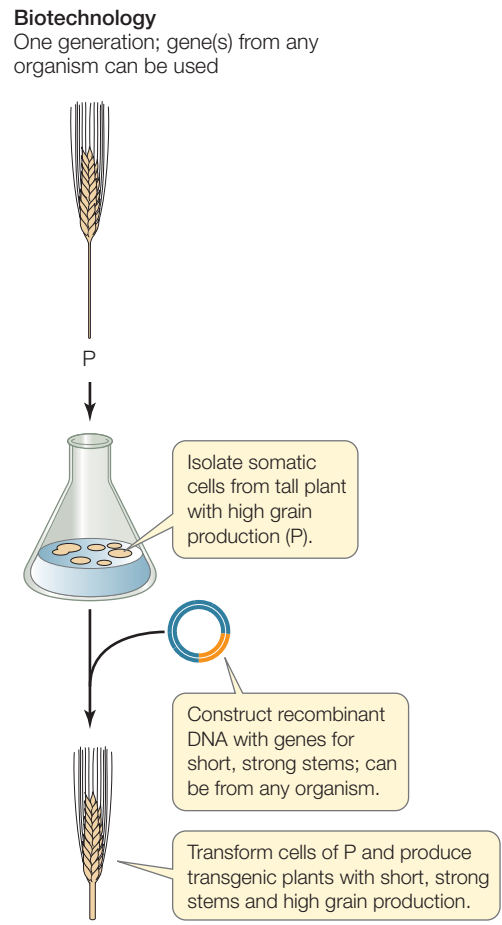

FIGURE 13.14 Genetic Modification of Plants versus Conventional Plant Breeding Plant biotechnology offers many potential advantages over conventional breeding. In the hypothetical example here, the objective is to transfer gene(s) for short, strong stems into a wheat plant that has high grain production but a tall, weak stem.

few examples to demonstrate the approaches that plant scientists have used to improve crop plants.

PLANTS THAT MAKE THEIR OWN INSECTICIDES From the locusts of biblical (and modern) times to the cotton boll weevil, insects have continually eaten the crops people grow. The development of insecticides has improved the situation somewhat, but insecticides have their own problems. Many are relatively non-specific and kill beneficial insects in the broader ecosystem as well as crop pests. Some have toxic effects on other groups of organisms, including people, and persist in the environment for a long time.

Some bacteria protect themselves by producing proteins that can kill insects. For example, the bacterium *Bacillus thuringiensis* (Bt) produces a protein that is toxic to the insect larvae that prey on it:

The toxicity of this protein is 80,000 times greater than that of a typical commercial insecticide. When a hapless larva eats the bacteria, the toxin becomes activated and binds specifically to the insect's gut, producing pores and killing the insect. Dried preparations of Bt have been sold for decades as safe insecticides that break down rapidly in the environment. But the biodegradation of these preparations is their limitation, because it means the dried bacteria must be applied repeatedly during the growing season.

A more permanent approach is to have the crop plants themselves make the toxin. The toxin gene from Bt has been isolated, cloned, and extensively modified by the addition of a plant promoter and other regulatory sequences. Transgenic (also called genetically modified or GM) corn, cotton, soybeans, tomatoes, and other crops are now being grown successfully with this added gene. Pesticide usage by farmers growing these transgenic crops is greatly reduced.

GRAINS WITH IMPROVED NUTRITIONAL CHARACTERISTICS To remain healthy, humans must consume adequate amounts of β -carotene, which the body converts into vitamin A. About 400 million people worldwide suffer from vitamin A deficiency, which makes them susceptible to infections and blindness. One reason is that rice grains, which do not contain β -carotene, make up a large part of their diets. Other parts of the rice plant—and indeed many plants and other organisms—contain enzymes for the biochemical pathway that leads to β -carotene production.

Plant biologists Ingo Potrykus and Peter Beyer isolated one of the genes for the β -carotene pathway from the bacterium *Erwinia uredovora* and another from daffodil plants. They added a promoter and other signals for expression in the developing rice grain, and then transformed rice plants with the two genes. The resulting rice plants produce grains that look yellow because of their high β -carotene content. A newer variety with a corn gene replacing the one from daffodils makes even more β -carotene and is golden in color (FIGURE 13.15). A daily intake of about 150 grams of this cooked rice can supply all the β -carotene a person needs. This new transgenic strain has been crossed with strains adapted for various local environments, in the hope of improving the diets of millions of people.

CROPS THAT ADAPT TO THE ENVIRONMENT Agriculture depends on ecological management—tailoring the environment to the needs of crop plants and animals. A farm field is an unnatural, human-designed system that must be carefully managed to maintain optimal conditions for crop growth. For example, repeated irrigation results in increases in soil salinity. The Fertile Crescent, the region between the Tigris and Euphrates rivers in the Middle East where agriculture was practiced 10,000 years ago, is no longer fertile. It is now a desert, largely because the soil has a high salt concentration. Few plants can grow on salty soils, partly because of osmotic effects that result in wilting, and partly because excess salt ions are toxic to plant cells.

Some plants can tolerate salty soils because they have a protein that transports Na^+ ions out of the cytoplasm and into the vacuole, where the ions can accumulate without harming plant

FIGURE 13.15 Transgenic Rice Rich in β -Carotene Right and middle: The grains from these transgenic rice strains are colored because they make the pigment β -carotene, which is converted to vitamin A in the human body. Left: Normal (wild-type) rice grains do not contain β -carotene.

growth (see Concept 4.3 for a description of the plant vacuole). In many salt-intolerant plants, including *Arabidopsis thaliana*, the gene for this protein exists but is inactive. Recombinant DNA technology has allowed scientists to create active versions of this gene and to use it to transform crop plants such as rapeseed, wheat, and tomatoes. When this gene was added to tomato plants, they grew in water that was four times as salty as the typical lethal level (FIGURE 13.16). This finding raises the prospect of growing useful crops on what were previously unproductive soils.

The example described here illustrates what could become a fundamental shift in the relationship between crop plants and the environment. *Instead of manipulating the environment to suit the plant, biotechnology may allow us to adapt the plant to the environment.* As a result, some of the negative effects of agriculture, such as water pollution, could be lessened.

There is public concern about biotechnology

Concerns have been raised about the safety and wisdom of genetically modifying crops and other organisms. These concerns are centered on three claims:

- Genetic manipulation is an unnatural interference with nature.
- Genetically altered foods are unsafe to eat.
- Genetically altered crop plants are dangerous to the environment.

Advocates of biotechnology tend to agree with the first claim. However, they point out that all crops are unnatural in the sense that they come from artificially bred plants growing in a manipulated environment (a farmer's field). Recombinant DNA technology just adds another level of sophistication to these technologies.

To counter the concern about whether genetically engineered crops are safe for human consumption, biotechnology advocates point out that only single genes are added, and that these genes have specific, known functions. For example, the Bt toxin produced by transgenic plants has no effect on people. However, as plant biotechnology moves from adding genes

that improve plant growth to adding genes that affect human nutrition, such concerns will become more pressing.

Various negative environmental impacts have been envisaged. There is concern about the possible “escape” of transgenes from crops to other species. For example, a drought-tolerant crop plant might spread into, and upset the ecology of, a desert. Or beneficial insects could eat plant materials containing Bt toxin and die. Transgenic organisms undergo extensive field-testing before they are approved for use, but the complexity of the biological world makes it impossible to predict all the potential environmental effects of releasing these organisms. In fact, some spreading of transgenes has been detected. Because of the potential benefits of agricultural biotechnology (see Table 13.2), most scientists believe that it is wise to proceed, but with abundant caution

Do You Understand Concept 13.4?

- In addition to the coding sequence for a gene of interest, what other DNA sequences are required for the gene to be expressed in a different host?
- What is pharming, how is it done, and what are its advantages over more conventional biotechnology approaches?
- What are the advantages of using biotechnology for plant breeding compared with traditional methods?
- What are some of the concerns that people might have about agricultural biotechnology?

FIGURE 13.16 Salt-tolerant Tomato Plants Transgenic plants containing a gene for salt tolerance thrive in salty water (A), whereas plants without the transgene die (B). This technology may allow crops to be grown on salty soils.

How is biotechnology used to alleviate environmental problems?

ANSWER Among the thousands of species of bacteria, there are many unique enzymes and biochemical pathways. New pathways are continually being discovered as new bacterial species are found (for example, by metagenomics; see Figure 12.7). Bacteria are nature’s recyclers, thriving on many types of nutrients—including what humans refer to as wastes.

Bioremediation is the use by humans of other organisms to remove contaminants from the environment. Two well-known examples of bioremediation are composting and wastewater treatment. *Composting* involves using bacteria and other microbes to break down the large molecules, including carbon-rich polymers and proteins, in waste products such as wood chips, paper, straw, and kitchen scraps. For example, some species of bacteria make cellulase, an enzyme that hydrolyzes cellulose. Bacteria are used in *wastewater treatment* to break down human wastes, paper products, and household chemicals.

In the opening story we described how conventional genetic crosses were used to produce (and patent) bacteria that have the capacity to break down oil. Since that time, scientists have improved on nature. The oil-degrading genes from such bacteria have been isolated and spliced into vectors to make recombinant DNA (Concept 13.1). This DNA has been used to transform several species of bacteria that live in the soils where oil spills have occurred (Concept 13.2), and these transgenic bacteria are used to help clean up oil spills.

In the summer of 1990, soldiers from Iraq invaded neighboring Kuwait. The reason was oil: the Iraqis were angry because Kuwait was pumping too much of it, keeping prices low. Six months later, a United Nations–sponsored coalition army from more than 30 countries drove the Iraqis out of Kuwait and back to their homeland. For Kuwait, the Gulf War was a success, but it left an environmental disaster. As they fled, the Iraqi soldiers set fire to more than 700 oil wells. It took over

six months to put out the fires, and in the meantime an astounding 250 million gallons of crude oil were spilled into the desert. Twenty years later, much of the oil remains as a gooey coating, severely affecting the organisms that live there (FIGURE 13.17). The government of Kuwait is using a variety of processes to get rid of the contaminating oil. Among them is bioremediation with bacteria that can break down oil and use the hydrocarbons as energy sources for growth.

The Kuwait episode is not the first major use of bacteria for bioremediation. In 2010, about 200 million gallons of oil escaped from an offshore well into the Gulf of Mexico. Although there was limited use of genetically modified microbes near the shore, naturally occurring microbes in the open ocean have been very important in breaking down the oil and reducing its adverse impacts on the environment.

FIGURE 13.17 The Spoils of War Massive oil spills occurred in Kuwait during the 1990–1991 Gulf War.

13

SUMMARY

concept 13.1 Recombinant DNA Can Be Made in the Laboratory

- **Biotechnology** is the use of living cells to make or modify materials and processes useful to people.
- **Restriction enzymes** make cuts in double-stranded DNA, creating fragments of various lengths.
- DNA fragments can be separated by size using gel electrophoresis. **Review Figure 13.2 and ANIMATED TUTORIAL 13.1**
- DNA fragments from different sources can be used to create recombinant DNA by splicing them together using **DNA ligase**. **Review Figures 13.3 and 13.4 and WORKING WITH DATA 13.1**

concept 13.2 DNA Can Genetically Transform Cells and Organisms

- One goal of recombinant DNA technology is to **clone** a particular gene, either for analysis or to produce its protein product in quantity.
- Bacteria, yeasts, and cultured plant and animal cells are commonly used as hosts for recombinant DNA. The insertion of foreign DNA into host cells is called **transformation**, or if the host cells are derived from an animal, **transfection**.
- Various methods are used to get recombinant DNA into cells. These include chemical and physical treatments for plasmids and the use of viral vectors.
- **Selectable markers** such as genes for antibiotic resistance are used to select for host cells that have taken up a foreign gene. **Review Figure 13.5**
- **Reporter genes** (of which selectable markers are one type) are genetic markers with easily identifiable phenotypes. **Review Figure 13.6**

concept 13.3 Genes and Gene Expression Can Be Manipulated

- DNA fragments from a genome can be inserted into host cells to create a **genomic library**. A **cDNA library** is made by reverse transcribing mRNA to make cDNA. **Review Figure 13.7**
- Synthetic DNA containing any desired sequence can be made in the laboratory.
- Manipulating gene expression is one way to study the functions of particular genes.
- Homologous recombination is used to knock out a gene in a living organism. **Review Figure 13.8**
- Gene silencing techniques using **antisense RNA** or siRNA are used to prevent the translation of genes. **Review Figure 13.9**
- DNA microarray technology permits the screening of thousands of cDNA sequences at the same time. **Review Figure 13.10 and ANIMATED TUTORIAL 13.2**

concept 13.4 Biotechnology Has Wide Applications

- **Expression vectors** allow transgenes to be expressed in host cells. **Review Figure 13.11 and WEB ACTIVITY 13.1**
- Recombinant DNA techniques have been used to make medically useful proteins. **Review Figure 13.12**
- **Pharming** is the use of transgenic plants or animals to produce pharmaceuticals. **Review Figure 13.13**
- Transgenic crop plants can be adapted to their environments, rather than vice versa. **Review Figure 13.16**
- There is public concern about the application of recombinant DNA technology to food production.

Genes, Development, and Evolution

14

After winning a race in 2005, the thoroughbred Greg's Gold was limping because of a shredded tendon in his right front leg. A tendon is like a rubber band connecting muscles and bones, and tendons in the legs store energy when an animal runs. Typically, a damaged tendon is allowed to heal naturally, but scar tissue makes it less flexible, and a horse cannot run as fast as it did before injuring a tendon. It looked as if Greg's Gold might have to retire from racing.

Greg's Gold's trainer, David Hofmans, decided to try a new therapy. A veterinarian removed a small amount of adipose (fatty) tissue from the horse's hindquarters and sent it to a cell biology laboratory, where biologists isolated mesenchymal stem cells. Stem cells are actively dividing, unspecialized cells that have the potential to produce different cell types depending on the signals they receive from the body. Mesenchymal stem cells are able to differentiate into various kinds of connective tissue, including bone, cartilage, blood vessels, tendons, and muscle.

Two days after the tissue was taken, Greg's Gold's veterinarian received the stem cells back from the lab and injected them into the site of the damaged tendon. After several months, the tendon healed with little scar tissue, and Greg's Gold's trainer returned him to the racetrack. Greg's Gold raced for almost two more years, winning over \$1 million in purse money before being retired. The mesenchymal stem cell treatment has been used successfully on several thousand horses, and on dogs with arthritis.

The processes by which an unspecialized stem cell proliferates and forms

specialized cells and tissues with distinctive appearances and functions are similar to the developmental processes that occur in the embryo. Much of our knowledge of developmental biology has come from studies on model organisms such as the fruit fly *Drosophila melanogaster*, the nematode worm *Caenorhabditis elegans*, zebrafish, the mouse, and the small flowering plant *Arabidopsis thaliana*. Eukaryotes share many similar genes, and the cellular and molecular principles underlying their development also turn out to be similar. Thus discoveries from one organism can aid us in understanding other organisms, including ourselves.

Fat stem cells helped repair damage to Greg's Gold's tendons, and he was able to race—and win—again.

- 14.5** Developmental Genes Contribute to Species Evolution but Also Pose Constraints

Why are stem cells so useful?

concept 14.1 Development Involves Distinct but Overlapping Processes

Development is the process by which a multicellular organism, beginning with a single cell, goes through a series of changes, taking on the successive forms that characterize its life cycle (FIGURE 14.1). After the egg is fertilized, it is called a *zygote*, and in the earliest stages of development a plant or animal is called an **embryo**. A series of embryonic stages precedes emergence of the new, independent organism. Many organisms continue to develop throughout their life cycle, with development ceasing only with death.

Four key processes underlie development

The developmental changes an organism undergoes as it progresses from an embryo to mature adulthood involve four processes:

- **Determination** sets the developmental *fate* of a cell—what type of cell it will become—even before any characteristics of that cell type are observable. For example, the mesenchymal stem cells described in the opening story look unspecialized, but their fate to become connective tissue cells has already been determined.

- **Differentiation** is the process by which different types of cells arise from less specialized cells, leading to cells with specific structures and functions. For example, mesenchymal stem cells differentiate to become muscle, fat, tendon, or other connective tissue cells.
- **Morphogenesis** (Greek for “origin of form”) is the organization and spatial distribution of differentiated cells into the multicellular body and its organs. For example, the stem cells used to heal Greg’s Gold became part of a tendon with a distinct structure. Morphogenesis can occur by cell division, cell expansion (especially in plants), cell movements, and apoptosis (programmed cell death).
- **Growth** is the increase in size of the body and its organs by cell division and cell expansion. Growth can occur by an increase in the number of cells or by the enlargement of existing cells. Growth continues throughout the individual’s life

Stages of Development

FIGURE 14.1 Development The stages and processes of development from zygote to maturity are shown for an animal and for a plant. The blastula is a hollow sphere of cells; the gastrula has three cell layers.

in some organisms, but reaches a more or less stable end point in others.

Cell fates become progressively more restricted during development

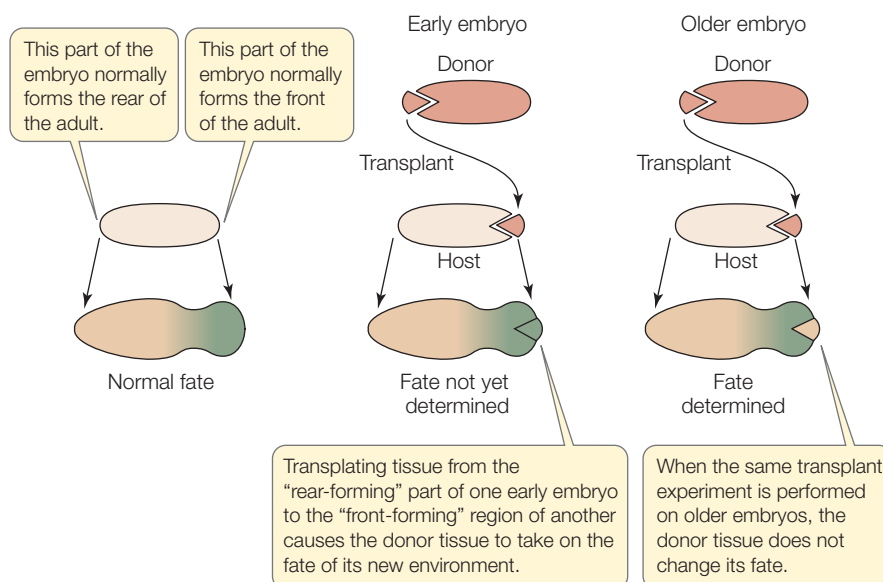

A zygote is a single cell that gives rise to all the cells in the individual organism that will develop from it. As the zygote divides to form a multicellular embryo, each of the embryo's undifferentiated cells are destined to become part of a particular type of tissue—this is referred to as the **cell fate** of that undifferentiated cell.

When is the fate determined? At what point does a cell become committed to a particular fate and no other? One way to find out is to transplant cells from one embryo to a different region of a recipient embryo (**FIGURE 14.2**). A dye is used to mark the transplanted cells so that their subsequent development can be followed. The question is, will the transplanted cells adopt the differentiation pattern of their new surroundings, or will they continue on their own path, with their fate already sealed?

Experiments with frog embryos give an answer for that organism: If the donor tissue is from an early-stage embryo (blastula), it adopts the fate of its new surroundings; its fate *has not* been sealed. But if the donor tissue is from an older embryo (gastrula), it continues on its own path; its fate *has* been sealed. Determination is influenced by changes in gene expression as well as the extracellular environment and is not something that is visible under the microscope—cells do not change their appearance when they become determined. Determination is followed by differentiation—the actual changes in biochemistry, structure, and function that result in cells of different types. *Determination is a commitment; the final realization of that commitment is differentiation.*

Cell Fates: Genetic vs. Environmental Influences

Cell differentiation is not irreversible

Once a cell's fate is determined, the cell differentiates. However, under the right experimental conditions, a determined or differentiated cell can become undetermined again. In some cases, the cell can even become **totipotent**, meaning it is able to form the entire organism, with all of its differentiated cells. Normally, this is a property of only the zygote.

PLANT CELL TOTIPOTENCY A carrot root cell normally faces a dark future. It cannot photosynthesize and generally does not give rise to new carrot plants. However, in 1958 Frederick Steward at Cornell University showed that if he isolated cells from a carrot root and maintained them in a suitable nutrient medium, he could induce them to *dedifferentiate*—to lose their differentiated characteristics. The cells could divide and give rise to masses of undifferentiated cells called *calli* (singular *callus*), which could be maintained in culture indefinitely. If they were provided with the right chemical cues, the cells could develop into embryos and eventually into complete new plants (**FIGURE 14.3**).

Since the new plants in Steward's experiments were genetically identical to the cells from which they came, they were *clones* of the original carrot plant. The ability to produce clones is evidence for the **genomic equivalence** of somatic (body) cells; that is, all cells in a plant have a complete genome and thus have all the genetic information needed to become any cell in the plant.

Many types of cells from other plant species show similar behavior in the laboratory. This ability to generate a whole plant from a single cell has been invaluable in agriculture and forestry. For example, trees from planted forests are used in making paper, lumber, and other products. To replace the trees reliably, forestry companies regenerate new trees from the leaves of selected trees with desirable traits. The characteristics of these clones are more uniform and predictable than those of trees grown from seeds.

NUCLEAR TOTIPOTENCY IN ANIMALS Animal somatic cells cannot be manipulated as easily as plant cells can. Until recently, it was not possible to induce a cell from a fully developed animal to dedifferentiate and then redifferentiate into another cell type. However, nuclear transfer experiments have shown that the genetic information from an animal cell can be used to create cloned animals. The nucleus from an unfertilized egg is removed, forming an *enucleated* egg. A donor nucleus from a differentiated cell

FIGURE 14.2 A Cell's Fate Is Determined in the Embryo Transplantation experiments using frog embryos show that the fate of cells is determined as the embryo develops.

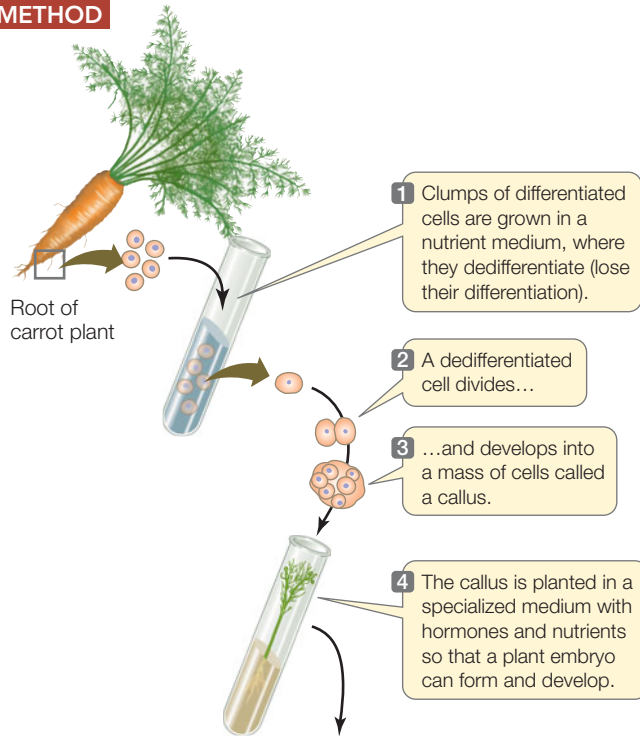

INVESTIGATION

FIGURE 14.3 Cloning a Plant When cells were removed from a plant and put into a medium with nutrients and hormones, they lost many of their specialized features—in other words, they dedifferentiated and became totipotent.

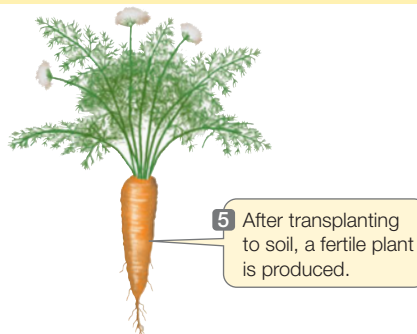

HYPOTHESIS

Differentiated plant cells can be totipotent and can be induced to generate all types of the plant's cells.

METHOD

RESULTS

CONCLUSION

Differentiated plant cells can be totipotent.

is then introduced into the “empty” egg. If it is then stimulated to divide, the egg forms an embryo and adult with the genetic composition of its nuclear donor. This is the basis of cloning animals such as Dolly, the landmark sheep born in 1996 as the first experimentally produced mammalian clone (FIGURE 14.4).

Many other animal species, including cats, dogs, horses, pigs, rabbits, and mice, have since been cloned by nuclear transfer. As in plants, the cloning of animals has shown that their differentiated cells have genomic equivalence. Cloning of animals has practical uses as well:

- *Expansion of the numbers of valuable animals:* One goal of the experiments that resulted in Dolly the sheep was to develop a method of cloning transgenic animals carrying genes with therapeutic properties (see Concept 13.4). For example, a cow that was genetically engineered to make human growth hormone in milk has been cloned to produce two more cows that do the same thing. Only 15 such cows would supply the world’s need for this medication, which is used to treat short stature due to growth hormone deficiency.
- *Preservation of endangered species:* The banteng, a relative of the cow, was the first endangered animal to be cloned, using a cow enucleated egg, the nucleus from a banteng cell, and a cow surrogate mother. Cloning may be the only way to save endangered species with low rates of natural reproduction, such as the Sumatran tiger.
- *Preservation of pets:* Many people get great personal benefit from pets, and the death of a pet can be devastating. Companies have been set up to clone cats and dogs from cells provided by their owners. Of course, the behavioral characteristics of the beloved pet, which were certainly determined in part from the environment, may not be the same in the cloned pet as in its genetic parent.

FRONTIERS Most male cattle are castrated as calves (they are referred to as steers) to improve the color and texture of their meat. Some steers may grow up to have superior phenotypes, and a cattle breeder may want to use such a steer for breeding purposes. Unfortunately, the steer is sterile. Cloning can produce a fertile animal, thereby “reversing” castration.

Stem cells differentiate in response to environmental signals

The embryo is not the only time and place where the processes of development occur. In adult plants, the growing regions at the tips of roots and stems contain *meristems*, which are clusters of undifferentiated, rapidly dividing *stem cells*. These cells can differentiate into the 15–20 specialized cell types that make up roots, stems, leaves, and flowers. As you will see in Chapter 26, the plant body undergoes constant growth and renewal, with new organs forming often. (Think of leaves in the spring and flowers.)

In adult mammals, stem cells occur in virtually all tissues, where they are used as a pool of cells that can differentiate and replace cells that are lost by “wear and tear” (necrosis) and programmed cell death (apoptosis). This is especially evident in tissues such as the skin, inner lining of the intestine, and blood. There are about 300 different cell types in a mammal.

INVESTIGATION

FIGURE 14.4 Cloning a Mammal The experimental procedure described here produced the first cloned mammal, a Dorset sheep named Dolly (shown on the left in the photo). As an adult, Dolly

mated and subsequently gave birth to a normal offspring (the lamb on the right), thus proving the genetic viability of cloned mammals.

ANALYZE THE DATA

The team that cloned Dolly the sheep used a nucleus from a mammary epithelium (ME) cell. They also tried cloning by transplanting nuclei from fetal fibroblasts (FB) and embryos (EC), with these results:

Stage	Number of attempts that progressed to each stage		
	ME	FB	EC
Egg fusions	277	172	385
Embryos transferred to recipients	29	34	72
Pregnancies	1	4	14
Live lambs	1	2	4

- Calculate the percentage survival of eggs from fusion to birth. What can you conclude about the efficiency of cloning?
- Compare the efficiencies of cloning using different nuclear donors. What can you conclude about the ability of nuclei at different stages to be totipotent?
- What statistical test would you use to show whether the differences in A and B were significant (see Appendix B)?

MULTIPOTENT STEM CELLS Stem cells in particular mammalian tissues are **multipotent**, meaning they can form a limited repertoire of differentiated cells. For example, there are two types of multipotent stem cells in bone marrow. One type (called *hematopoietic stem cells*) produces the various kinds of red and

white blood cells, whereas the other type (*mesenchymal stem cells*) produces the cells that make bone and surrounding tissues, such as muscle.

The differentiation of multipotent stem cells is “on demand.” The blood cells that differentiate in the bone marrow do so in

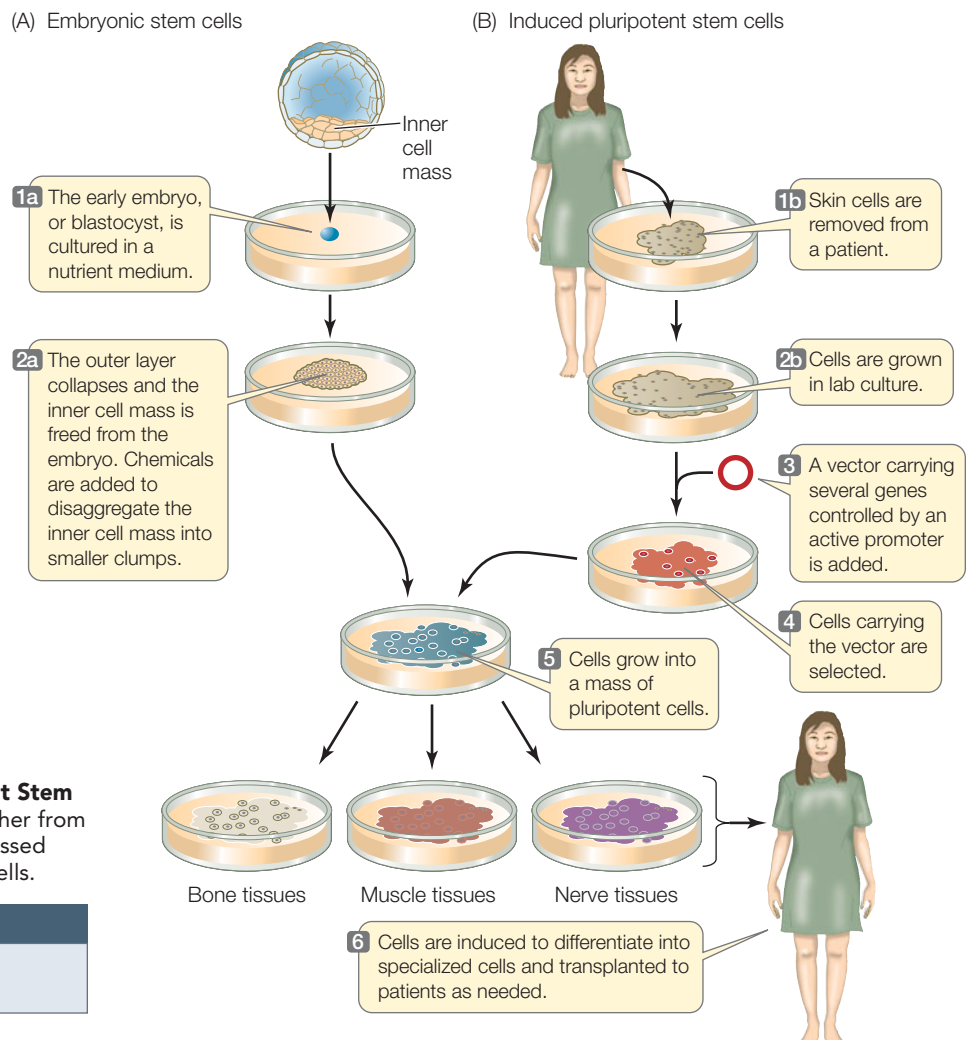

FIGURE 14.5 Multipotent Stem Cells In hematopoietic stem cell transplantation, blood stem cells are used to replace stem cells destroyed by cancer therapy.

response to specific signals. These can be from adjacent cells (as in the repairing tendon of Greg’s Gold) or from the circulation (as in the differentiation of bone marrow stem cells to form blood cells). This is the basis of an important cancer therapy called *hematopoietic stem cell transplantation* (HSCT; **FIGURE 14.5**). Because some treatments that kill cancer cells also kill other dividing cells, bone marrow stem cells in patients will die if exposed to these treatments. To circumvent this problem, stem cells are removed from the patient’s blood before treatments begin, and are given signals to increase their numbers in the laboratory. The cells are stored during treatment, and then added back to populate the depleted bone marrow when treatment is over. The stored stem cells retain their ability to differentiate in the bone marrow environment. By allowing the use of high doses of treatment to kill tumors, bone marrow transplantation saves thousands of lives each year.

FIGURE 14.6 Two Ways to Obtain Pluripotent Stem Cells Pluripotent stem cells can be obtained either from (A) human embryos or (B) by adding highly expressed genes to skin cells to transform them into stem cells.

PLURIPOTENT STEM CELLS In mammals, totipotent stem cells that can individually give rise to an organism are found only in very early embryos. In both mice and humans, the earliest embryonic stage before differentiation occurs is called a *blastocyst* (the term for a mammalian blastula; see Figures 14.1 and 33.4). Although they cannot form an entire embryo, a group of cells in the blastocyst still retains the ability to form all of the cells in the body; these cells are **pluripotent**. These **embryonic stem cells (ESCs)** can be removed from the blastocyst and grown in laboratory culture almost indefinitely if provided with the right conditions. They can also be induced to express appropriate genes and differentiate in a particular way if the right signal is provided (**FIGURE 14.6A**). For example, treatment of mouse ESCs with a derivative of vitamin A causes them to form neurons (nerve cells), while other growth factors induce them to form blood cells. Such experiments demonstrate both the cells’

yourBioPortal.com

Embryonic Stem Cells

developmental potential and the roles of environmental signals. This finding raises the possibility of using ESC cultures as sources of differentiated cells to repair specific tissues, such as a damaged pancreas in diabetes, or a brain that malfunctions in Parkinson's disease.

ESCs can be harvested from human embryos conceived by in vitro ("under glass"—in the laboratory) fertilization, with the consent of the donors. Since more than one embryo is usually conceived in this procedure, embryos not used for reproduction might be available for embryonic stem cell isolation. These cells could then be grown in the laboratory and used as sources of tissues for transplantation into patients with tissue damage. There are two problems with this approach:

- Some people object to the destruction of human embryos for this purpose.
- The stem cells, and tissues derived from them, would provoke an immune response in a recipient (see Chapter 31).

Shinya Yamanaka and coworkers at Kyoto University in Japan and the Gladstone Institute, San Francisco, have developed another way to produce pluripotent stem cells that uses the concepts of gene expression and development (**FIGURE 14.6B**). Instead of extracting ESCs from blastocysts, they make **induced pluripotent stem cells (iPS cells)** from skin cells. They developed this method systematically (see Chapter 13 for more information on the techniques discussed here):

1. First, they used microarrays to compare the genes expressed in ESCs with nonstem cells. They found several genes that were uniquely expressed at high levels in ESCs. These genes were believed to be essential to the undifferentiated state and function of stem cells.
2. Next, they isolated the genes and inserted them into a vector for genetic transformation of skin cells. They found that the skin cells now expressed the newly added genes at high levels.
3. Finally, they showed that the transformed cells were pluripotent and could be induced to differentiate into many tissues—they had become iPS cells.

Because iPS cells can be made from skin cells of the individual who is to be treated, an immune response may be avoided. Such cells have already been used for cell therapy in animals for diseases similar to human Parkinson's disease (a brain disorder), diabetes, and sickle-cell anemia. Human uses are sure to follow.

Do You Understand Concept 14.1?

- Describe the four major processes of development and, using Figure 14.1, describe when these processes occur in plant and animal development.
- Not all the DNA in a cell is in the nucleus. What are the genetic differences between cloning in carrot plants and cloning in sheep? How would you show this?
- Identical twins are formed when a zygote divides once by mitosis and then each mitotic product forms an embryo. Are identical twins clones? Explain your answer.

Having considered the general principles of development, we now turn to the mechanisms that govern developmental events. Not surprisingly, these mechanisms have been studied at the molecular level and involve changes in gene expression and the activities of specific proteins.

concept 14.2 Changes in Gene Expression Underlie Cell Differentiation in Development

Every cell of an individual organism contains all the genes needed to produce every protein encoded by the organism's genome. Each cell, however, expresses only a subset of these genes; the identity of these genes and the processes by which they are activated form the basis of cell determination and differentiation. For example, certain cells in hair follicles produce keratin, the protein that makes up hair, while other cell types in the body do not. What determines whether a cell will produce keratin? Chapter 11 describes a number of ways in which cells regulate gene expression and protein production—by controlling transcription, translation, and posttranslational protein modifications. The mechanisms that control gene expression resulting in cell differentiation generally work at the level of transcription. So in the case of keratin, skin cells produce keratin mRNA, but other cells, such as liver cells, do not.

Differential gene transcription is a hallmark of cell differentiation

What leads to this differential gene expression? One well-studied example of cell differentiation is the conversion of undifferentiated muscle precursor cells into cells that are destined to form muscle (**FIGURE 14.7**). In the vertebrate embryo, muscle precursor cells come from a tissue layer called the *mesoderm* (see Concept 33.3), and they are multipotent. A key event in the commitment of these cells to become muscle is that they stop dividing. Indeed, in many parts of the embryo, *cell division and cell differentiation are mutually exclusive*. Cell signaling activates the gene for a transcription factor called **MyoD** (*myoblast-determining gene*). Recall that transcription factors are DNA binding proteins that regulate the expression of specific genes. In this case, MyoD activates the gene for p21, an inhibitor of cyclin-dependent kinases (Cdk's) that normally stimulate the cell cycle at G1 (see Figure 7.10). Expression of the *p21* gene causes the cell cycle to stop, and other transcription factors then enter the picture so that differentiation into myoblasts (muscle precursor cells) can begin.

Genes such as *myoD* that direct the most fundamental decisions in development (often by regulating the expression of other genes on other chromosomes) usually encode transcription factors. In some cases, a single transcription factor can cause a cell to differentiate in a certain way. In other cases, complex interactions between genes and proteins determine a sequence of transcriptional events that leads to differential

FIGURE 14.7 Transcription and Differentiation in the Formation of Muscle Cells Activation of a transcription factor, MyoD, is important in muscle cell differentiation.

gene expression. There are two ways a cell can be made to transcribe a different set of genes than another cell:

- by asymmetrical distribution of a cytoplasmic factor inside the cell so that its two progeny cells receive unequal amounts of the factor
- by differential exposure of the two cells to an external inducer

Gene expression can be regulated by cytoplasmic polarity

An early event in development is often the establishment of axes that relate to the body plan of the organism. For example, an embryo may develop a distinct “top” and “bottom” corresponding to what will become opposite ends of the mature organism; such a difference is called **polarity**. Many examples of polarity are observed as development proceeds. Our heads are distinct from our rear ends, and the distal (far from the center) ends of our arms and legs (wrists, ankles, fingers, toes) differ from the proximal (near) ends (shoulders and hips).

Polarity may develop early; even within the egg, the yolk and other factors are often distributed asymmetrically. During early development in animals, polarity is specified by an *animal pole* at the top of the zygote and a *vegetal pole* at the bottom. This

polarity can lead to determination of cell fates at a very early stage of development. For example, sea urchin embryos can be bisected at the eight-cell stage in two different ways:

If the two halves (with four cells each) of these embryos are allowed to develop, the results are dramatically different for the two different cuts:

- For an embryo cut into a top half and a bottom half (left, above), the bottom half develops into a small sea urchin and the top half does not develop at all.
- For an embryo cut into two side halves (right, above), both halves develop normally, though smaller.

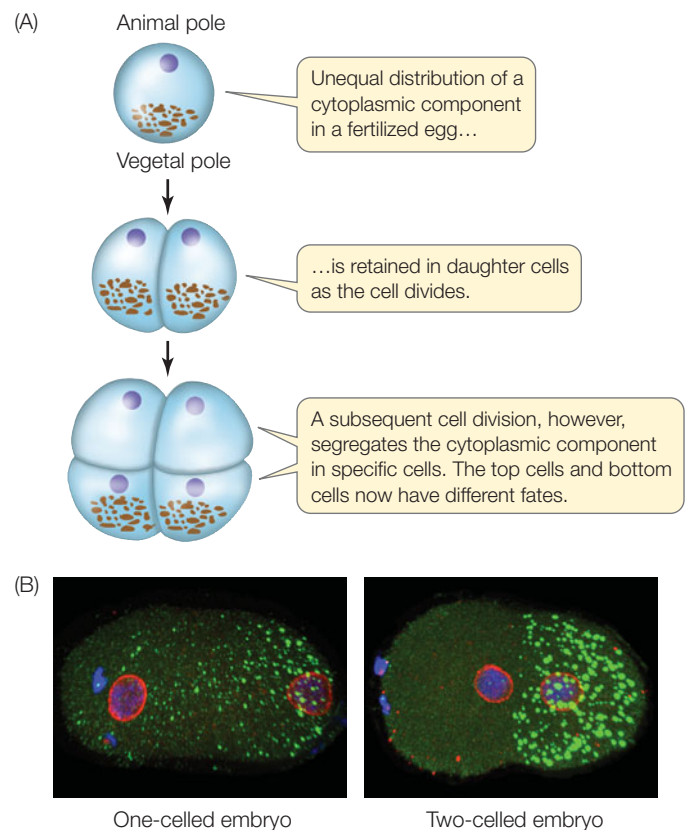

FIGURE 14.8 The Concept of Cytoplasmic Segregation

(A) The unequal distribution of some component in the cytoplasm of a cell may determine the fates of its descendants. (B) The zygote of the nematode worm (left) shows an asymmetrical distribution of cytoplasmic particles (stained green). The progeny of the first cell division (right) receive unequal amounts of the particles.

yourBioPortal.com

Go to ANIMATED TUTORIAL 14.2
Early Asymmetry in the Embryo

In sum, the top and bottom halves of an eight-cell sea urchin embryo have already developed distinct fates. These observations led to the model of **cytoplasmic segregation** shown in **FIGURE 14.8A**. This model states that certain materials, called **cytoplasmic determinants**, are distributed unequally in the egg cytoplasm. During the early cell divisions of the embryo's development, the progeny cells receive unequal amounts of these determinants. The amount of determinant received determines each cell's fate and its pattern of gene expression.

Cytoplasmic determinants play roles in directing the embryonic development of many organisms. What is the chemical nature of these determinants, and how is their asymmetrical distribution established? It turns out that the cytoskeleton contributes to the asymmetrical distribution of these determinants in the egg. Recall from Concept 4.4 that an important function of the microtubules and microfilaments in the cytoskeleton is to help move materials in the cell. Two properties allow these structures to accomplish this:

- Microtubules and microfilaments have polarity—they grow by adding subunits to the plus end.
- Cytoskeletal elements can bind specific proteins, which can be used in the transport of mRNA.

For example, in the sea urchin egg, a protein binds to both the growing (+) end of a microfilament and to an mRNA encoding a cytoplasmic determinant. As the microfilament grows toward one end of the cell, it carries the mRNA along with it. The asymmetrical distribution of the mRNA leads to asymmetrical distribution of the protein it encodes, a regulator of gene transcription. A similar process is also seen in other organisms (**FIGURE 14.8B**). So what biologists once called unspecified "cytoplasmic determinants" can now be defined in terms of cellular structures, mRNAs, and proteins.

Inducers passing from one cell to another can determine cell fates

The second way that embryos stimulate differential gene transcription is by **induction**, exemplified here by vulval development in the model organism *Caenorhabditis elegans* (**FIGURE 14.9**). The term "induction" has different meanings in different contexts. In biology it can be used broadly to refer to the initiation of, or cause of, a change or process.

FIGURE 14.9 Induction during Vulval Development in *Caenorhabditis elegans* (A) In the nematode *C. elegans*, it has been possible to follow all of the cell divisions from the fertilized egg to the 959 cells found in the fully developed adult. (B) During vulval development, a molecule secreted by the anchor cell (the LIN-3 protein) acts as the primary inducer. The primary precursor cell (the one that received the highest concentration of LIN-3) then secretes a secondary inducer (the lateral signal) that acts on its neighbors. The gene expression patterns triggered by these molecular switches determine cell fates.

But in the context of cellular differentiation, it refers to the signaling events by which cells in a developing embryo communicate and influence one another's developmental fate. Induction involves chemical signals and signal transduction mechanisms (see Concepts 5.5 and 5.6). Exposure to different amounts of such inductive signals can lead to differences in gene expression among cells in a developing organism.

The nematode worm *Caenorhabditis elegans*, whose genome was one of the first eukaryotic genomes to be sequenced (see Chapter 12), develops from fertilized egg to larva in only about 8 hours and reaches the adult stage in just 3.5 days. The process is easily observed using a low-magnification dissecting microscope because the body covering is transparent (see Figure 14.9A). To illustrate the principles of induction, we focus here on the development of one part of the *C. elegans* body: the vulva.

The adult nematode is *hermaphroditic*, containing both male and female reproductive organs. It lays eggs through a pore called the *vulva* on the ventral (lower) surface of the worm. During development, a single cell, called the *anchor cell*, induces the vulva to form from six cells on the worm's ventral surface. In this case, there are two molecular signals, the *primary inducer* and the *secondary inducer*. Each of the six ventral cells has three

possible fates: it may become a primary vulval precursor cell, a secondary vulval precursor cell, or simply become part of the worm's skin—an epidermal cell. You can follow the sequence of events in Figure 14.9B. The concentration gradient of the primary inducer, LIN-3, is key: the anchor cell produces LIN-3, which diffuses out of the cell and forms a concentration gradient with respect to adjacent cells. The three cells that are closest to the anchor cell receive the most LIN-3 and become vulval precursor cells; cells slightly farther from the anchor cell receive less LIN-3 and become epidermal cells. A second induction event results in the two classes of vulval precursor cells: primary and secondary. Induction involves the activation or inactivation of specific sets of genes through signal transduction cascades in the responding cells (FIGURE 14.10).

LINK For more on signal transduction cascades, see Concepts 5.5 and 5.6

This example from nematode development illustrates an important observation: *much of development is controlled by molecular switches that allow a cell to proceed down one of two alternative tracks*. One challenge for developmental biologists is to find these switches and determine how they work. The primary inducer, LIN-3, released by the *C. elegans* anchor cell is a growth factor that is orthologous (evolutionarily related) to a vertebrate growth factor called EGF (*epidermal growth factor*). LIN-3 binds to a receptor on the surfaces of vulval precursor cells, setting in motion a signal transduction cascade that results in increased transcription of the genes involved in the differentiation of vulval cells.

Do You Understand Concept 14.2?

- What would be the effect of injecting an inhibitor of microtubule polymerization into the fertilized eggs of a sea urchin embryo?
- Compare the internal and external stimuli that lead to differential gene expression in embryonic cells.
- What would be the consequences of a homozygous deletion mutation for *lin-3*?

Cytoplasmic polarity and inducers alter the expression of genes that determine cell fate. We will now see that the expression of genes also results in the next phase of development, the formation of tissues and organs in morphogenesis.

FIGURE 14.10 The Concept of Embryonic Induction The concentration of an inducer directly affects the degree to which a transcription factor is activated. The inducer acts by binding to a receptor on the target cell. This binding is followed by signal transduction involving transcription factor activation or translocation from the cytoplasm to the nucleus. In the nucleus, the transcription factor acts to stimulate the expression of genes involved in cell differentiation.

concept 14.3 Spatial Differences in Gene Expression Lead to Morphogenesis

Pattern formation is the developmental process that results in the spatial organization of a tissue or organism. It is inextricably linked to morphogenesis, the creation of body form. Underlying both of these processes are spatial differences in gene expression, which determine whether, for example, a particular piece of tissue will become a leg or a wing or a flower petal. These spatial differences in gene expression, in turn, depend on two cellular processes:

- The cells in the tissue must “know” where they are in relation to rest of the body.
- The cells must activate the pattern of gene expression that is appropriate for their location.

In the sections that follow, we will explore the mechanisms used by various organisms to direct pattern formation and morphogenesis.

Multiple genes interact to determine developmental programmed cell death

You might expect morphogenesis to involve a lot of cell division, followed by differentiation—and it does. But what you might not expect is the amount of programmed cell death—apoptosis—that occurs during morphogenesis. For example, in an early human embryo, the hands and feet look like tiny paddles: the tissues that will become fingers and toes are linked by connective tissue. Between days 41 and 56 of development, the cells between the digits die, freeing the individual fingers and toes:

Many cells and structures form and then disappear during development, in processes involving apoptosis.

LINK Concept 7.5 describes some of the cellular events of apoptosis

Model organisms have been very useful in studying the genes involved in apoptosis. For example, the nematode worm *C. elegans* produces precisely 1,090 somatic cells as it develops from a fertilized egg into an adult, but 131 of those cells die (leaving 959 cells in the adult worm). The sequential expression of two genes called *ced-4* and *ced-3* (for *cell death*) is essential to this programmed cell death. The CED-3 protein is a caspase (a protease involved in apoptosis) that turns out to be similar to

the caspase protein encoded by an orthologous gene in humans. Several other genes involved in the nematode apoptosis pathway (including *ced-4*) also have relatives in humans. So humans and nematodes, two species separated by more than 600 million years of evolutionary history, have similar genes controlling programmed cell death. The commonality of this pathway indicates its importance: mutations are harmful and evolution selects against them. We will return to other examples of links between evolution and development in Concept 14.4.

Our example of apoptosis in the development of fingers and toes shows one of the many ways that the behavior of cells can give rise to body form during development. It also illustrates the two cellular processes underlying pattern formation: only cells in a particular place (between the digits) activate a specific pattern of gene expression (to trigger apoptosis).

FRONTIERS The genes that control apoptosis in the worm have orthologs in humans. One of them, *BCL2*, prevents apoptosis. In a type of human cancer called follicular lymphoma, a chromosome translocation occurs in white blood cells such that the *BCL2* gene is next to a highly active promoter. The resulting high levels of BCL2 protein prevent the apoptosis that normally occurs in the white blood cells, and cancer results. Drugs that prevent expression of *BCL2* result in apoptosis of the tumor cells and shrinkage of the tumor. These drugs are being tested for other cancers as well.

Expression of transcription factor genes determines organ placement in plants

Like animals, plants have organs—for example, leaves and roots. Many plants form flowers, and many flowers are composed of four types of organs: sepals, petals, stamens (male reproductive organs), and carpels (female reproductive organs). These floral organs occur in concentric *whorls* (rings), with groups of each organ type encircling a central axis. The sepals are on the outside and the carpels are on the inside (**FIGURE 14.11A**).

In the model plant *Arabidopsis thaliana* (thale cress), the whorls develop from a meristem of about 700 undifferentiated cells arranged in a dome, which is at the growing point on the stem. A group of genes called **organ identity genes** encode proteins that act in combination to produce specific whorl features (**FIGURE 14.11B,C**):

- Genes in class A are expressed in whorls 1 and 2 (which form sepals and petals, respectively).
- Genes in class B are expressed in whorls 2 and 3 (which form petals and stamens).
- Genes in class C are expressed in whorls 3 and 4 (which form stamens and carpels).

Genes in classes A, B, and C code for transcription factors (see Concept 11.3) that are active as dimers, that is, proteins with two polypeptide subunits (see Figure 14.11B). Gene regulation in these cases is *combinatorial*—that is, the composition of the dimer depends on the location of the cell and determines which

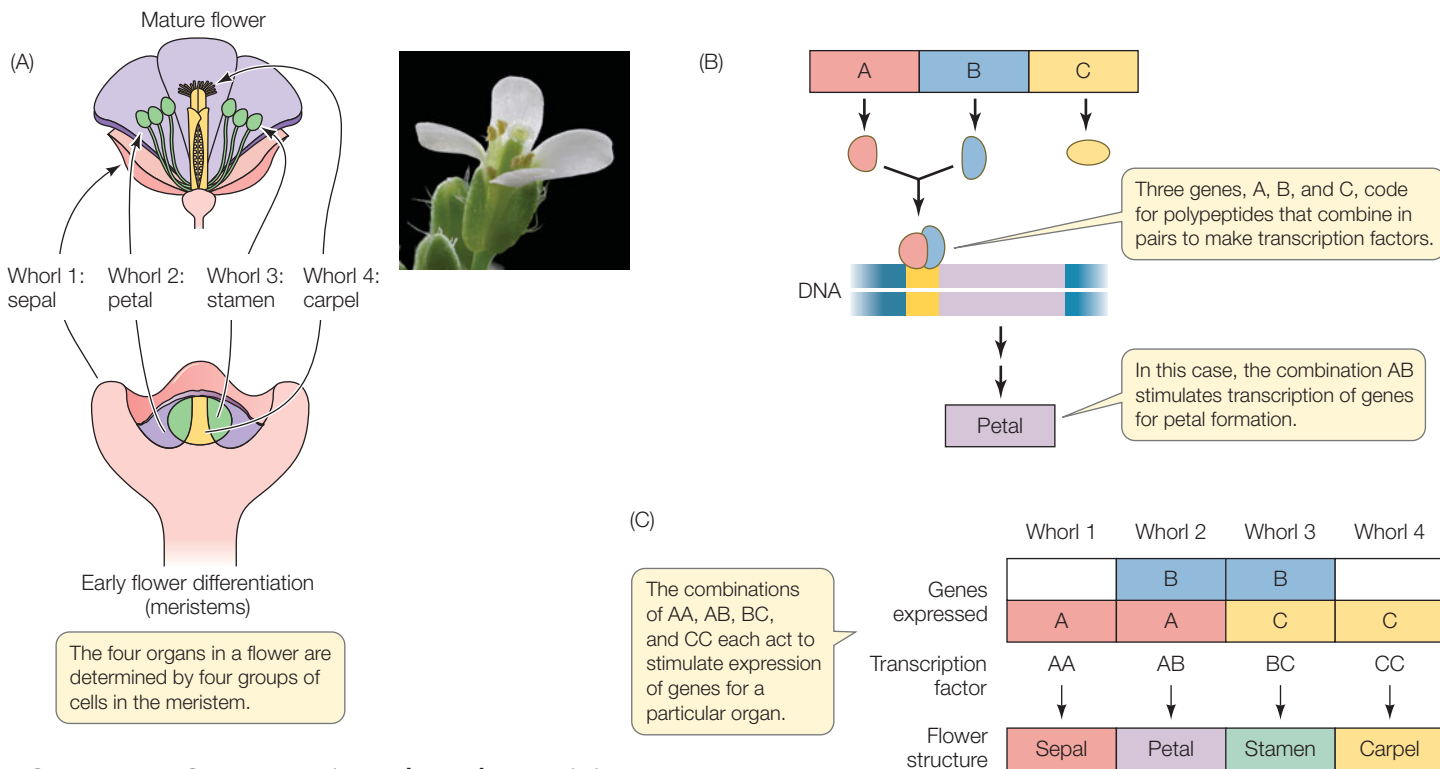

FIGURE 14.11 Gene Expression and Morphogenesis in Arabidopsis Flowers (A) The four organs of a flower—carpels (yellow), stamens (green), petals (purple), and sepals (pink)—grow in whorls that develop from the floral meristem. (B) Floral organs are determined by three genes whose polypeptide products combine in pairs to form transcription factors. (C) Combinations of polypeptide subunits in transcription factors activate gene expression for specific organs.

genes will be activated. For example, a dimer made up of two class A monomers, which is found only in cells in whorl 1, activates transcription of the genes that make sepals; a dimer made up of A and B monomers results in petals, and so forth.

Two lines of experimental evidence support this model of organ identity gene function:

- **Loss-of-function mutations:** for example, a mutation in a class A gene results in no sepals or petals. Instead, carpels and stamens form in their place. In any organism, the replacement of one organ for another is called *homeosis*, and this type of mutation is a **homeotic mutation**.
- **Gain-of-function mutations:** for example, a promoter for a class C gene can be artificially coupled to a class A gene that is then placed in a transgenic plant. In this case, class A genes are expressed in all four whorls (in the first two whorls from their natural promoters, and in the second two whorls from the class C gene promoter), resulting in only sepals and petals.

Transcription of the floral organ identity genes is controlled by other gene products, including the LEAFY protein, which is a transcription factor that stimulates the expression of the class A, B, and C genes. This finding has practical applications. It usually takes 6–20 years for a citrus tree to produce flowers and fruits. Scientists have made transgenic orange trees expressing the LEAFY gene coupled to a strongly expressed promoter. These trees flower and fruit years earlier than normal trees.

Morphogen gradients provide positional information during development

During development, the key cellular question “What am I (or what will I be)?” is often answered in part by “Where am I?” Think of the cells in the developing nematode, which develop into different parts of the vulva depending on their positions relative to the anchor cell. The same is true for the cells between the digits of a developing hand and in different whorls of a developing flower. This spatial “sense” is called **positional information**.

Positional information often comes in the form of an inducer called a **morphogen**, which diffuses from one group of cells to surrounding cells, setting up a concentration gradient. There are two requirements for a signal to be considered a morphogen:

- It must specifically affect target cells.
- Different concentrations of the signal must cause different effects.

Developmental biologist Lewis Wolpert uses the “French flag model” to explain the action of morphogens (**FIGURE 14.12A**). This model can be applied to the differentiation of the vulva in *C. elegans* (see Figure 14.9), which relies on a gradient of LIN-3. Another example can be seen in the development of vertebrate limbs.

As we described earlier for humans, the vertebrate limb develops from a paddle-shaped *limb bud* (**FIGURE 14.12B**). The cells that develop into different digits must receive positional information; if they do not, the limb will not be organized properly (imagine a hand with only thumbs or only little fingers). How do the cells know where they are? A group of cells at the posterior base of the limb bud, just where it joins the

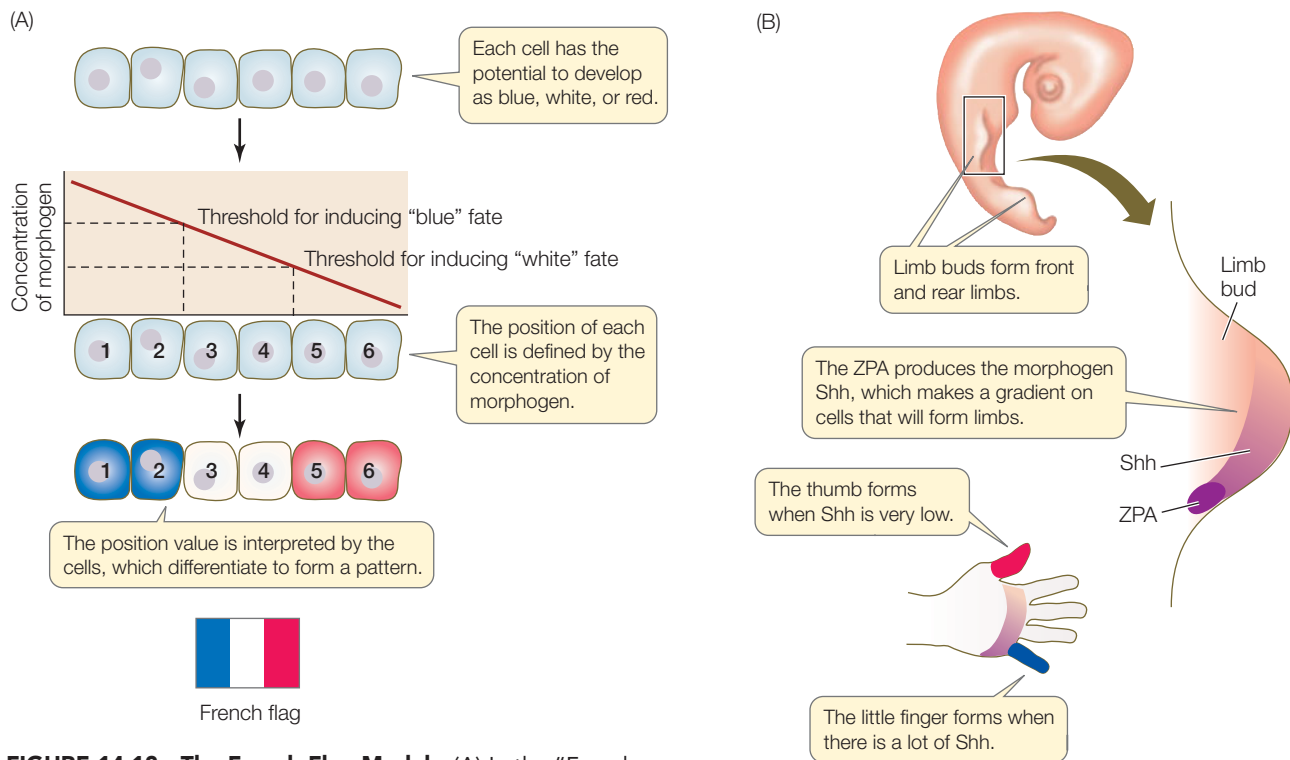

FIGURE 14.12 The French Flag Model (A) In the “French flag” model, a concentration gradient of a diffusible morphogen signals each cell to specify its position. (B) The zone of polarizing activity (ZPA) in the limb bud of the embryo secretes the morphogen Sonic hedgehog (Shh). Cells in the bud form different digits depending on the concentration of Shh.

body wall, is called the *zone of polarizing activity* (ZPA). The cells of the ZPA secrete a morphogen called *Sonic hedgehog* (Shh), which forms a gradient that determines the posterior–anterior (little finger to thumb) axis of the developing limb. The cells getting the highest dose of Shh form the little finger; those getting the lowest dose develop into the thumb. Recall the French flag model when considering the gradient of Shh.

A cascade of transcription factors establishes body segmentation in the fruit fly

A major achievement in studies of developmental biology has been the ever-advancing description of how morphogens act in another model organism, the fruit fly *Drosophila melanogaster*.

As you will see in Concept 14.4, the molecular events that underlie fruit fly development turn out to be similar to events that occur in many other organisms, including ourselves. So they merit examination in some detail.

The insect body is made up of *segments* that differ from one another. The adult fly has an anterior *head* (composed of several fused segments), three different *thoracic* segments, and eight *abdominal* segments at the posterior end. Each segment gives rise to different body parts: for example, antennae and eyes develop from head segments, wings from the thorax, and so on.

The life cycle of *Drosophila* from fertilized egg to adult takes about 2 weeks. The egg hatches into a larva, which then forms a pupa, which finally is transformed into the adult fly. By the time a larva appears—about 24 hours after fertilization—there are recognizable segments. The thoracic and abdominal segments all look similar, but *the fates of the cells to become different adult segments are already determined*.

As with other organisms, fertilization in *Drosophila* leads to a rapid series of mitoses. However, until the 13th division cycle,

APPLY THE CONCEPT

Spatial differences in gene expression lead to morphogenesis

Molecular biologists can attach genes to active promoters and insert them into cells. This results in higher than normal expression (overexpression) of the gene. What would happen if the genes listed at right were inserted and overexpressed? Explain your answers.

1. *ced-3* in embryonic neuron precursors of *C. elegans*
2. *myoD* in undifferentiated myoblasts
3. *Sonic hedgehog* in a chick limb bud
4. *LEAFY* in a leaf bud meristem of *Arabidopsis*

these mitoses are not accompanied by cytokinesis. So instead of a multicellular embryo, there is a *multinucleate embryo* (the nuclei are brightly stained in the micrographs below):

This is an important property, as it allows for relatively easy diffusion of morphogens from one part of the embryo to another (because there are no cell membranes to cross). As you will see, many of these morphogens end up affecting transcription in the nuclei. The determination events in the first 24 hours will be our focus here.

Experimental genetics was used to elucidate these events in *Drosophila*:

- First, developmental mutations were identified. For example, a mutant strain might produce larvae with two heads or no segments.
- Second, each mutant was compared with wild-type flies, and the gene responsible for the developmental mistake, and its protein product (if appropriate), was isolated.
- Finally, experiments with the gene (making transgenic flies) and protein (injecting the protein into an egg or embryo) were done to confirm the proposed developmental pathway.

Together, these approaches revealed a sequential pattern (cascade) of gene expression that results in the determination of each segment within 24 hours after fertilization. Several classes of genes are involved:

- *Maternal effect genes*, which set up the major axes (anterior–posterior and dorsal–ventral) of the egg
- *Segmentation genes*, which determine the boundaries and polarity of each of the segments
- *Hox genes*, which determine what organ will be made at a given location

MATERNAL EFFECT GENES Like the eggs and early embryos of many other organisms (see Figure 14.8), *Drosophila* eggs and larvae are characterized by unevenly distributed cytoplasmic determinants. These molecular determinants, which include both mRNAs and proteins, are the products of specific **maternal effect genes**. These genes are transcribed in the cells of the mother’s ovary that surround what will be the anterior portion of the egg. The transcription products are passed to the egg by cytoplasmic bridges. Two maternal effect genes, called *bicoid* and *nanos*, help determine the anterior–posterior axis of the egg. (The dorsal–ventral, or back–belly, axis is determined by other maternal effect genes that will not be described here.)

The mRNAs for *bicoid* and *nanos* diffuse from the mother’s cells into what will be the anterior end of the egg. The *bicoid* mRNA is translated to produce Bicoid protein, which diffuses away from the anterior end, establishing a concentration gradient in the egg cytoplasm:

At this point, the egg is in its multinucleate stage.

Where it is present in sufficient concentration, Bicoid acts as a transcription factor to stimulate the transcription of the *hunchback* gene in the early embryo. Consequently, the nuclei nearest the anterior end are most active in the transcription of the *hunchback* gene, and the resulting gradient of Hunchback protein (itself a transcription factor) establishes the head, or anterior, region.

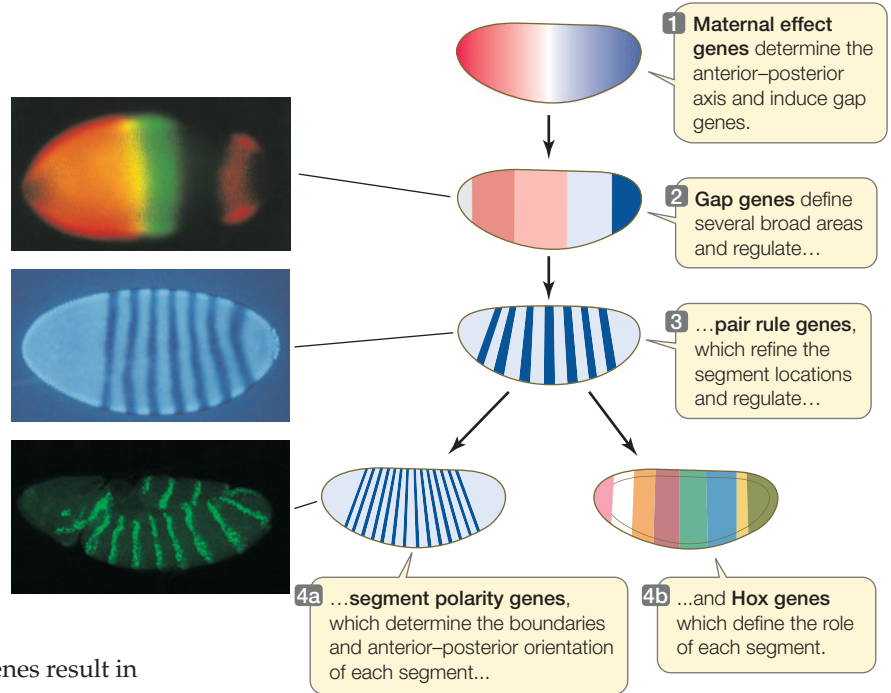

Meanwhile, the egg’s cytoskeleton transports the *nanos* mRNA from the anterior end of the egg, where it was deposited by the maternal cells, to the posterior end, where it is translated. This results in a gradient of the Nanos protein, with the highest concentration at the posterior end. At that end, the Nanos protein inhibits the translation of *hunchback* mRNA, preventing accumulation of Hunchback protein. Thus, the actions of both Bicoid and Nanos establish a Hunchback protein gradient, which determines the anterior and posterior ends of the embryo by influencing the gene expression patterns of the nuclei along the gradient.

The events involving *bicoid*, *nanos*, and *hunchback* begin before fertilization and continue after it, during the multinucleate stage, which lasts a few hours. At this stage, the embryo looks like a bunch of indistinguishable nuclei under the light microscope. But the fates of the individual nuclei and the cells they will occupy have already begun to be determined. After the anterior and posterior ends have been established, the next step in pattern formation in fruit flies is the determination of segment number and locations.

SEGMENTATION GENES The number, boundaries, and polarity of the *Drosophila* larval segments are determined by proteins encoded by the **segmentation genes**. These genes are expressed when there are about 6,000 nuclei in the embryo (about 3 hours after fertilization). Three classes of segmentation genes act one after the other to regulate finer and finer

FIGURE 14.13 A Gene Cascade Controls Pattern Formation in the *Drosophila* Embryo

Maternal effect genes induce gap, pair rule, and segment polarity genes—collectively referred to as segmentation genes. By the end of this cascade, a group of nuclei at the anterior of the embryo, for example, is determined to become the first head segment in the adult fly. In the micrographs at left various staining methods have been used to highlight the different gene products.

details of the segmentation pattern (FIGURE 14.13):

- **Gap genes** organize broad areas along the anterior–posterior axis. Mutations in gap genes result in gaps in the body plan—the omission of several consecutive larval segments.
- **Pair rule genes** divide the embryo into units of two segments each. Mutations in pair rule genes result in embryos missing every other segment.
- **Segment polarity genes** determine the boundaries and anterior–posterior organization of the individual segments. Mutations in segment polarity genes can result in segments in which posterior structures are replaced by reversed (mirror-image) anterior structures.

By the end of this cascade, nuclei throughout the embryo “know” which segment they will be part of in the adult fly. The next set of genes in the cascade determines the form and function of each segment.

HOX GENES *Hox* genes encode a family of transcription factors that are expressed in different combinations along the length of the embryo, and help determine cell fates within each segment. *Hox* gene expression tells certain cells in a head segment to make eyes, other cells in a thorax segment to make wings, and so on. *Hox* genes are homeotic genes that are shared by all animals, and they are functionally similar to the organ identity genes of plants (see Figure 14.11).

How do we know that the *Hox* genes determine segment identity? A clue comes from homeotic mutations in *Drosophila*. A mutation in the *Hox* gene *Antennapedia* causes legs to grow on the head in place of antennae (FIGURE 14.14). When another *Hox* gene, *bithorax*, is mutated, an extra pair of wings grows in a thoracic segment where wings do not normally occur. So the normal (wild-type) functions of the *Hox* genes must be to “tell” a segment what organ to form. The *Antennapedia* and *bithorax* genes both encode transcription factors and have a common 180-bp sequence called the **homeobox** (from which *Hox* genes get their name). The homeobox encodes a 60-amino acid sequence called the *homeodomain*. The homeodomain

FIGURE 14.14 A Homeotic Mutation in *Drosophila* Mutations of the *Hox* genes cause body parts to form on inappropriate segments. (A) A wild-type fruit fly. (B) An *Antennapedia* mutant fruit fly. Mutations such as this reveal the normal role of the *Antennapedia* gene in determining segment function.

Pattern Formation in the *Drosophila* Embryo

recognizes and binds to a specific DNA sequence in the promoters of its target genes. As you will see in Concept 14.4, this domain is found in transcription factors that regulate development in many other animals with an anterior–posterior axis.

LINK To review mechanisms of transcriptional regulation, see Concept 11.3

Do You Understand Concept 14.3?

- Outline the steps that determine that a nucleus and cell in the developing *Drosophila* embryo will be part of an antenna.
- Compare the determination of organ identity in *Ara-bidopsis* and *Drosophila*.
- How does the “French flag” model apply to development of *Drosophila*?
- In the nematode nervous system, 302 neurons come from 405 precursors. How would you investigate the fate of the 103 “missing” cells? What gene(s) might be involved?

We have seen how positional information leads to changes in the expression of key developmental genes, which in turn control morphogenesis. It turns out that there are remarkable similarities in the genes used to guide development in diverse organisms, and this has led to a new way to look at the evolution of development.

concept 14.4 Gene Expression Pathways Underlie the Evolution of Development

The discovery of the genes that control the development of *Drosophila* provided biologists with tools to investigate the development of other organisms. For example, when scientists used homeobox DNA as a hybridization probe (see Figure 10.7) to search for similar genes elsewhere, they found that the homeobox is present in many genes in many other organisms. This, and other astounding discoveries that followed, showed a similarity in the molecular events underlying morphogenesis in organisms ranging from flies to fish to mammals. These results suggested that just as the forms of organisms evolved through descent with modification from a common ancestor, so did the molecular mechanisms that produce those forms. Biologists started to ask new questions about the interplay between evolutionary and developmental processes—a field of study called **evolutionary developmental biology (evo-devo)**. The major ideas of evo-devo are:

- Many groups of animals and plants, even distantly related ones, share similar molecular mechanisms for morphogenesis and pattern formation. These mechanisms can be thought of as “toolkits,” in the same sense that a few tools in a carpenter’s toolkit can be used to build many different structures.

- The molecular pathways that determine different developmental processes, such as anterior–posterior polarity and organ formation in animals, operate independently from one another. This is called **modularity**.
- Changes in the location and timing of expression of key genes are important in the evolution of new body forms and structures.
- Development produces morphology, and much of morphological evolution occurs by modifications of existing development genes and pathways, rather than the introduction of radically new developmental mechanisms.

Plant and Animal Development

Developmental genes in distantly related organisms are similar

Initially through hybridization with a homeobox probe, and then by genome sequencing and comparative genomics (see Concept 12.3), biologists have found that diverse animals share numerous molecular pathways that govern gene expression during development. For example, fruit fly homeotic genes such as *Antennapedia* and *bithorax* have mouse (and human) orthologs that are also developmental genes. Remarkably, these orthologous genes are arranged along a chromosome in both the fruit fly and mouse in the same order as they are expressed along the anterior–posterior axis of their embryos (**FIGURE 14.15**). This means that the positional information controlled by these genes has been conserved, even as the structures formed at each position have changed. Over the millions of years that have elapsed since these animals diverged from a common ancestor, the genes in question have mostly been maintained, suggesting that their functions were favored under many different conditions.

These and other examples have led biologists to the idea that certain developmental mechanisms, controlled by specific DNA sequences, have been conserved over long periods during the evolution of multicellular organisms. These sequences comprise a **genetic toolkit**, the contents of which have been modified and reshuffled over the course of evolution to produce the remarkable diversity of plants, animals, and other organisms in the world today.

Genetic switches govern how the genetic toolkit is used

The genetic toolkit is also used to generate diverse structures within a single organism. Different structures can evolve within a single organism using a common set of genetic instructions because there are mechanisms called **genetic switches** (also called molecular switches) that control how the genetic toolkit is used. These mechanisms involve promoters and the transcription factors that bind them, as well as enhancers and their associated proteins. The signal cascades that converge on and operate these switches determine when and where genes will

FIGURE 14.15 Regulatory Genes Show Similar Expression Patterns Orthologous genes encoding similar transcription factors are expressed in similar patterns along the anterior–posterior axes of both insects and vertebrates. Orthologous genes and the locations of their expression are indicated by shared colors. The mouse (and human) *Hox* genes are actually present in multiple copies; this prevents a single mutation from having drastic effects.

be turned on and off. Multiple switches control each gene by influencing its expression at different times and in different places. In this way, elements of the genetic toolkit can be involved in multiple developmental processes while still allowing individual modules to develop independently. You have seen several examples of this phenomenon in Concept 14.3. For example, the morphogenesis of flower organs is determined by combinations of transcription factors (the ABC model; see Figure 14.11) acting at specific times and locations.

Genetic switches translate positional information in the embryo into specific changes in gene expression. In this way, they play key roles in determining the developmental pathways of different modules. For example, each *Hox* gene codes for a transcription factor that is expressed in a particular segment or appendage of the developing fruit fly. The pattern formation and functioning of each segment depend on the unique *Hox* gene or combination of *Hox* genes that is expressed in the segment. Genetic switches determine when and where each *Hox* gene (each one a tool from the genetic toolkit) is expressed.

Consider the formation of fruit fly wings. *Drosophila* has three thoracic segments, the first of which bears no wings. The second segment bears the large forewings, and the third segment bears small hindwings, called *halteres*, that function as balancing organs. The *Hox* gene *Ultrabithorax* (*Ubx*) is not expressed in forewing cells, but hindwing cells express the *Ubx* gene because a set of genetic switches activates it in the third thoracic segment. The *Ubx* transcription factor turns off genes that promote the formation of the veins and other structures of the forewing, and it turns on genes that promote the formation of hindwing features (FIGURE 14.16).

This same genetic switch turns on different genes in butterflies, where instead of turning *off* wing-forming genes in the third thoracic segment as in fruit flies, *Ubx* turns them *on*, so that full hindwings develop. Therefore, a simple genetic change in the effect of *Ubx* on genes that promote wing development results in a major morphological difference in the wings of flies and butterflies. This phenomenon—the same switch having different effects on target genes in different species—is important in evolution.

FRONTIERS Signaling pathways involving transcription factors often regulate numerous pathways in an organism. *Sonic hedgehog* (*Shh*) is a gene in humans that is orthologous to the developmentally important *hedgehog* gene in fruit flies. In both organisms, the product is a secreted protein that activates a signaling pathway involved in several aspects of development. In humans, over-production of *Shh* occurs in basal cell carcinoma, a tumor that is a common form of skin cancer. Understanding the pathway activated by *Shh* may lead to better treatment of this tumor.

APPLY THE CONCEPT

Gene expression pathways underlie the evolution of development

Control of eye formation during development of many animals is under the control of a genetic switch involving a transcription factor. Here are partial DNA sequences for the control gene from two organisms:

Mouse

Pax6 gene: 5'-GTATCCAACGGTGTGTGAGTAAAATT-3'

Fruit fly

eyeless gene: 5'-GTATCAAATGGATGTGTGAGCAAAAATT-3'

1. Calculate the percentage of identity between the two DNA sequences.
2. Use the genetic code (see Figure 10.11) to determine the amino acid sequences encoded by the two regions, and calculate their percentage of similarity.
3. The fruit fly and mouse evolved from a common ancestor about 500 million years ago. Comment on your answers to 1 and 2 in terms of the evolution of developmental pathways.

FIGURE 14.16 Segments Differentiate under Control of Genetic Switches The binding of a single protein, Ultrabithorax (Ubx), determines whether a thoracic segment in *Drosophila* produces full wings or halteres (balancers).

Modularity allows for differences in the pattern of gene expression among organisms

The modularity of development means that the molecular pathways for developmental processes such as organ formation operate independently from one another. For example, an *Antennapedia* mutant grows a leg where an antenna should be, but all of the mutant's other organs develop normally and in their proper places. On an evolutionary time scale, modularity means that the timing and position of a particular developmental process can change without disrupting the whole organism.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 14.4**
Modularity

TIMING DIFFERENCES The genes regulating the development of a module may be expressed at different developmental stages or for different durations in different species, a phenomenon called **heterochrony**. An example is the evolution of the giraffe's neck. As in virtually all mammals (with the exception of manatees and sloths), there are seven vertebrae in the neck of the giraffe. So the giraffe did not get a longer neck than other mammals by adding vertebrae. Instead, each of the cervical (neck) vertebrae of the giraffe is much longer than those of other mammals (**FIGURE 14.17**). How does this happen?

Bones grow because of the proliferation of cartilage-producing cells called *chondrocytes*. Bone growth is stopped by a signal that results in death of the chondrocytes and calcification of the bone matrix. In giraffes this signaling process is delayed in the cervical vertebrae, with the result that these vertebrae grow longer. Thus, the evolution of longer necks occurred through *changes in the timing of expression* of the genes that control bone formation.

SPATIAL DIFFERENCES Changes in the *spatial expression pattern* of a developmental gene can also result in evolutionary change. For example, the difference in foot webbing in ducks versus chickens is determined by an alteration in the spatial expression of a single gene. The feet of all bird embryos have webs of skin that connect their toes. This webbing is retained in adult ducks (and other aquatic birds) but not in adult chickens (and other non-aquatic birds). The loss of webbing is caused by a

(A) Giraffe

FIGURE 14.17 Heterochrony in the Development of a Longer Neck There are seven vertebrae in the neck of the giraffe (left) and human (right; not to scale). But the vertebrae of the giraffe are much longer (25 cm compared with 1.5 cm) because during development, growth continues for a longer period of time. This timing difference is called heterochrony.

signaling protein called bone morphogenetic protein 4 (BMP4) that instructs the cells in the webbing to undergo apoptosis. The death of these cells destroys the webbing between the toes.

Embryonic duck and chicken hindlimbs both express the *BMP4* gene in the webbing between the toes, but they differ in expression of a gene called *Gremlin*, which encodes a BMP inhibitor protein (FIGURE 14.18). In ducks, but not chickens, the *Gremlin* gene is expressed in the webbing cells. The Gremlin protein inhibits the BMP4 protein from signaling for apoptosis, and the result is a webbed foot.

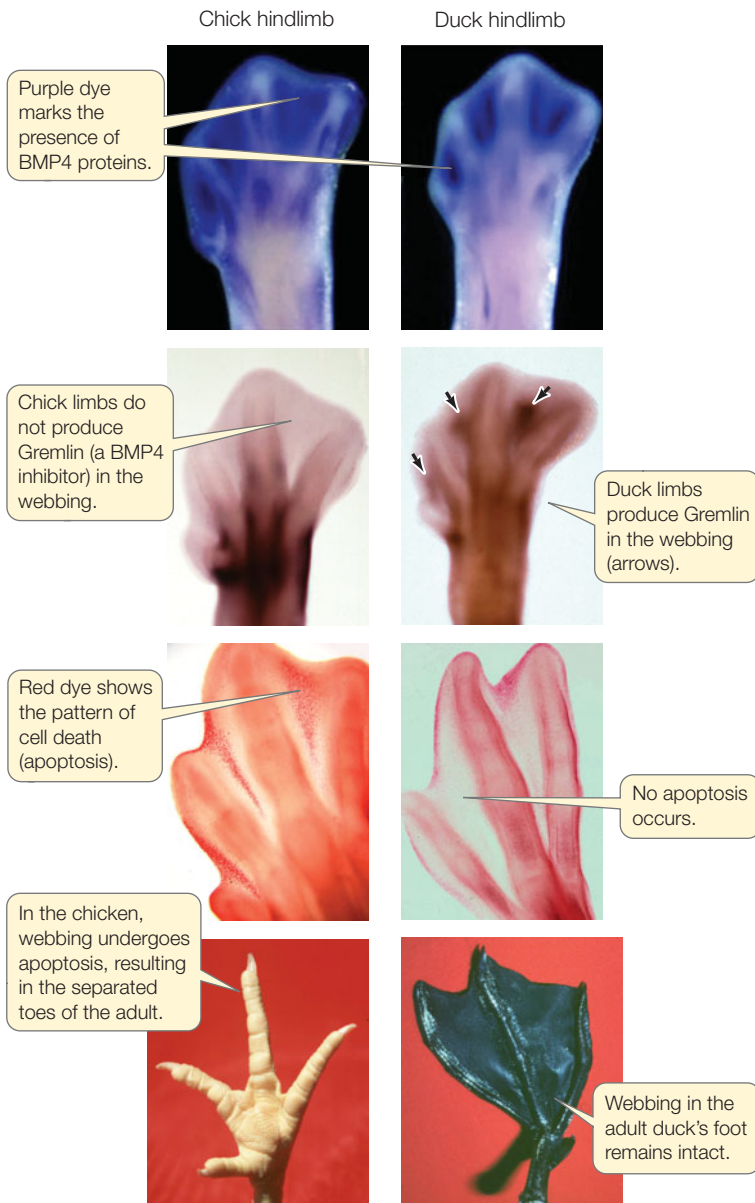

FIGURE 14.18 Changes in Gremlin Expression Correlate with Changes in Hindlimb Structure The left column of photos shows the development of a chicken's foot; the right column shows foot development in a duck. Gremlin protein in the webbing of the duck foot inhibits BMP4 signaling, thus preventing the embryonic webbing from undergoing apoptosis.

Do You Understand Concept 14.4?

- Describe the major ideas of evolutionary developmental biology.
- What is the evidence that there was a common ancestor for the developmental pathways leading to segment identity in insects and the organization of the spinal cord in mice?
- What is the evidence that changes in the transcription of a single gene can lead to differences in morphogenesis between different regions of an embryo?
- Examine Figure 14.18 and the related text. If Gremlin protein were added to the webbed region between the developing toes of a chicken, what would be the result?

The tools in the genetic toolkit guide morphogenesis of an individual organism in accordance with the individual's species. In the next concept, we turn to the roles some of these same tools play in the evolution of new forms and new species.

concept 14.5

Developmental Genes Contribute to Species Evolution but Also Pose Constraints

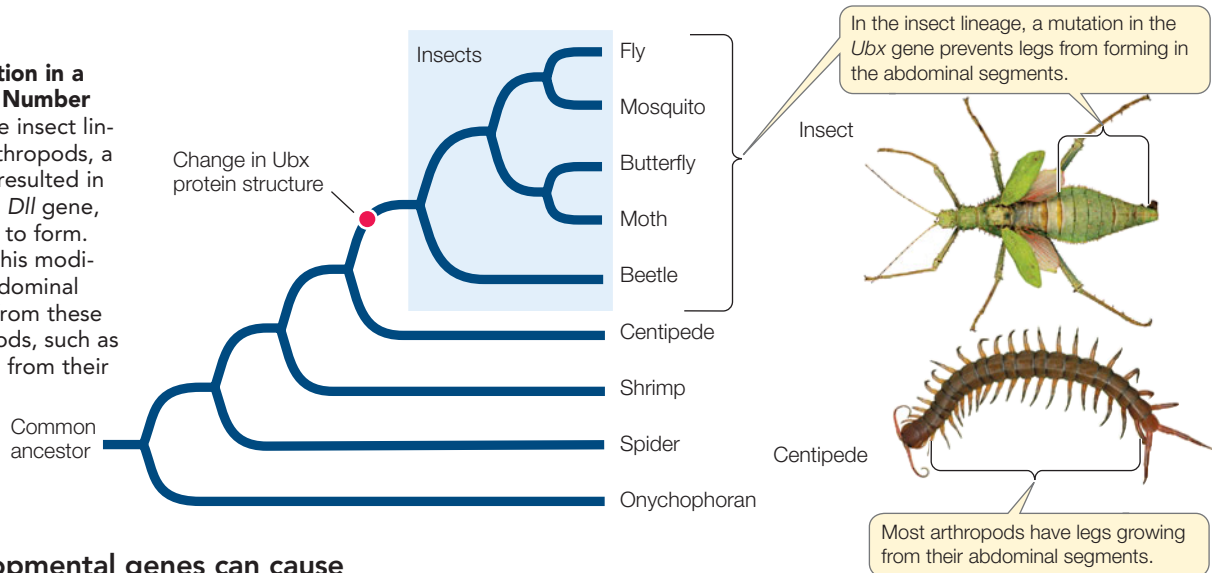

The genetic switches that allow different structures to develop in different regions of an embryo can also give rise to major morphological differences among species. We have already seen examples of this in the development of cervical vertebrae in giraffes versus other mammals, and in the differences in Gremlin expression that determine whether a bird's foot will be webbed or not. Thus changes in the timing and position of genetic switch activity can generate morphological variation, which then can be acted on by natural selection.

At the same time, the reliance of development on a genetic toolkit with a limited set of tools places constraints on how radically organisms can differ from one another. Four decades ago, the French geneticist François Jacob made the analogy that evolution works like a tinker, assembling new structures by *combining and modifying the available materials*, and not like an engineer, who is free to develop dramatically different designs (say, a jet engine to replace a propeller-driven engine). The evolution of morphology has not been governed by the appearance of radically new genes, but by modifications of existing genes and their regulatory pathways. Thus, developmental genes and their expression constrain evolution in two major ways:

- Nearly all evolutionary innovations are modifications of previously existing structures.
- The genes that control development are highly conserved; that is, the regulatory genes themselves change slowly over the course of evolution.

FIGURE 14.19 A Mutation in a Hox Gene Changed the Number of Legs in Insects

In the insect lineage (blue box) of the arthropods, a change to the *Ubx* gene resulted in a protein that inhibits the *Dll* gene, which is required for legs to form. Because insects express this modified *Ubx* gene in their abdominal segments, no legs grow from these segments. Other arthropods, such as centipedes, do grow legs from their abdominal segments.

Mutations in developmental genes can cause major evolutionary changes

The arthropods (which include crustaceans, centipedes, spiders, and insects) are segmented, with head, thoracic, and abdominal segments. In centipedes, both thoracic and abdominal segments form legs; but in insects, only the thoracic segments do. Arthropods express a gene called *Distal-less* (*Dll*) that causes legs to form from segments. What shuts down *Dll* expression in insect abdominal segments? The product of the Hox gene *Ubx* (which by now should be a familiar tool from the genetic toolkit) is produced in arthropod abdominal segments. But it has very different effects in different organisms. In centipedes, the *Ubx* protein apparently activates expression of the *Dll* gene to promote the formation of legs. But during the evolution of insects, a change in the *Ubx* gene sequence resulted in a modified *Ubx* protein that *represses* *Dll* expression in abdominal segments, so that leg formation is inhibited. A phylogenetic tree of arthropods shows that this change in *Ubx* occurred in the ancestor of insects at the same time that abdominal legs were lost (FIGURE 14.19).

LINK Arthropod evolution and diversity are discussed in Concept 23.4

Evolution proceeds by changing what's already there

The features of organisms almost always evolve from preexisting features in their ancestors. New “wing genes” did not suddenly appear in birds and bats; instead, wings arose as modifications of existing structures (FIGURE 14.20). In vertebrates, the wings are modified limbs.

Although the wings of birds and bats look different, they are made from the same basic parts. Like limbs, wings have a common structure: a humerus that connects to the body; two longer bones, the radius and ulna, that project away from the humerus; and then metacarpals and phalanges (digits). During development these bones take on different lengths and weights in different organisms. For example, the phalanges are relatively short in birds and relatively long in bats. These differences arise from changes in the molecular mechanisms

that control development, as we saw for cervical vertebrae in giraffes.

Developmental controls also influence how organisms *lose* structures. The ancestors of present-day snakes lost their forelimbs as a result of changes in the segmental expression of Hox genes. The snake lineage subsequently lost its hindlimbs by the loss of expression of the *Sonic hedgehog* gene in the limb bud tissue. But some snake species such as boas and pythons still have rudimentary pelvic bones and upper leg bones. Recall that we encountered an ortholog of *Sonic hedgehog* earlier as a morphogen in hand development (see p. 273). This is yet another example of how the same basic genetic tools are used in different ways in different species.

Conserved developmental genes can lead to parallel evolution

The nucleotide sequences of many of the genes that govern development have been highly conserved throughout the evolution of multicellular organisms—in other words, these genes exist in similar form across a broad spectrum of species.

The existence of highly conserved developmental genes makes it likely that similar traits will evolve repeatedly, especially among closely related species—a phenomenon called **parallel phenotypic evolution**. A good example is provided by a small fish, the three-spined stickleback (*Gasterosteus aculeatus*: “bony stomach with spines”).

Sticklebacks are widely distributed across the Atlantic and Pacific oceans and are also found in many freshwater lakes. Marine populations of this species spend most of their lives at sea but return to fresh water to breed. Members of freshwater populations live in lakes and never journey to salt water. Genetic evidence shows that freshwater populations have arisen independently from marine populations many times, most recently at the end of the last ice age. Marine sticklebacks have several structures that protect them from predators: well-developed pelvic bones with pelvic spines, and bony plates. In the freshwater populations descended from them, this body

FIGURE 14.20 Wings Evolved Three Times in Vertebrates

The wings of pterosaurs (the earliest flying vertebrates, which lived from 265 to 220 million years ago), birds, and bats are all modified forelimbs constructed from the same skeletal components. However, the components have different forms in the different groups of vertebrates.

armor is greatly reduced, and dorsal and pelvic spines are much shorter or even lacking (FIGURE 14.21).

The difference between marine and freshwater sticklebacks is not induced by environmental conditions. Marine species that are reared in fresh water still grow spines. Not surprisingly, the difference is due to a gene that affects development. The *Pituitary homoeobox transcription factor 1* (*Pitx1*) gene codes for a transcription factor that is normally expressed in regions of the developing embryo that form the head, trunk, tail, and pelvis of the marine stickleback. However, David Kingsley and his colleagues

at Stanford University have found that in independent populations from Japan, British Columbia, California, and Iceland, an enhancer sequence that drives the expression of *Pitx1* has been deleted, so that the gene has evolved so that it is no longer expressed in the pelvis, and the spines do not develop. *This same gene sequence has evolved to produce similar phenotypic changes in several independent populations*, and is thus a good example of parallel evolution. What could be the common selective mechanism in these cases? Possibly, the decreased predation pressure in the freshwater environment allows for increased reproductive success in animals that invest less energy in the development of unnecessary protective structures.

Do You Understand Concept 14.5?

- How have diverse body forms such as wings evolved by means of modifications in the functioning of existing genes?
- What would happen at the molecular and phenotypic levels if a *Ubx* gene from a spider replaced the *Ubx* gene in a fertilized insect egg?
- When several freshwater populations of stickleback fish were compared, the *Pitx1* gene coding region was identical to that of marine populations. But in every case, the freshwater fish had mutations in noncoding regions of *Pitx1* that led to reduced expression. What might these noncoding region mutations be?

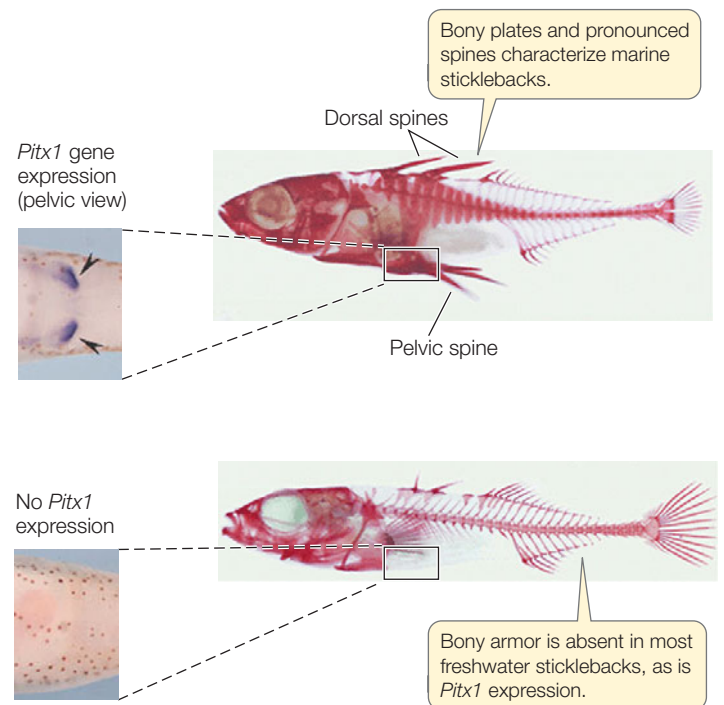

FIGURE 14.21 Parallel Phenotypic Evolution in Sticklebacks

A developmental gene, *Pitx1*, encodes a transcription factor that stimulates the production of plates and spines. This gene is active in marine sticklebacks but is mutated and inactive in various freshwater populations of the fish. The fact that this mutation is found in geographically distant and isolated freshwater populations is evidence for parallel evolution.

Why are stem cells so useful?

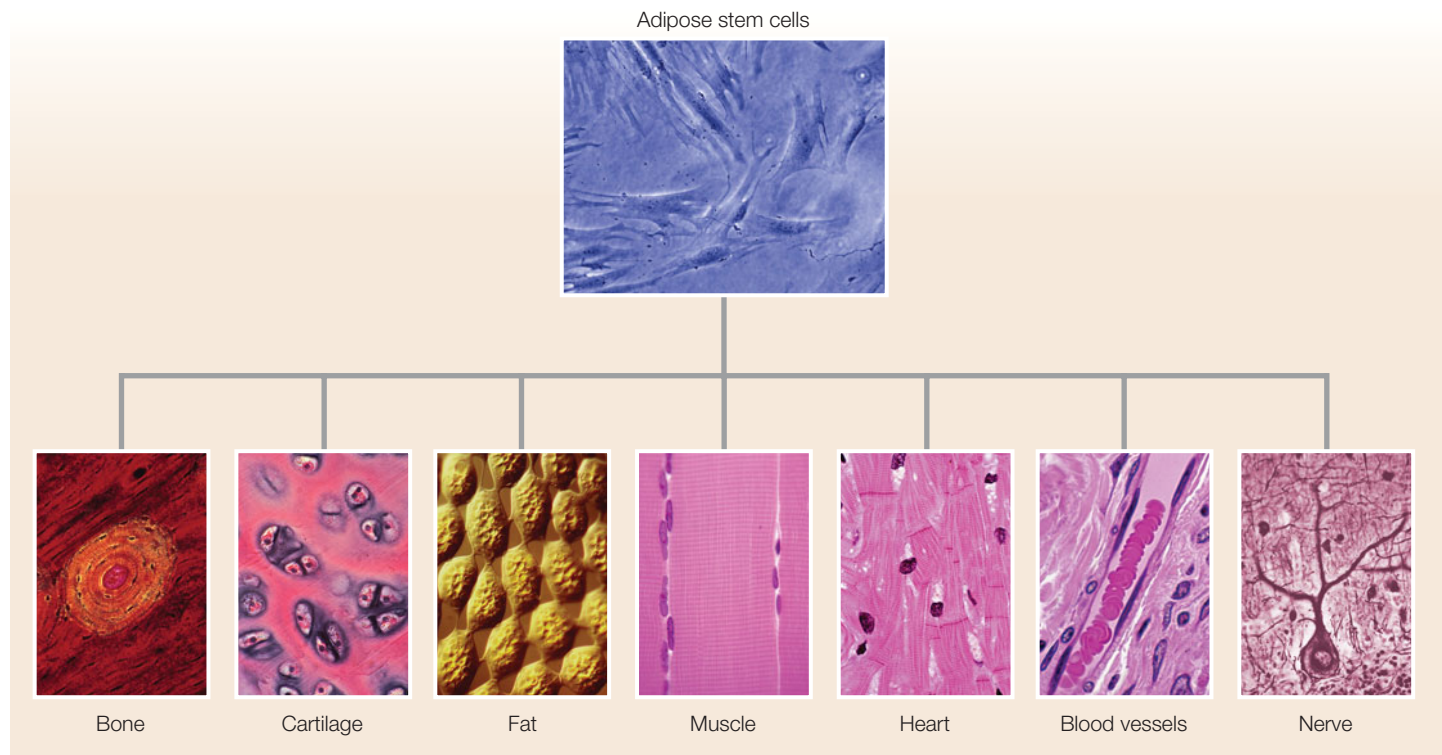

ANSWER The use of stem cells to help heal injuries in horses applies many of the concepts of developmental biology. The zygote and early embryonic cells are totipotent and can give rise to an entire new organism. But as development proceeds, cells become restricted in their fate (Concept 14.1). In adult mammals, however, not all the cells are fully differentiated. Some are rapidly dividing, undifferentiated stem cells, as occur in fat tissue.

Gene expression underlies the differentiation of stem cells (Concept 14.2). In the case of fat stem cells, specific proteins

are formed as they differentiate into bone, cartilage, muscle, fat, organ, blood vessel, and nerve cells (**FIGURE 14.22**). In the clinical setting where fat stem cells are injected into a damaged tissue, as in the case of Greg's Gold's damaged tendon, the environment around the stem cells largely determines the products of cell differentiation, probably by inducers (Concept 14.3).

Fat stem cells are being used therapeutically in humans. As with horses, human fat stem cells are easily isolated, and indeed a procedure has been developed to isolate them in large quantities in the operating room, where they can then be used to repair tissues, for example, after surgery for breast cancer.

FIGURE 14.22 Differentiation Potential of Stem Cells from Fat Stem cells isolated from adipose tissue can differentiate into a variety of cell types.

SUMMARY

concept 14.1 Development Involves Distinct but Overlapping Processes

- A multicellular organism begins its development as an embryo, and several embryonic stages precede the birth of an independent organism. **Review Figure 14.1 and WEB ACTIVITY 14.1**
- The processes of development are **determination, differentiation, morphogenesis**, and **growth**.
- The zygote is **totipotent**; it is capable of producing an entire new organism, with every type of cell in the adult body. **Review INTERACTIVE TUTORIAL 14.1**
- The ability to create clones from differentiated cells demonstrates the principle of **genomic equivalence**. **Review Figures 14.3 and 14.4 and WORKING WITH DATA 14.1**
- **Multipotent** stem cells occur in the growing regions of plants and in most tissues of mammals. They constantly divide and form a pool of cells that can be used for differentiation to specialized cells. **Review Figure 14.5**
- **Pluripotent** stem cells can form every cell type of a mammal, but not an entire organism. They occur in the embryo and can be induced to form in the laboratory. They may have medical uses. **Review Figure 14.6 and ANIMATED TUTORIAL 14.1**

concept 14.2 Changes in Gene Expression Underlie Cell Differentiation in Development

- Differential gene expression results in cell differentiation. Transcription factors are especially important in regulating gene expression during differentiation.
- **Cytoplasmic segregation**—the unequal distribution of **cytoplasmic determinants** in the egg, zygote, or early embryo—can establish **polarity** and lead to cell fate determination. **Review Figure 14.8 and ANIMATED TUTORIAL 14.2**
- **Induction** is a process by which embryonic animal tissues direct the development of neighboring cells and tissues by secreting chemical signals called inducers. **Review Figure 14.10**

concept 14.3 Spatial Differences in Gene Expression Lead to Morphogenesis

- During development, selective elimination of cells by apoptosis results from the expression of specific genes.
- In plants, **organ identity genes** encode polypeptides that associate to form transcription factors. These proteins determine the formation of flower organs. **Review Figure 14.11**
- Both plants and animals use **positional information** in the form of a signal called a **morphogen** to stimulate cell determination. **Review Figure 14.12**
- In the fruit fly *Drosophila melanogaster*, a cascade of transcriptional activation sets up the axes of the embryo, the development of the segments, and the determination of cell fate in each segment. **Review Figure 14.13 and ANIMATED TUTORIAL 14.3**
- **Hox genes** determine cell fate in the embryos of many animals. The **homeobox** is a DNA sequence found in Hox genes and other genes that code for transcription factors. The sequence of amino acids encoded by the homeobox is called the homeodomain.

concept 14.4 Gene Expression Pathways Underlie the Evolution of Development

- **Evolutionary developmental biology (evo-devo)** is the modern study of the evolutionary aspects of development, and it focuses on molecular mechanisms. **Review WEB ACTIVITY 14.2**
- Hox genes have evolved from a common ancestor. **Review Figure 14.15**
- Genes such as Hox genes underlie evolutionary changes in morphology that produce major differences in body forms.
- Evolutionary diversity is produced using a modest number of regulatory genes. **Review Figure 14.16**
- The transcription factors and chemical signals that govern pattern formation in the bodies of multicellular organisms, and the genes that encode them, can be thought of as a **genetic toolkit**.
- The bodies of developing and mature organisms are organized into self-contained units that can be modified independently in space and time. **Review ANIMATED TUTORIAL 14.4**
- Changes in **genetic switches** that determine where and when a set of genes will be expressed underlie the transformation of an individual from egg to adult.

concept 14.5 Developmental Genes Contribute to Species Evolution but Also Pose Constraints

- Evolutionary innovations are modifications of preexisting structures. **Review Figure 14.20**
- Because many genes that govern development have been highly conserved, similar traits are likely to evolve repeatedly, especially among closely related species. This process is called **parallel phenotypic evolution**. **Review Figure 14.21**

Evolution

Mechanisms of Evolution

15

On November 11, 1918, an armistice agreement signed in France signaled the end of World War I. But the death toll from four years of war was soon surpassed by the casualties of a massive influenza epidemic that began in the spring of 1918 among soldiers in a U.S. Army barracks. Over the next 18 months, this particular strain of flu virus spread across the globe, killing more than 50 million people worldwide—more than twice the number of World War I-related combat deaths.

The 1918–1919 pandemic was noteworthy because the death rate among young adults—who are usually less likely to die from influenza than are the elderly or the very young—was 20 times higher than in flu epidemics before or since. Why was that particular virus so deadly, especially to typically hardy individuals? The 1918 flu strain triggered an especially intense reaction in the human immune system. This overreaction meant that people with strong immune systems were likely to be more severely affected.

In most cases, however, our immune system helps us fight viruses; this response is the basis of *vaccination*. Since 1945, programs to administer flu vaccines have helped keep the number and severity of influenza outbreaks in check. Last year's vaccine, however, will probably not be effective against this year's virus. New strains of flu virus are evolving continuously, ensuring genetic variation in the population. If these viruses did not evolve, we would become resistant to them and annual vaccination would become unnecessary. But because they do evolve, biologists must develop a new and different flu vaccine each year.

Flu victims are treated at a U.S. Army hospital in 1918.

Vertebrate immune systems recognize proteins on the viral surface, and changes in these proteins mean that the virus can escape immune detection. Virus strains with the greatest number of changes to their surface proteins are most likely to avoid detection and infect their hosts, and thus have an advantage over other strains. Biologists can observe evolution in action by following changes in influenza virus proteins from year to year.

We learn a great deal about the processes of evolution by examining rapidly evolving organisms such as viruses, and these studies contribute to the development of evolutionary theory. Evolutionary theory, in turn, is put to practical uses, such as the development of better strategies for combating deadly diseases.

How do biologists use evolutionary theory to develop better flu vaccines?

*You will find the answer to this question on page 312.

KEY CONCEPTS

- 15.1** Evolution Is Both Factual and the Basis of Broader Theory
- 15.2** Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution
- 15.3** Evolution Can Be Measured by Changes in Allele Frequencies
- 15.4** Selection Can Be Stabilizing, Directional, or Disruptive
- 15.5** Genomes Reveal Both Neutral and Selective Processes of Evolution
- 15.6** Recombination, Lateral Gene Transfer, and Gene Duplication Can Result in New Features
- 15.7** Evolutionary Theory Has Practical Applications

concept 15.1 Evolution Is Both Factual and the Basis of Broader Theory

That biological populations change over time, or **evolve**, is a fact that is not disputed by scientists. We can, and do, observe evolutionary change on a regular basis, both in laboratory experiments and in natural populations. We measure the rate at which new mutations arise, observe the spread of new genetic variants through a population, and see the effects of genetic change on the form and function of organisms. In the fossil record, we observe the long-term morphological changes (which are the result of underlying genetic changes) that have occurred among living organisms. These underlying changes in the genetic makeup of populations (sometimes referred to as *microevolution*) drive the origin and extinction of species and fuel the diversification of life (*macroevolution*).

In addition to observing and recording physical changes over evolutionary time, biologists have accumulated a large body of evidence about *how* these changes occur, and about *what* evolutionary changes have occurred in the past. The resulting understanding and application of the mechanisms of evolutionary change to biological problems is known as **evolutionary theory**.

Evolutionary theory has many useful applications. We constantly apply it to the study and treatment of diseases; to the development of better agricultural crops and practices; and to the development of industrial processes that produce new molecules with useful properties. At a more basic level, knowledge of evolutionary theory allows biologists to understand how life diversified and has provided insight into how species interact. It also helps us to make predictions about the biological world.

In everyday speech, people tend to use the word “theory” to mean an untested hypothesis, or even a guess. But *evolutionary theory* does not refer to any single hypothesis, and it certainly is not guesswork. The concept of evolutionary change among living organisms was present among a few scientists even before Charles Darwin so clearly described his observations, presented his conclusions, and articulated the premise of natural selection in *The Origin of Species*. The rediscovery of Mendel’s experiments and the subsequent establishment of the principles of genetic inheritance early in the 1900s set the stage for vast amounts of research. By the end of the twentieth century, findings from many fields of biology firmly upheld Darwin’s basic premises about the common ancestry of life and the role of natural selection as an important mechanism of evolution. Today a vast and rich array of geological, morphological, and molecular data all support and expand the factual basis of evolution.

When we refer to evolutionary theory, we are referring to our understanding of the mechanisms that result in genetic changes in populations over time and to our use of that understanding to interpret changes in and interactions among living organisms. We can directly observe the evolution of influenza viruses, but it is evolutionary theory that allows us to apply our observations to the task of developing more effective vaccines. Several mechanisms of evolutionary change are recognized, and the scientific community is continually using evolutionary theory to expand

its understanding of how and when these mechanisms apply to particular biological problems.

Darwin and Wallace introduced the idea of evolution by natural selection

In the early 1800s, it was not yet evident to many people that life evolves. But several biologists had suggested that the species living on Earth had changed over time—that is, that evolution had taken place. Jean-Baptiste Lamarck, for one, presented strong evidence for the fact of evolution in 1809, but his ideas about *how* it occurred were not convincing. At that time, no one had yet envisioned a viable mechanism for evolution.

Charles Robert Darwin

In the 1820s, a young Charles Darwin became passionately interested in the subjects of geology (with its new sense of Earth’s great age) and *natural history* (the scientific study of how different organisms function and carry out their lives in nature). Despite these interests, he planned, at his father’s behest, to become a doctor. But surgery conducted without anesthesia nauseated Darwin, and he gave up medicine to study at Cambridge University for a career as a clergyman in the Church of England. Always more interested in science than in theology, he gravitated toward scientists on the faculty, especially the botanist John Henslow. In 1831, Henslow recommended Darwin for a position on HMS *Beagle*, a Royal Navy vessel that was preparing for a survey voyage around the world.

HMS *Beagle*

Whenever possible during the 5-year voyage (**FIGURE 15.1**), Darwin went ashore to study rocks and to observe and collect plants and animals. He noticed striking differences between the species he saw in South America and those of Europe. He

FIGURE 15.1 The Voyage of the *Beagle*

The mission of HMS *Beagle* was to chart the oceans and collect oceanographic and biological information from around the world. The world map indicates the ship's path; the inset map shows the Galápagos Islands, whose organisms were an important source of Darwin's ideas on natural selection.

observed that the species of the temperate regions of South America (Argentina and Chile) were more similar to those of tropical South America (Brazil) than they were to temperate European species. When he explored the islands of the Galápagos archipelago west of Ecuador, he noted that most of the animals were *endemic* to the islands (that is, unique and found nowhere else), although they were similar to animals found on the mainland of South America. Darwin also observed that the fauna of the Galápagos differed from island to island. He postulated that some animals had come to the archipelago from mainland South America and had subsequently undergone different changes on each of the islands. He wondered what might account for these changes.

When he returned to England in 1836, Darwin continued to ponder his observations. His ruminations were strongly influenced by the geologist Charles Lyell, who had recently popularized the idea that Earth had been shaped by slow-acting forces that are still at work today. Darwin reasoned that similar thinking could be applied to the living world. Within a decade, he had developed the framework of an explanatory theory for evolutionary change based on three major propositions:

- Species are not immutable; they change over time.
- Divergent species share a common ancestor.
- The mechanism that produces changes in species is **natural selection**: the differential survival and reproduction of individuals in a population based on variation in their traits.

The first of these propositions was not unique to Darwin; several earlier authors had argued for the fact of evolution. A more revolutionary idea was his second proposition, that *divergent species are related to one another through common descent*. In 1844, Darwin

wrote a long essay on his third proposition, describing natural selection as the mechanism of evolution, but he was reluctant to publish it, preferring to assemble more evidence first.

Darwin's hand was forced in 1858, when he received a letter and manuscript from another traveling English naturalist, Alfred Russel Wallace, who was studying the biota of the Malay Archipelago. Wallace asked Darwin to evaluate his manuscript, which included an explanation of natural selection almost identical to Darwin's. Darwin was at first dismayed, believing Wallace to have preempted his idea. Parts of Darwin's 1844 essay, together with Wallace's manuscript, were presented to the Linnaean Society of London on July 1, 1858, thereby crediting both men for the idea of natural selection. Darwin then worked quickly to finish his own book, *The Origin of Species*, which was published the following year.

Go to **ANIMATED TUTORIAL 15.1**
Natural Selection

Although Darwin and Wallace independently articulated the concept of natural selection, Darwin developed his ideas first. Furthermore, *The Origin of Species* proved to be a stunning work of scholarship that provided exhaustive evidence from many fields supporting both the premise of evolution itself and the notion of natural selection as a mechanism of evolution. Thus both concepts are more closely associated with Darwin than with Wallace.

The publication of *The Origin of Species* in 1859 stirred considerable interest (and controversy) among scientists and the public alike. Scientists spent much of the rest of the nineteenth century amassing biological and paleontological data to test evolutionary ideas and document the history of life on Earth. By 1900, the fact of biological evolution (by then defined as change in the physical characteristics of populations over time)

was established beyond any reasonable doubt. But the *genetic* basis of evolutionary change was not yet understood.

Evolutionary theory has continued to develop over the past century

In 1900, several individuals rediscovered the work of Gregor Mendel (which had been published in 1866 but rarely read or cited), and the basic mechanisms of genetic inheritance began to be unraveled. In the first decades of the twentieth century, Thomas Hunt Morgan's studies on fruit flies led to his discovery of the role of chromosomes in inheritance. In the 1920s and early 1930s, the major principles of population genetics were established, the genetic basis of new variation (i.e., mutations) began to be understood, and mechanisms of evolution such as genetic drift were described (see Concept 15.2). This work set the stage for a "modern synthesis" of genetics and evolution that took place over the period 1936–1947. Some of the major contributors to this synthesis and a few of their books are listed in **FIGURE 15.2**.

Although chromosomes were now understood to be the basis of genetic transmission in eukaryotes, their molecular structure remained a mystery until soon after the modern synthesis. Then, in 1953, Watson and Crick published their paper on the

structure of DNA, opening the door to our current detailed understanding of molecular evolutionary mechanisms. By the 1960s, biologists could study and document changes in allele frequencies in populations over time (see Concept 15.3). Most of this early work necessarily focused on variants of proteins that differed within and between populations and species; even

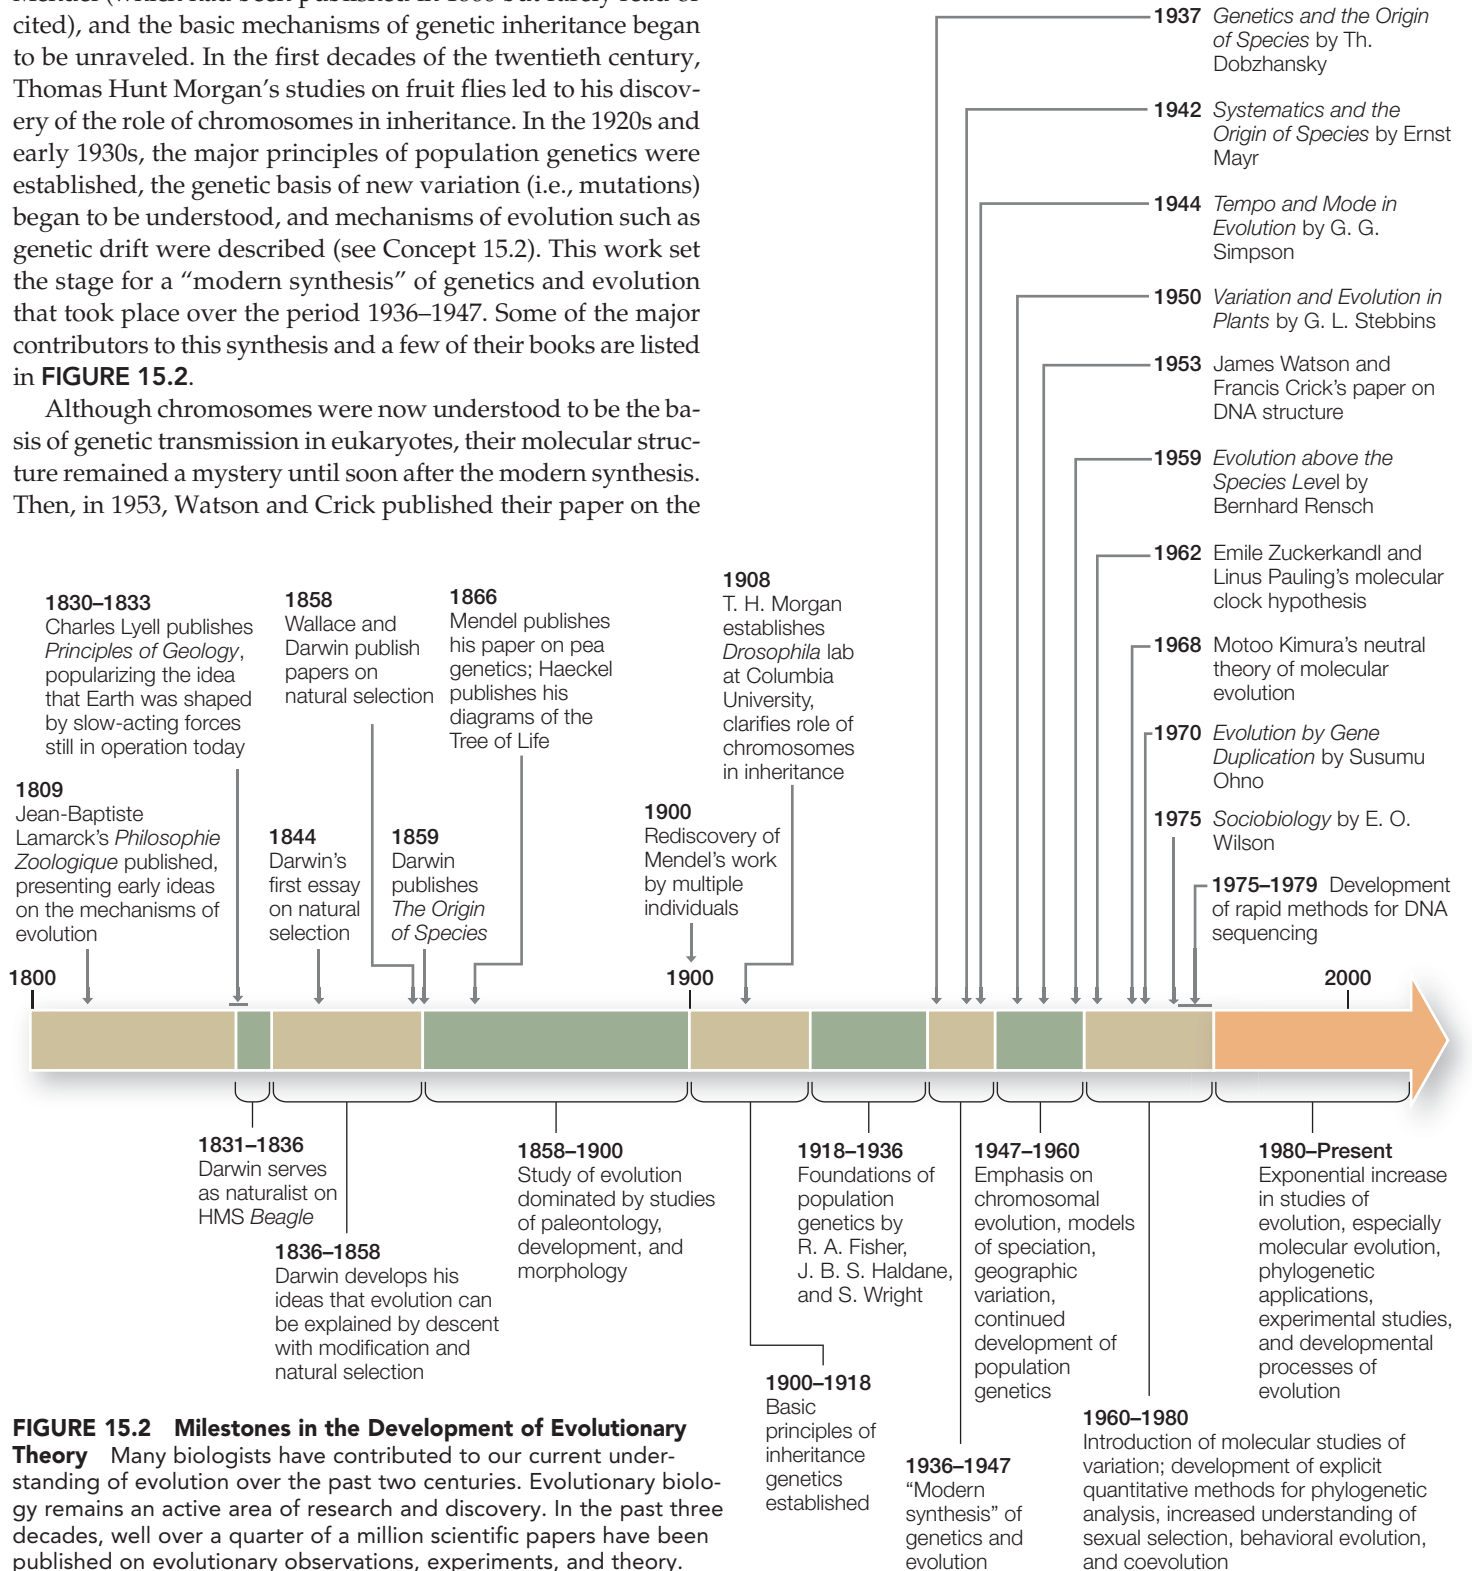

FIGURE 15.2 Milestones in the Development of Evolutionary Theory Many biologists have contributed to our current understanding of evolution over the past two centuries. Evolutionary biology remains an active area of research and discovery. In the past three decades, well over a quarter of a million scientific papers have been published on evolutionary observations, experiments, and theory.

though the molecular structure of DNA was known, it was not yet practical to sequence long stretches of DNA. Nonetheless, many important advances occurred in evolutionary theory during this time (see Figure 15.2), and these advances were not focused solely on a genetic understanding of evolution. E. O. Wilson's 1975 book *Sociobiology*, for example, invigorated studies of the evolution of behavior (a subject that had fascinated Darwin).

In the late 1970s, several techniques were developed that allowed the rapid sequencing of long stretches of DNA, which in turn allowed researchers to ascertain the amino acid sequences of proteins. This ability opened a new door for evolutionary biologists, who can now explore the structure of genes and proteins and document evolutionary changes within and between species in ways never before possible.

Do You Understand Concept 15.1?

- Why do biologists speak of “evolutionary theory” if the facts of evolution are not in doubt?
- Why do you think Darwin and Wallace formulated their ideas on natural selection at about the same time?
- Discuss the significance of each of the following scientific advances for evolutionary theory:
 - a. Elucidation of the principles of chromosomal inheritance
 - b. The discovery of DNA, its structure, and the universal genetic code
 - c. Technology that allows us to sequence long segments of DNA

Keep your discussion in mind as you continue reading this chapter.

Darwin had important insights into the mechanisms of evolution, even though he had a poor understanding of genetic transmission. Next we'll consider the primary mechanisms of evolution in light of our current understanding of genetics.

concept 15.2

Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution

Although the word “evolution” is often used in a general sense to mean simply “change,” in a biological context **evolution** refers specifically to changes in the genetic makeup of populations over time. Developmental changes that occur in a single individual over the course of the life cycle are not the result of evolutionary change. Evolution is genetic change occurring in a **population**—a group of individuals of a single species that live and interbreed in a particular geographic area at the same time. It is important to remember that *individuals do not evolve; populations do*.

The premise of natural selection was one of Darwin's principal insights and has been demonstrated to be an important

mechanism of evolution, but natural selection does not act alone. Three additional processes—gene flow, genetic drift, and nonrandom mating—affect the genetic makeup of populations over time. Before we consider how these processes change the frequencies of gene variants in a population, however, we need to understand how mutation brings such variants into existence.

Mutation generates genetic variation

The origin of genetic variation is mutation. As described in Concept 9.3, a *mutation* is any change in the nucleotide sequences of an organism's DNA. The process of DNA replication is not perfect, and some changes appear almost every time a genome is replicated. Mutations occur randomly with respect to an organism's needs; it is natural selection acting on this random variation that results in adaptation. Most mutations are either harmful to their bearers (*deleterious mutations*) or have no effect (*neutral mutations*). But a few mutations are *beneficial*, and even previously deleterious or neutral alleles may become advantageous if environmental conditions change. In addition, mutation can restore genetic variation that other evolutionary processes have removed. Thus mutation both creates and helps maintain genetic variation in populations.

Mutation rates can be high, as we saw in the case of the influenza viruses described at the opening of this chapter, but in many organisms the mutation rate is very low (on the order of 10^{-8} to 10^{-9} changes per base pair of DNA per generation). Even low overall mutation rates, however, create considerable genetic variation, because each of a large number of genes may change, and populations often contain

FIGURE 15.3 A Gene Pool A gene pool is the sum of all the alleles found in a population or at a particular locus. This figure shows the gene pool for one locus, X. The allele frequencies in this case are 0.20 for X_1 , 0.50 for X_2 , and 0.30 for X_3 (see Figure 15.10).

large numbers of individuals. For example, if the probability of a point mutation (an addition, deletion, or substitution of a single base) were 10^{-9} per base pair per generation, then each human gamete—the DNA of which contains 3×10^9 base pairs—would average three new point mutations ($3 \times 10^9 \times 10^{-9} = 3$), and each zygote would carry an average of six new mutations. The current human population of about 7 billion people would thus be expected to carry about 42 billion new mutations (i.e., changes in the nucleotide sequences of their DNA that were not present one generation earlier). So even though the mutation rate in humans is low, human populations still contain enormous genetic variation on which other evolutionary mechanisms can act.

As a result of mutation, different forms of a gene, known as *alleles*, may exist at a particular chromosomal locus. At any particular locus, a single diploid individual has no more than two of the alleles found in the population to which it belongs. The sum of all copies of all alleles at all loci found in a population constitutes its **gene pool** (FIGURE 15.3). (We can also refer to the gene pool for a particular chromosomal locus or loci.) The gene pool is the sum of the genetic variation in the population. The proportion of each allele in the gene pool is the **allele**

frequency. Likewise, the proportion of each genotype among individuals in the population is the **genotype frequency**.

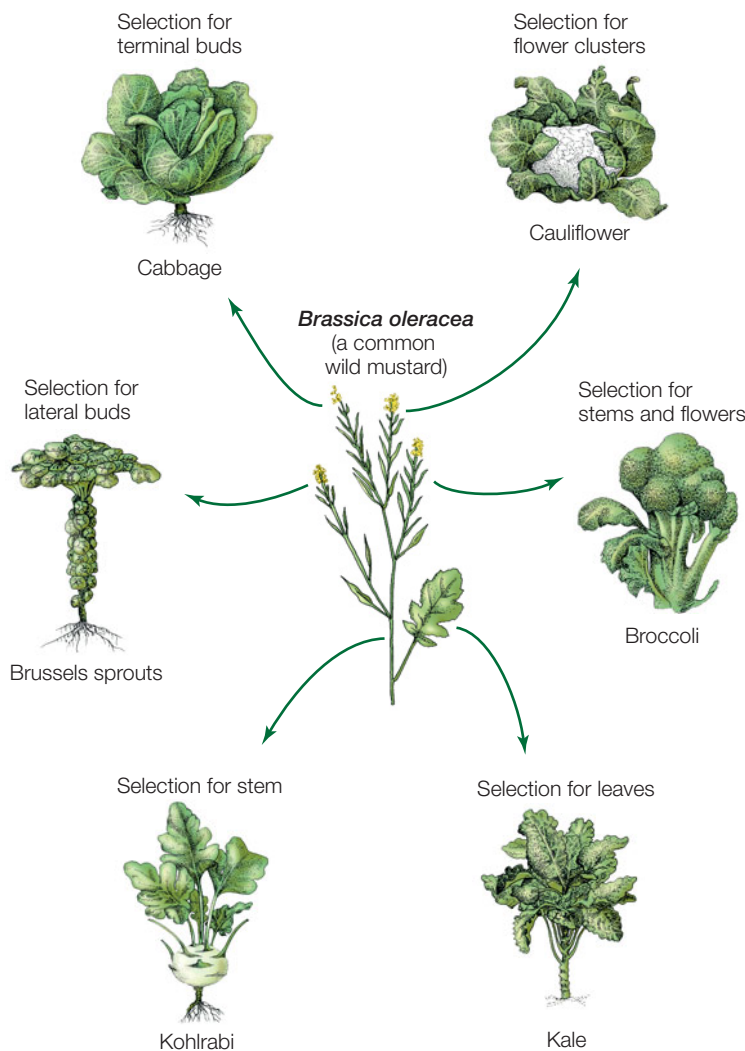

LINK Review the nature of alleles and genetic inheritance in Concepts 8.1 and 8.2

Selection on genetic variation leads to new phenotypes

As a result of mutation, the gene pools of nearly all populations contain variation for many characters. Selection on different characters in a single European species of wild mustard produced many important crop plants (FIGURE 15.4). Agriculturalists were able to achieve these results because the original mustard population had genetic variation for the characters of interest (such as stem thickness or number of leaves).

Darwin compared this **artificial selection** by animal and plant breeders with natural selection. Many of Darwin's observations on the nature of variation and selection came from domesticated plants and animals. Darwin bred pigeons and thus knew firsthand the astonishing diversity in color, size, form, and behavior that breeders could achieve (FIGURE 15.5). He recognized close parallels between selection by breeders and selection in nature. Natural selection resulted in traits that helped organisms survive and reproduce more effectively; artificial selection resulted in traits that were preferred by the human breeders, for whatever reason.

Laboratory experiments also demonstrate the existence of considerable genetic variation in populations. In one such experiment, investigators bred populations of the fruit fly *Drosophila melanogaster* with high or low numbers of bristles on their abdomens from an initial population with intermediate numbers of bristles. After 35 generations, all flies in both the high- and low-bristle lineages had bristle numbers that fell well outside the range found in the original population (FIGURE 15.6). Selection for high and low bristle numbers resulted in new combinations of the many different genes that were present in the original population, so that the phenotypic variation seen in subsequent generations fell outside the phenotypic variation seen in the original population.

Natural selection increases the frequency of beneficial mutations in populations

Darwin knew that far more individuals of most species are born than survive to reproduce. He also knew that, although offspring tend to resemble their parents, the offspring of most organisms are not identical either to their parents or to one another. He suggested that slight differences among individuals affect the chance that a given individual will survive and

FIGURE 15.4 Many Vegetables from One Species All of the crop plants shown here derive from a single wild mustard species. European agriculturalists produced these crop species by selecting and breeding plants with unusually large buds, stems, leaves, or flowers. The results substantiate the vast amount of variation present in a gene pool.

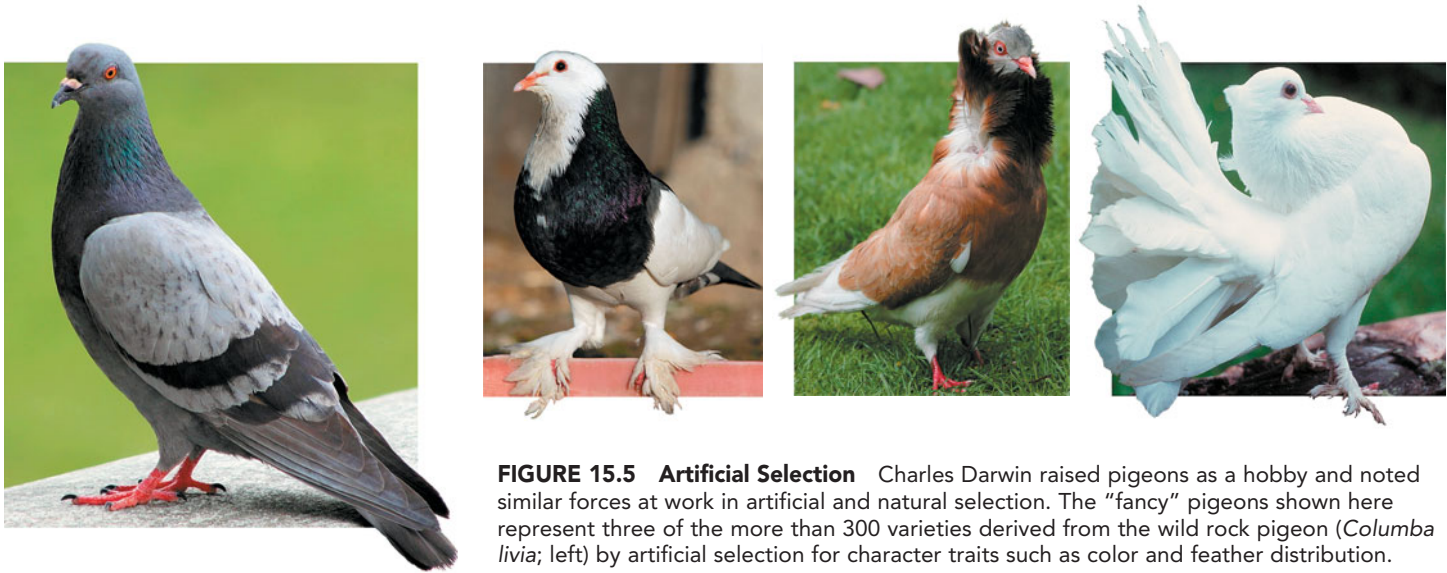

FIGURE 15.5 Artificial Selection Charles Darwin raised pigeons as a hobby and noted similar forces at work in artificial and natural selection. The “fancy” pigeons shown here represent three of the more than 300 varieties derived from the wild rock pigeon (*Columba livia*; left) by artificial selection for character traits such as color and feather distribution.

reproduce, which increases the frequency of the favored trait in the next generation. A favored trait that evolves through natural selection is known as an **adaptation**; this word is used to describe both the trait itself and the process that produces the trait.

Biologists regard an organism as being *adapted* to a particular environment when they can demonstrate that a slightly different organism reproduces and survives less well in that environment. To understand adaptation, biologists compare the performances of individuals that differ in their traits.

Natural selection also acts to remove deleterious mutations from populations. Individuals with deleterious mutations are less likely to survive and reproduce, so they are less likely to pass their alleles on to the next generation.

Gene flow may change allele frequencies

Few populations are completely isolated from other populations of the same species. Migration of individuals and movements of gametes between populations—a phenomenon called **gene flow**—can change allele frequencies in a population. If the arriving individuals survive and reproduce in their new location, they may add new alleles to the population’s gene pool, or they may change the frequencies of alleles present in the original population.

LINK If gene flow between two populations stops, those populations may diverge and become different species; see Concept 17.2

FIGURE 15.6 Artificial Selection Reveals Genetic Variation When investigators subjected *Drosophila melanogaster* to artificial selection for abdominal bristle number, that trait evolved rapidly. The graph shows the number of flies with different numbers of bristles in the original population and after 35 generations of artificial selection. The bristle numbers of the selected lineages clearly diverged from those of the original population.

Genetic drift may cause large changes in small populations

In small populations, **genetic drift**—random changes in allele frequencies from one generation to the next—may produce large changes in allele frequencies over time. Harmful alleles may increase in frequency, and rare advantageous alleles may be lost. Even in large populations, genetic drift can influence the frequencies of neutral alleles (which do not affect the survival and reproductive rates of their bearers).

As an example, suppose there are only two females in a small population of mice, and one of these females carries a newly arisen dominant allele that produces black fur. Even in the absence of any selection, it is unlikely that the two females will produce exactly the same number of offspring. Even if they do produce identical litter sizes and identical numbers of litters, chance events that have nothing to do with genetic

characteristics are likely to result in differential mortality among their offspring. If each female produces one litter, but a flood envelops the black female's nest and kills all of her offspring, the novel allele could be lost from the population in just one generation. In contrast, if the wild-type female's litter is lost, then the frequency of the newly arisen allele (and phenotype) for dark fur will rise dramatically in just one generation.

Genetic drift also operates when a population is reduced dramatically in size. Even populations that are normally large may occasionally pass through environmental events that only a small number of individuals survive, a situation known as a **population bottleneck**. The effect of genetic drift in such a situation is illustrated in **FIGURE 15.7**, in which red and yellow beans represent two alleles of a gene. Most of the beans in the small sample of the "population" that "survives" the bottleneck event are, just by chance, red, so the new population has a much higher frequency of red beans than the previous generation had. In a real population, the red and yellow allele frequencies would be described as having "drifted."

A population forced through a bottleneck is likely to lose much of its genetic variation. For example, when Europeans first arrived in North America, millions of greater prairie-chickens (*Tympanuchus cupido*) inhabited the midwestern prairies. As a result of hunting and habitat destruction by the new settlers, the Illinois population of this species plummeted from about 100 million birds in 1900 to fewer than 50 individuals in the 1990s. A comparison of DNA from birds collected in Illinois during the middle of the twentieth century with DNA from the surviving population in the 1990s showed that Illinois prairie-chickens have lost most of their genetic diversity. Loss of genetic variation in small populations is one of the problems facing biologists who attempt to protect endangered species.

Genetic drift can have similar effects when a few pioneering individuals colonize a new region. Because of its small size, the colonizing population is unlikely to possess all of the alleles found in the gene pool of its source population. The resulting change in genetic variation, called a **founder effect**, is equivalent to that in a large population reduced by a bottleneck.

Nonrandom mating can change genotype or allele frequencies

Mating patterns often alter genotype frequencies because the individuals in a population do not choose mates at random. For example, self-fertilization (*selfing*) is common in many groups of organisms, especially plants. Any time individuals mate preferentially with other individuals of the same genotype (including themselves), homozygous genotypes will increase in frequency and heterozygous genotypes will decrease in frequency over time. The opposite effect (more heterozygotes, fewer homozygotes) is expected when individuals mate primarily or exclusively with individuals of different genotypes.

Sexual selection results from a specific type of nonrandom mating in which an organism's phenotype influences its ability to attract mates. For example, female peacocks may choose their male mates on the basis of his bright tail feathers and associated mating display. Males with brighter feathers are more likely to attract females. The higher reproductive success of colorful males results in an increase in the frequency of the alleles associated with colorful tail feathers in the next generation.

In *The Origin of Species*, Darwin devoted a few pages to sexual selection, but in 1871 he wrote an entire book about it: *The Descent of Man, and Selection in Relation to Sex*. Sexual selection was Darwin's explanation for the evolution of conspicuous characters that would appear to inhibit survival, such as bright colors, long tails, and elaborate courtship displays in males of many species. He hypothesized that these features either improved the ability of their bearers to compete for access to mates (*intrasexual selection*) or made their bearers more attractive to members of the opposite sex (*intersexual selection*). The concept of sexual selection was either ignored or questioned for many decades, but recent investigations have demonstrated its importance.

Whereas Darwin associated natural selection with traits that enhance the survival of their bearers or their bearers' descendants, sexual selection is primarily about successful reproduction. Of course, an animal must survive long enough to reproduce, but if it survives and fails to reproduce, it makes no contribution to the next generation. Thus sexual selection may favor traits that enhance an individual's chances of reproduction even when these traits reduce its chances of survival. For example, females may be more likely to see or hear males with a given trait (and thus be more likely to mate with those males), even though the favored trait also increases the chances that the male will be seen or heard by a predator.

FIGURE 15.7 A Population Bottleneck Population bottlenecks occur when only a few individuals survive a random event. The result may be a shift in allele frequencies within the population.

In other cases, a male's sexual signal directly indicates a successful genotype. In many species of frogs, for example, females prefer males with low-frequency calls. Males' calls vary with body size, and a low-frequency call is indicative of a large-bodied frog. Frogs exhibit *indeterminate growth*—that is, they continue to grow throughout their lives—so a large frog is a long-lived frog, and size is an indication of survivorship. In this case, the sexual signal represents what is known as an *honest signal* of the male's ability to survive in the local environment.

LINK Some of the animal behaviors that have evolved in response to sexual selection are described in Concepts 41.5 and 41.6

One example of a trait that Darwin attributed to sexual selection is the remarkable tail of the male African long-tailed widowbird (*Euplectes progne*), which is longer than the bird's head and body combined (FIGURE 15.8). Male widowbirds normally select, and defend from other males, a territory where they perform courtship displays to attract females. To investigate whether sexual selection drove the evolution of widowbird tails, Malte Andersson, a behavioral ecologist at Gothenburg University in Sweden, clipped the tails of some captured male widowbirds and lengthened the tails of others by gluing on additional feathers. He then cut and reglued the tail feathers of still other males, which served as controls. Both short- and long-tailed males successfully defended their display territories, indicating that

Euplectes progne

FIGURE 15.8 What Is the Advantage? The extensive tail of the male African long-tailed widowbird actually inhibits its ability to fly. Darwin attributed the evolution of this seemingly nonadaptive trait to sexual selection.

INVESTIGATION

FIGURE 15.9 Sexual Selection in Action Behavioral ecologist Malte Andersson tested Darwin's hypothesis that excessively long tails evolved in male widowbirds because female preference for longer-tailed males increased their mating and reproductive success.

HYPOTHESIS

Female widowbirds prefer to mate with the male that displays the longest tail; longer-tailed males thus are favored by sexual selection because they will father more offspring.

METHOD

1. Capture males and artificially lengthen or shorten tails by cutting or gluing on feathers. In a control group, cut and replace tails to their normal length (to control for the effects of tail-cutting).
2. Release the males to establish their territories and mate.
3. Count the nests with eggs or young on each male's territory.

RESULTS

Male widowbirds with artificially shortened tails established and defended display sites successfully but fathered fewer offspring than did control or unmanipulated males. Males with artificially lengthened tails fathered the most offspring.

CONCLUSION

Sexual selection in *Euplectes progne* has favored the evolution of long tails in the male.

ANALYZE THE DATA

Are the differences plotted above significantly different? See Working with Data 15.1 at yourBioPortal.com for a simple method to test the statistical significance of the differences using the following data.

Group	Number of nests per male		
	Shortened tail	Control	Elongated tail

a long tail does not confer an advantage in male–male competition. However, males with artificially elongated tails attracted about four times more females than did males with shortened tails (FIGURE 15.9).

Why do female widowbirds prefer males with long tails? One possibility is that the ability to grow and maintain a costly feature such as a long tail may indicate that the male bearing it is vigorous and healthy, even though the tail impairs his ability to fly. If so, then females that are attracted to long tails are indirectly attracted to vigorous, healthy males, which are likely to carry beneficial genes that will lead to higher survivorship of their offspring.

Do You Understand Concept 15.2?

- How do deleterious, neutral, and beneficial mutations differ?
- Can you explain how natural selection results in an increase in the frequency of beneficial alleles in a population over time, and a decrease in the frequency of deleterious alleles?
- How can genetic drift cause large changes in small populations?
- How do selfing and sexual selection differ in their expected effects on genotype and allele frequencies over time?

The mechanisms of mutation, selection, gene flow, genetic drift, and nonrandom mating can all result in evolutionary change. We will consider next how evolutionary change that results from these mechanisms is measured.

concept 15.3 Evolution Can Be Measured by Changes in Allele Frequencies

Much of evolution occurs through gradual changes in the relative frequencies of different alleles in a population from one generation to the next. Major genetic changes can also be sudden, as happens when two formerly separated populations merge and hybridize, or when genes within a population are duplicated within the genome (see Concept 15.6). We can measure evolution by looking at changes in allele frequencies in populations.

Allele frequencies are usually estimated in locally interbreeding populations. To measure allele frequencies in a population precisely, we would need to count every allele at every locus in every individual in the population. Fortunately, we do not need to make such complete measurements because we can reliably estimate allele frequencies for a given locus by counting alleles in a sample of individuals from the population. The sum of all allele frequencies at a locus is equal to 1, so measures of allele frequency range from 0 to 1.

Genetic Drift

An allele's frequency is calculated using the following formula:

$$\frac{\text{number of copies of the allele in the population}}{\text{total number of copies of all alleles in the population}}$$

If only two alleles (we'll call them A and a) for a given locus are found among the members of a diploid population, those alleles can combine to form three different genotypes: AA , Aa , and aa (see Figure 15.3). A population with more than one allele at a locus is said to be *polymorphic* ("many forms") at that locus. Applying the formula above as shown in FIGURE 15.10, we can calculate the relative frequencies of alleles A and a in a population of N individuals as follows:

- Let N_{AA} be the number of individuals that are homozygous for the A allele (AA).
- Let N_{Aa} be the number that are heterozygous (Aa).
- Let N_{aa} be the number that are homozygous for the a allele (aa).

Note that $N_{AA} + N_{Aa} + N_{aa} = N$, the total number of individuals in the population, and that the total number of copies of both

RESEARCH TOOLS

FIGURE 15.10 Calculating Allele and Genotype Frequencies
Allele and genotype frequencies for a gene locus with two alleles in the population can be calculated using the equations in panel 1. When the equations are applied to two populations (panel 2), we find that the frequencies of alleles A and a in the two populations are the same, but the alleles are distributed differently between heterozygous and homozygous genotypes.

- 1 In any population, where N is the total number of individuals in the population:

$$\text{Frequency of allele } A = p = \frac{2N_{AA} + N_{Aa}}{2N} \quad \text{Frequency of allele } a = q = \frac{2N_{aa} + N_{Aa}}{2N}$$

$$\text{Frequency of genotype } AA = N_{AA}/N$$

$$\text{Frequency of genotype } Aa = N_{Aa}/N$$

$$\text{Frequency of genotype } aa = N_{aa}/N$$

- 2 Compute the allele and genotype frequencies for two separate populations of $N = 200$:

Population 1
(mostly homozygotes)

$$N_{AA} = 90, N_{Aa} = 40, \text{ and } N_{aa} = 70$$

$$p = \frac{180 + 40}{400} = 0.55$$

$$q = \frac{140 + 40}{400} = 0.45$$

$$\text{Freq. } AA = 90/200 = 0.45$$

$$\text{Freq. } Aa = 40/200 = 0.20$$

$$\text{Freq. } aa = 70/200 = 0.35$$

Population 2
(mostly heterozygotes)

$$N_{AA} = 45, N_{Aa} = 130, \text{ and } N_{aa} = 25$$

$$p = \frac{90 + 130}{400} = 0.55$$

$$q = \frac{50 + 130}{400} = 0.45$$

$$\text{Freq. } AA = 45/200 = 0.225$$

$$\text{Freq. } Aa = 130/200 = 0.65$$

$$\text{Freq. } aa = 25/200 = 0.125$$

alleles present in the population is $2N$, because each individual is diploid. Each AA individual has two copies of the A allele, and each Aa individual has one copy of the A allele. Therefore, the total number of A alleles in the population is $2N_{AA} + N_{Aa}$. Similarly, the total number of a alleles in the population is $2N_{aa} + N_{Aa}$. If p represents the frequency of A , and q represents the frequency of a , then

$$p = \frac{2N_{AA} + N_{Aa}}{2N}$$

and

$$q = \frac{2N_{aa} + N_{Aa}}{2N}$$

Figure 15.10 applies these formulas to calculate the allele and genotype frequencies in two hypothetical populations, each containing 200 diploid individuals. The calculations in Figure 15.10 demonstrate two important points. First, notice that for each population, $p + q = 1$, which means that $q = 1 - p$. So when there are only two alleles at a given locus in a population, we can calculate the frequency of one allele and obtain the second allele's frequency by subtraction. If there is only one allele at a given locus in a population, its frequency is 1: the population is then *monomorphic* at that locus, and the allele is said to be *fixed*.

The second thing to notice is that population 1 (consisting mostly of homozygotes) and population 2 (consisting mostly of heterozygotes) have the same allele frequencies for A and a . Thus they have the same gene pool for this locus. Because the alleles in the gene pool are distributed differently among individuals, however, the *genotype frequencies* of the two populations differ.

The frequencies of the different alleles at each locus and the frequencies of the different genotypes in a population describe that population's **genetic structure**. Allele frequencies measure the amount of genetic variation in a population; genotype frequencies show how a population's genetic variation is distributed among its members. Other measures, such as the proportion of loci that are polymorphic, are also used to measure variation in populations. With these measurements, it becomes possible to consider how the genetic structure of a population changes or remains the same over generations—that is, to measure evolutionary change.

Hardy–Weinberg Equilibrium

Evolution will occur unless certain restrictive conditions exist

In 1908, the British mathematician Godfrey Hardy and the German physician Wilhelm Weinberg independently deduced the conditions that must prevail if the genetic structure of a population is to remain the same over time. If the conditions they identified do not exist, then evolution will occur. The resulting principle is known as **Hardy–Weinberg equilibrium**. Hardy–Weinberg equilibrium describes a model in which allele frequencies do not change across generations and

genotype frequencies can be predicted from allele frequencies (**FIGURE 15.11**). The principles of Hardy–Weinberg equilibrium apply only to sexually reproducing organisms. Several conditions must be met for a population to be at Hardy–Weinberg equilibrium (which, you should notice, correspond precisely to the five principal mechanisms of evolution discussed in Concept 15.2):

- *There is no mutation.* The alleles present in the population do not change, and no new alleles are added to the gene pool.

Generation I (Founder population)

Generation II (Hardy–Weinberg equilibrium restored)

FIGURE 15.11 One Generation of Random Mating Restores Hardy–Weinberg Equilibrium

Generation I of this population is made up of migrants from several source populations, and so is not initially in Hardy–Weinberg equilibrium. After one generation of random mating, the allele frequencies are unchanged, and the genotype frequencies return to Hardy–Weinberg expectations. The lengths of the sides of each rectangle are proportional to the allele frequencies in the population; the areas of the rectangles are proportional to the genotype frequencies.

- *There is no differential selection among genotypes.* Individuals with different genotypes have equal probabilities of survival and equal rates of reproduction.
- *There is no gene flow.* There is no movement of individuals into or out of the population or reproductive contact with other populations.
- *Population size is infinite.* The larger a population, the smaller will be the effect of genetic drift.
- *Mating is random.* Individuals do not preferentially choose mates with certain genotypes.

If these “ideal” conditions hold, two major consequences follow. First, the frequencies of alleles at a locus remain constant from generation to generation. Second, following one generation of random mating, the genotype frequencies occur in the following proportions:

Genotype	<i>AA</i>	<i>Aa</i>	<i>aa</i>
Frequency	p^2	$2pq$	q^2

To understand why these consequences are important, start by considering a population that is *not* in Hardy–Weinberg equilibrium, such as generation I in Figure 15.11. This could occur, for example, if the initial population is founded by migrants from several other populations, thus violating the Hardy–Weinberg assumption of no gene flow. In this example, generation I has more homozygous individuals and fewer heterozygous individuals than would be expected under Hardy–Weinberg equilibrium (a condition known as *heterozygote deficiency*).

Even with a starting population that is not in Hardy–Weinberg equilibrium, we can predict that after a single generation of random mating, and if the other Hardy–Weinberg

assumptions are not violated, the *allele frequencies* will remain unchanged, but the *genotype frequencies* will return to Hardy–Weinberg expectations. Let’s explore why this is true.

In generation I of Figure 15.11, the frequency of the *A* allele (p) is 0.55. Because we assume that individuals select mates at random, without regard to their genotype, gametes carrying *A* or *a* combine at random—that is, as predicted by the allele frequencies p and q . Thus, in this example, the probability that a particular sperm or egg will bear an *A* allele is 0.55. In other words, 55 out of 100 randomly sampled sperm or eggs will bear an *A* allele. Because $q = 1 - p$, the probability that a sperm or egg will bear an *a* allele is $1 - 0.55 = 0.45$.

LINK You may wish to review the discussion of probability and inheritance in Concept 8.1

To obtain the probability of two *A*-bearing gametes coming together at fertilization, we multiply the two independent probabilities of their occurrence:

$$p \times p = p^2 = (0.55)^2 = 0.3025$$

Therefore, 0.3025, or 30.25 percent, of the offspring in generation II will have homozygous genotype *AA*. Similarly, the probability of two *a*-bearing gametes coming together is

$$q \times q = q^2 = (0.45)^2 = 0.2025$$

Thus 20.25 percent of generation II will have the *aa* genotype.

There are two ways of producing a heterozygote: an *A* sperm may combine with an *a* egg, the probability of which is $p \times q$; or an *a* sperm may combine with an *A* egg, the probability of which is $q \times p$. Consequently, the overall probability

APPLY THE CONCEPT

Evolution can be measured by changes in allele frequencies

Imagine you have discovered a new population of curly-tailed lizards established on an island after immigrants have arrived from several different source populations during a hurricane. You collect and tabulate genotype data (right) for the lactate dehydrogenase gene (*Ldh*) for each of the individual lizards. Use the table to answer the following questions.

1. Calculate the allele and genotype frequencies of *Ldh* in this newly founded population.
2. Is the population in Hardy–Weinberg equilibrium? If not, which genotypes are over- or underrepresented? Given the population’s history, what is a likely explanation of your answer?
3. Under Hardy–Weinberg assumptions, what allele and genotype frequencies do you predict for the next generation?
4. Imagine that you are able to continue studying this population and determine the next generation’s actual allele and genotype frequencies. What are some of the

INDIVIDUAL NUMBER	SEX	INDIVIDUAL GENOTYPE FOR <i>Ldh</i>
1	Male	<i>Aa</i>
2	Male	<i>AA</i>
3	Female	<i>AA</i>
4	Male	<i>aa</i>
5	Female	<i>aa</i>
6	Female	<i>AA</i>
7	Male	<i>aa</i>
8	Male	<i>aa</i>
9	Female	<i>Aa</i>
10	Male	<i>AA</i>

principal reasons you might expect the observed allele and genotype frequencies to differ from the Hardy–Weinberg expectations you calculated in question 3?

of obtaining a heterozygote is $2pq$, or 0.495. The frequencies of the AA , Aa , and aa genotypes in generation II of Figure 15.11 now meet Hardy–Weinberg expectations, and the frequencies of the two alleles (p and q) have not changed from generation I.

Under the assumptions of Hardy–Weinberg equilibrium, allele frequencies p and q remain constant from generation to generation. If Hardy–Weinberg assumptions are violated and the genotype frequencies in the parental generation are altered (say, by the loss of a large number of AA individuals from the population), then the allele frequencies in the next generation will be altered. However, based on the new allele frequencies, another generation of random mating will be sufficient to restore the genotype frequencies to Hardy–Weinberg equilibrium.

Deviations from Hardy–Weinberg equilibrium show that evolution is occurring

You probably have realized that populations in nature never meet the stringent conditions necessary to be at Hardy–Weinberg equilibrium—which explains why all biological populations evolve. Why, then, is this model considered so important for the study of evolution? There are two reasons. First, the equation is useful for predicting the approximate genotype frequencies of a population from its allele frequencies. Second—and crucially—the model allows biologists to evaluate which mechanisms are acting on the evolution of a particular population. The specific patterns of deviation from Hardy–Weinberg equilibrium can help us identify the various mechanisms of evolutionary change.

Do You Understand Concept 15.3?

- Why is the concept of Hardy–Weinberg equilibrium important even though the assumptions on which it is based are never completely met in nature?
- Although the stringent assumptions of Hardy–Weinberg equilibrium are never met completely in real populations, the genotype frequencies of many populations do not deviate significantly from Hardy–Weinberg expectations. Can you explain why?
- Suppose you examine a population of toads breeding in a single pond and find that heterozygous genotypes at several different loci are present at significantly lower frequencies than predicted by Hardy–Weinberg equilibrium. What are some possible explanations?

Our discussion so far has focused on changes in allele frequencies at a single gene locus. Genes do not exist in isolation, however, but interact with one another (and with the environment) to produce an organism’s phenotype. What effects can these interactions have on selection?

concept 15.4 Selection Can Be Stabilizing, Directional, or Disruptive

Until now, we have only discussed traits influenced by alleles at a single locus. Such traits are often distinguished by discrete qualities (black versus white, or smooth versus wrinkled), and so are called *qualitative traits*. Many traits, however, are influenced by alleles at more than one locus. Such traits are likely to show continuous quantitative variation rather than discrete qualitative variation, and so are known as *quantitative traits*. For example, the distribution of body sizes of individuals in a population, a trait that is influenced by genes at many loci as well as by the environment, is likely to resemble a continuous bell-shaped curve.

Natural selection can act on characters with quantitative variation in any one of several different ways, producing quite different results (FIGURE 15.12):

(A) Stabilizing selection

(B) Directional selection

(C) Disruptive selection

FIGURE 15.12 Natural Selection Can Operate in Several Ways

The graphs in the left-hand column show the fitness of individuals with different phenotypes of the same trait. The graphs on the right show the distribution of the phenotypes in the population before (light green) and after (dark green) the influence of selection.

- **Stabilizing selection** preserves the average characteristics of a population by favoring average individuals.
- **Directional selection** changes the characteristics of a population by favoring individuals that vary in one direction from the mean of the population.
- **Disruptive selection** changes the characteristics of a population by favoring individuals that vary in both directions from the mean of the population.

Stabilizing selection reduces variation in populations

If the smallest and largest individuals in a population contribute fewer offspring to the next generation than do individuals closer to the average size, then stabilizing selection is operating on size (see Figure 15.12A). Stabilizing selection reduces variation in populations, but it does not change the mean. Natural selection frequently acts in this way, countering increases in variation brought about by sexual recombination, mutation, or gene flow. Rates of phenotypic change in many species are slow because natural selection is often stabilizing. Stabilizing selection operates, for example, on human birth weight. Babies who are lighter or heavier at birth than the population mean die at higher rates than babies whose weights are close to the mean (FIGURE 15.13). In discussions of specific genes, stabilizing selection is often called *purifying selection* because there is selection against any deleterious mutations to the usual gene sequence.

Directional selection favors one extreme

Directional selection is operating when individuals at one extreme of a character distribution contribute more offspring to the next generation than other individuals do, shifting the

FIGURE 15.13 Human Birth Weight Is Influenced by Stabilizing Selection Babies that weigh more or less than average are more likely to die soon after birth than babies with weights close to the population mean.

FIGURE 15.14 Long Horns Are the Result of Directional Selection Long horns were advantageous for defending young calves from attacks by predators, so horn length increased in feral herds of Spanish cattle in the American Southwest between the early 1500s and the 1860s. The result was the familiar Texas Longhorn breed. This evolutionary trend has been maintained in modern times by ranchers practicing artificial selection.

average value of that character in the population toward that extreme. In the case of a single gene locus, directional selection may result in favoring a particular genetic variant—referred to as *positive selection* for that variant. By favoring one phenotype over another, directional selection results in an increase of the frequencies of alleles that produce the favored phenotype (as with the surface proteins of influenza discussed in the opening of this chapter).

If directional selection operates over many generations, an *evolutionary trend* is seen in the population (see Figure 15.12B). Evolutionary trends often continue for many generations, but they can be reversed if the environment changes and different phenotypes are favored, or halted when an optimal phenotype is reached or trade-offs between different adaptational advantages oppose further change. The character then undergoes stabilizing selection.

Many cases of directional selection have been observed directly, and long-term examples abound in the fossil record. The long horns of Texas Longhorn cattle (FIGURE 15.14) are an example of a trait that has evolved through directional selection. Texas Longhorns are descendants of cattle brought to the New World by Christopher Columbus, who picked up a few cattle in the Canary Islands and brought them to the island of Hispaniola in 1493. The cattle multiplied, and their descendants were taken to the mainland of Mexico. Spaniards exploring what would become Texas and the southwestern United States brought these cattle with them, some of which escaped and formed feral herds. Populations of feral cattle increased greatly over the next few hundred years, but there was heavy predation from bears, mountain lions, and wolves, especially on the young calves. Cows with longer horns were more successful in protecting their calves against attacks, and over a few hundred years the average horn length in the feral herds increased considerably. In addition, the cattle evolved resistance to endemic diseases of the Southwest, as well as higher fecundity and longevity. Texas Longhorns often live and produce calves

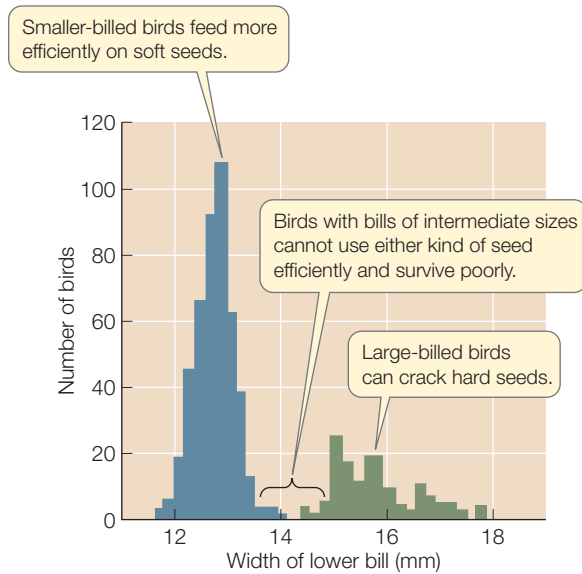

FIGURE 15.15 Disruptive Selection Results in a Bimodal Character Distribution The bimodal distribution of bill sizes in the black-bellied seedcracker of West Africa is a result of disruptive selection, which favors individuals with larger and smaller bill sizes over individuals with intermediate-sized bills.

well into their twenties—about twice as long as many breeds of cattle that have been artificially selected by humans for traits such as high fat content or high milk production (which are examples of artificial directional selection).

Disruptive selection favors extremes over the mean

When disruptive selection operates, individuals at opposite extremes of a character distribution contribute more offspring to the next generation than do individuals close to the mean, which increases variation in the population (see Figure 15.12C).

The strikingly *bimodal* (two-peaked) distribution of bill sizes in the black-bellied seedcracker (*Pyrenestes ostrinus*), a West African finch (FIGURE 15.15), illustrates how disruptive selection can influence populations in nature. The seeds of two types of sedges (marsh plants) are the most abundant food source for these finches during part of the year. Birds with large bills can readily crack the hard seeds of the sedge *Scleria verrucosa*. Birds with small bills can crack *S. verrucosa* seeds only with difficulty; however, they feed more efficiently on the soft seeds of *S. goossensii* than do birds with larger bills. Young finches whose bills deviate markedly from the two predominant bill sizes do not survive as well as finches whose bills are close to one of the two sizes represented by the distribution peaks. Because there are few abundant food sources in the finches' environment, and because the seeds of the two sedges do not overlap in hardness, birds with intermediate-sized bills are less efficient in using either one of the species' principal food sources. Disruptive selection therefore maintains a bimodal bill size distribution.

Do You Understand Concept 15.4?

- What are the different expected outcomes of stabilizing, directional, and disruptive selection?
- Why would you expect selection on human birth weight to be stabilizing rather than directional?
- Can you think of examples of extreme phenotypes in animal or plant populations that could be explained by directional selection?

Our discussion so far has largely focused on the evolution of phenotypes (what organisms look like and how they behave). We will now consider the specific mechanistic processes that operate at the level of genes and genomes.

concept 15.5 Genomes Reveal Both Neutral and Selective Processes of Evolution

Most natural populations harbor far more genetic variation than we would expect to find if genetic variation were influenced by natural selection alone. This discovery, combined with the knowledge that many mutations do not change molecular function, provided a major stimulus to the development of the field of *molecular evolution*.

To discuss the evolution of genes, we need to consider the specific types of mutations that are possible. A *nucleotide substitution* is a change in a single nucleotide in a DNA sequence (a type of point mutation). Many nucleotide substitutions have no effect on phenotype, even if the change occurs in a gene that encodes a protein, because most amino acids are specified by more than one codon. A substitution that does not change the encoded amino acid is known as a *silent substitution* or **synonymous substitution** (FIGURE 15.16A). Synonymous substitutions do not affect the functioning of a protein (although they may have other effects, such as changes in mRNA stability or translation rates) and are therefore less likely to be influenced by natural selection.

A nucleotide substitution that *does* change the amino acid sequence encoded by a gene is known as a *missense substitution* or **nonsynonymous substitution** (FIGURE 15.16B). In general, nonsynonymous substitutions are likely to be deleterious to the organism. But not every amino acid replacement alters a protein's shape and charge (and hence its functional properties). Therefore, some nonsynonymous substitutions are selectively neutral, or nearly so. A third possibility is that a nonsynonymous substitution alters a protein in a way that confers an advantage to the organism, and is therefore favored by natural selection.

LINK The genetic code determines the amino acid that is encoded by each codon; see Figure 10.11

The rate of synonymous substitutions in most protein-coding genes is much higher than the rate of nonsynonymous substitutions. In other words, *substitution rates are highest at nucleotide*

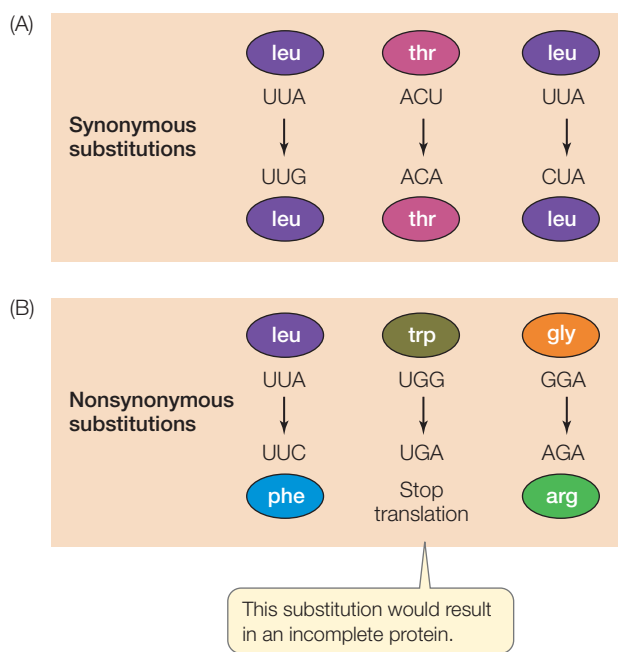

FIGURE 15.16 When One Nucleotide Changes (A) Synonymous substitutions do not change the amino acid specified and do not affect protein function. Such substitutions are less likely to be subject to natural selection, although they contribute greatly to the buildup of neutral genetic variation in a population. (B) Nonsynonymous substitutions do change the amino acid sequence and are likely to have an effect (often deleterious, but sometimes beneficial) on protein function. Such nucleotide substitutions are targets for natural selection.

positions that do not change the amino acid being expressed (FIGURE 15.17). The rate of substitution is even higher in **pseudogenes**, which are copies of genes that are no longer functional.

Insertions, deletions, and rearrangements of DNA sequences are all mutations that may affect a larger portion of the gene or genome than do point mutations (see Concept

FIGURE 15.17 Rates of Substitution Differ Rates of nonsynonymous substitution are typically much lower than rates of synonymous substitution, and much lower than substitution rates in pseudogenes. This pattern reflects stronger stabilizing selection in functional genes than in pseudogenes.

9.3). Insertions and deletions of nucleotides in a protein-coding sequence interrupt its reading frame, unless they occur in multiples of three nucleotides (the length of one codon). Rearrangements may merely change the order of whole genes along chromosomes, or they may rearrange functional domains among individual genes.

When biologists began to examine the details of genetic variation of populations, they soon discovered many gene variants that had little or no effect on function. This gave rise to new ideas about how these *neutral variants* arise and spread in populations.

Much of molecular evolution is neutral

Motoo Kimura proposed the **neutral theory** in 1968. He suggested that, at the molecular level, the majority of variants found in most populations are selectively neutral. That is, most gene variants confer neither an advantage nor a disadvantage on their bearers. Therefore, these neutral variants must accumulate through genetic drift rather than through positive selection.

We saw in Concept 15.2 that genetic drift of existing gene variants tends to be greatest in small populations. However, the *rate of fixation* of neutral mutations by genetic drift is independent of population size. To see why this is so, consider a population of size N and a neutral mutation rate of μ (mu) per gamete per generation at a particular locus. The number of new mutations would be, on average, $\mu \times 2N$, because $2N$ gene copies are available to mutate in a population of diploid organisms. The probability that a given mutation will be fixed by drift alone is its frequency, which equals $1/(2N)$ for a newly arisen mutation. We can multiply these two terms to get the rate of fixation of neutral mutations in a given population of N individuals:

$$2N\mu \frac{1}{2N} = \mu$$

Therefore, the rate of fixation of neutral mutations depends only on the neutral mutation rate μ and is independent of population size. Any given mutation is more likely to appear in a large population than in a small one, but any mutation that does appear is more likely to become fixed in a small population. These two influences of population size cancel each other out. Therefore, the rate of fixation of neutral mutations is equal to the mutation rate.

As long as the underlying mutation rate is constant, macromolecules evolving in different populations should diverge from one another in neutral changes at a constant rate. The rate of evolution of particular genes and proteins is indeed often relatively constant over time, and therefore can be used as a “molecular clock” to calculate evolutionary divergence times between species (see Concept 16.3).

Although much of the genetic variation present in a population is the result of neutral evolution, the neutral theory does not imply that most mutations have no effect on the individual organism. Many mutations are never observed in populations because they are lethal or strongly detrimental, and the individuals that carry them are quickly removed from the population through natural selection. Similarly, because mutations that confer a selective advantage tend to be quickly fixed in

populations, they also do not result in significant variation at the population level. Nonetheless, if we compare homologous proteins from different populations or species, some amino acid positions will remain constant under purifying selection, others will vary through neutral genetic drift, and still others will differ between species as a result of positive selection for change. How can these evolutionary processes be distinguished?

Positive and purifying selection can be detected in the genome

Positive and purifying selection are defined with respect to the **fitness** of the genotype, or change in the relative frequency of the genotype in the population from one generation to the next. Genotypes of higher fitness increase in frequency over time; those of lower fitness decrease over time.

Relative rates of synonymous and nonsynonymous substitution differ among codons of protein-coding genes as a function of selection. Each codon specifies an amino acid residue in the encoded protein. Changes in some amino acid residues have a large effect on protein function, whereas other changes have little or no effect on function. The nature and rates of substitutions in the corresponding genes can identify codons and genes that are evolving under neutral or selective processes:

- If the rates of synonymous and nonsynonymous substitution at a codon position are very similar (that is, the ratio of the two rates is close to 1), then the corresponding amino acid residue is likely drifting neutrally among states.
- If the rate of nonsynonymous substitution exceeds the rate of synonymous substitution at a codon position, then positive selection likely accounts for change in the corresponding amino acid residue.
- If the rate of synonymous substitution exceeds the rate of nonsynonymous substitution at a codon position, then purifying selection is likely resisting change in the corresponding amino acid residue.

FRONTIERS Biologists have compared the complete genomes of humans and our closest living relatives, chimpanzees. Analysis of ratios of rates of nonsynonymous to synonymous substitution reveals hundreds of genes that are evolving under positive selection in one or both lineages. Further analysis of these genes is expected to provide insights into the major selective changes that have occurred in humans and chimpanzees since our most recent common ancestor.

The evolution of lysozyme illustrates how and why particular codons in a gene sequence might be under different modes of selection. Lysozyme is an enzyme that is found in almost all animals; it is produced in the tears, saliva, and milk of mammals and in the albumen (whites) of bird eggs. Lysozyme digests the cell walls of bacteria, rupturing and killing them. Most animals defend themselves against bacteria by digesting them, which is probably why most animals have lysozyme. Some animals, however, also use lysozyme to digest their food.

Among mammals, a mode of digestion called *foregut fermentation* has evolved twice. In mammals with this mode of digestion, the foregut—consisting of the posterior esophagus and/or the stomach—has been converted into a chamber in which bacteria break down ingested plant matter by fermentation. Foregut fermenters can obtain nutrients from the otherwise indigestible cellulose that makes up a large proportion of plant tissue. Foregut fermentation evolved independently in *ruminants* (a group of hoofed mammals that includes cattle) and in certain leaf-eating monkeys, such as langurs. We know that these evolutionary events were independent because both langurs and ruminants have close relatives that are not foregut fermenters.

In both mammalian foregut-fermenting lineages, lysozyme has been modified to play a new, nondefensive role. The modified lysozyme enzyme ruptures some of the bacteria that live in the foregut, releasing nutrients metabolized by the bacteria, which the mammal then absorbs. How many changes in the lysozyme molecule were needed to allow it to perform this function amid the digestive enzymes and acidic conditions of the mammalian foregut? To answer this question, biologists compared the lysozyme-coding sequences in foregut fermenters with those in several of their nonfermenting relatives. They determined which amino acids differed and which were shared among the species (**FIGURE 15.18A**), as well as the rates of synonymous and nonsynonymous substitution in lysozyme genes across the evolutionary history of the sampled species.

The researchers found that the rate of synonymous substitution within the gene that codes for lysozyme was much higher than the rate of nonsynonymous substitution. This observation indicates that many of the amino acids that make up lysozyme are evolving under purifying selection. In other words, there is selection against change in the lysozyme protein at these positions, and the encoded amino acids must therefore be critical for lysozyme function. At other positions, several different amino acids function equally well, and the corresponding codons have similar rates of synonymous and nonsynonymous substitution.

The most striking finding was that amino acid replacements in lysozyme happened at a much higher rate in the lineage leading to langurs than in any other primates. The high rate of nonsynonymous substitution in the langur lysozyme gene shows that lysozyme went through a period of rapid change in adapting to the stomachs of langurs. Moreover, the lysozymes of langurs and cattle share five convergent amino acid replacements, all of which lie on the surface of the lysozyme molecule, well away from the enzyme's active site. Several of these shared replacements are changes from arginine to lysine, which make the protein more resistant to degradation by the stomach enzyme pepsin. By understanding the functional significance of amino acid replacements, biologists can explain the observed changes in amino acid sequences in terms of changes in the functioning of the protein.

A large body of fossil, morphological, and molecular evidence shows that langurs and cattle do not share a recent common ancestor. However, langur and ruminant *lysozymes* share several amino acids that neither mammal shares with the

(A) *Semnopithecus* sp.

Bos taurus

 (B) *Opisthocomus hoazin*

The lysozymes of langurs and cattle are convergent for 5 amino acid residues, indicative of the independent evolution of foregut fermentation in these two species.

	Langur	Baboon	Human	Rat	Cattle	Horse
Langur		14	18	38	32	65
Baboon	0		14	33	39	65
Human	0	1		37	41	64
Rat	0	0	0		55	64
Cattle	5	0	0	0		71
Horse	0	0	0	0	1	

FIGURE 15.18 Convergent Molecular Evolution of Lysozyme

(A) The numbers of amino acid differences in the lysozymes of several pairs of mammals are shown above the diagonal line; the numbers of similarities that arose from convergence between species are shown below the diagonal. The two foregut-fermenting species (cattle and langur) share five convergent amino acid replacements related to this digestive adaptation. (B) The hoatzin—the only known foregut-fermenting bird species—has been evolving independently from mammals for hundreds of millions of years but has independently evolved modifications to lysozyme similar to those found in cattle and langurs.

lysozymes of its own closer relatives. The lysozymes of these two mammals have undergone *convergent evolution* of some amino acid residues despite their very different ancestry. The amino acids they share give these lysozymes the ability to lyse the bacteria that ferment plant material in the foregut.

The hoatzin, an unusual leaf-eating South American bird (FIGURE 15.18B) and the only known avian foregut fermenter, offers another remarkable example of the convergent evolution of lysozyme. Many birds have an enlarged esophageal chamber called a *crop*. The hoatzin crop contains lysozyme and bacteria and acts as a fermentation chamber. Many of the amino acid replacements that occurred in the adaptation of hoatzin lysozyme are identical to those that evolved in ruminants and langurs. Thus, even though the hoatzin and foregut-fermenting mammals have not shared a common ancestor in hundreds of millions of years, similar adaptations have evolved in their lysozyme enzymes, enabling both groups to recover nutrients from fermenting bacteria.

APPLY THE CONCEPT

Genomes reveal both neutral and selective processes of evolution

Analysis of synonymous and nonsynonymous substitutions in protein-coding genes can be used to detect neutral evolution, positive selection, and purifying selection. An investigator compared many gene sequences that encode the protein hemagglutinin (a surface protein of influenza virus) sampled over time, and collected the data at right. Use the table to answer the following questions.

1. Which codon positions encode amino acids that have probably changed as a result of positive selection? Why?
2. Which codon position is most likely to encode an amino acid that drifts neutrally among states? Why?
3. Which codon positions encode amino acids that have probably changed as a result of purifying selection? Why?

CODON POSITION	NUMBER OF SYNONYMOUS SUBSTITUTIONS IN CODON	NUMBER OF NONSYNONYMOUS SUBSTITUTIONS IN CODON
12	0	7
15	1	9
61	0	12
80	7	0
137	12	1
156	24	2
165	3	4
226	38	3

Heterozygote advantage maintains polymorphic loci

In many cases, different alleles of a particular gene are advantageous under different environmental conditions. Most organisms, however, experience a wide diversity of environments. A night is dramatically different from the preceding day. A cold, cloudy day differs from a clear, hot one. Day length and temperature change seasonally. For many genes, a single allele is unlikely to perform well under all these conditions. In such situations, a heterozygous individual (with two different alleles) is likely to outperform individuals that are homozygous for either one of the alleles.

Colias butterflies of the Rocky Mountains live in environments where dawn temperatures often are too cold, and afternoon temperatures too hot, for the butterflies to fly. Populations of these butterflies are polymorphic for the gene that encodes phosphoglucose isomerase (PGI), an enzyme that influences how well an individual flies at different temperatures. Butterflies with certain PGI genotypes can fly better during the cold hours of early morning; those with other genotypes perform better during midday heat. The optimal body temperature for flight is 35°C–39°C, but some butterflies can fly with body temperatures as low as 29°C or as high as 40°C. Heat-tolerant genotypes are favored during spells of unusually hot weather; during spells of unusually cool weather, cold-tolerant genotypes are favored.

Heterozygous *Colias* butterflies can fly over a greater temperature range than homozygous individuals because they produce two different forms of PGI. This greater range of activity should give them an advantage in foraging and finding mates. A test of this prediction did find a mating advantage in heterozygous males, and further found that this mating advantage maintains the polymorphism in the population (FIGURE 15.19). The heterozygous condition can never become fixed in the population, however, because the offspring of two heterozygotes will always include both classes of homozygotes in addition to heterozygotes.

Genome size and organization also evolve

We know that genome size varies tremendously among organisms. Across broad taxonomic categories, there is some correlation between genome size and organismal complexity. The genome of the tiny bacterium *Mycoplasma genitalium* has only 470 genes. *Rickettsia prowazekii*, the bacterium that causes typhus, has 634 genes. *Homo sapiens*, by

INVESTIGATION

FIGURE 15.19 A Heterozygote Mating Advantage Among butterflies of the genus *Colias*, males that are heterozygous for two alleles of the PGI enzyme can fly farther under a broader range of temperatures than males that are homozygous for either allele. Does this ability give heterozygous males a mating advantage?

HYPOTHESIS

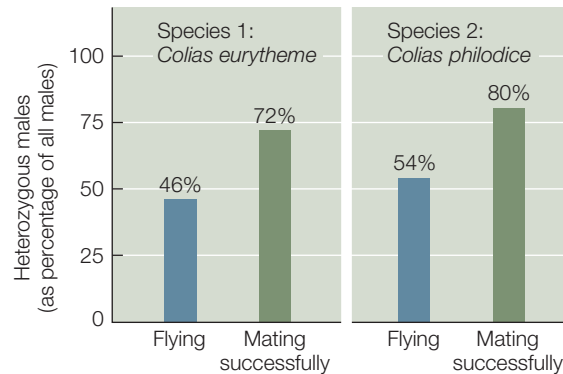

Heterozygous male *Colias* will have proportionally greater mating success than homozygous males.

METHOD

1. For each of two *Colias* species, capture butterflies in the field. In the laboratory, determine their genotypes and allow them to mate.
2. Determine the genotypes of the offspring, thus revealing paternity and mating success of the males.

RESULTS

For both species, the proportion of heterozygous males that mated successfully was higher than the proportion of all males seeking females (“flying”).

CONCLUSION

Heterozygous *Colias* males have a mating advantage over homozygous males.

ANALYZE THE DATA

Analyze this sampling data collected during the experiment (only one of several samples is shown for each species).

Species	All viable males*		Mating males	
	Heterozygous/ total	% heterozygous	Heterozygous/ total	% heterozygous
<i>C. philodice</i>	32/74	43.2	31/50	62.0
<i>C. eurytheme</i>	44/92	47.8	45/59	76.3

*“Viable males” are all males captured flying with females (hence with the potential to mate)

- Under the assumption that the proportions of each genotype should be the same as the proportions seen among all viable males, calculate the number of *mating males* expected to be heterozygous.
- Use a chi-square test (see Appendix B) to evaluate the significance of the difference in your expected numbers in (A) and the observed percentages of heterozygous mating males. The critical value ($P = 0.05$) of the chi-square distribution with one degree of freedom is 3.841. Are the observed and expected numbers of heterozygotes among mating males significantly different in these samples?

contrast, has about 23,000 protein-coding genes. **FIGURE 15.20** shows the number of genes from a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships. As this figure reveals, however, a larger genome does not always indicate greater complexity (compare rice with the other plants, for example). It is not surprising that more complex genetic instructions are needed for building and maintaining a large, multicellular organism than a small, single-celled bacterium. What is surprising is that some organisms, such as lungfishes, some salamanders, and lilies, have about 40 times as much DNA as humans do (**FIGURE 15.21**). Structurally, a lungfish or a lily is not 40 times more complex than a human. So why does genome size vary so much?

Differences in genome size are not so great if we take into account only the portion of DNA that actually encodes RNAs or proteins. The organisms with the largest total amounts of nuclear DNA (some ferns and flowering plants) have 80,000 times as much DNA as do the bacteria with the smallest genomes, but no species has more than about 100 times as many protein-coding genes as a bacterium. Therefore, much of the variation in genome size lies not in the number of functional genes, but in the amount of noncoding DNA (see Figure 15.21).

FIGURE 15.20 Genome Size Varies Widely This figure shows the number of genes from a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships. Bacteria and archaea (black branches) typically have fewer genes than most eukaryotes. Among eukaryotes, multicellular organisms with tissue organization (plants and animals; blue branches) have more genes than single-celled organisms (red branches) or multicellular organisms that lack pronounced tissue organization (green branches).

Why do the cells of most eukaryotic organisms have so much noncoding DNA? Does this noncoding DNA have a function? Although some of this DNA does not appear to have a direct function, it can alter the expression of the genes surrounding it. The degree or timing of gene expression can vary dramatically depending on the gene's position relative to noncoding sequences. Other regions of noncoding DNA consist of pseudogenes that are simply carried in the genome because the cost of doing so is very small. These pseudogenes may become the raw material for the evolution of new genes with novel functions. Some noncoding sequences function in maintaining chromosomal structure. Still others consist of parasitic transposable elements that spread through populations because they reproduce faster than the host genome.

FIGURE 15.21 A Large Proportion of DNA Is Noncoding
Most of the DNA of bacteria and yeasts encodes RNAs or proteins, but a large percentage of the DNA of multicellular species is noncoding.

Another hypothesis is that the proportion of noncoding DNA is related primarily to population size. Noncoding sequences that are only slightly deleterious to the organism are likely to be purged by selection most efficiently in species with large population sizes. In species with small populations, the effects of genetic drift can overwhelm selection against noncoding sequences that have small deleterious consequences. Therefore, selection against the accumulation of noncoding sequences is most effective in species with large populations, so such species (such as bacteria or yeasts) have relatively little noncoding DNA compared with species with small populations (see Figure 15.21).

Do You Understand Concept 15.5?

- How can the ratio of synonymous to nonsynonymous substitutions be used to determine whether a particular gene is evolving neutrally, under positive selection, or under stabilizing selection?
- Why is the rate of fixation of neutral mutations independent of population size?
- Why do heterozygous individuals sometimes have an advantage over homozygous individuals?
- Why can a mutation that results in the replacement of one amino acid by another be a neutral event in some cases and in other cases be detrimental or beneficial? (Hint: Review the information about amino acids in Table 3.2 and the details of protein structure in Concept 3.2.)
- Postulate and contrast two hypotheses for the wide diversity of genome sizes among different organisms.

Most of our discussion so far has centered on changes in existing genes and phenotypes. Next we consider how new genes with novel functions arise in populations in the first place.

concept 15.6

Recombination, Lateral Gene Transfer, and Gene Duplication Can Result in New Features

Several evolutionary processes can result in the acquisition of major new characteristics in populations. Each of these processes results in larger and more rapid evolutionary changes than do single point mutations.

Sexual recombination amplifies the number of possible genotypes

In asexually reproducing organisms, each new individual is genetically identical to its parent unless there has been a mutation. When organisms reproduce sexually, however, offspring differ from their parents because of crossing over and independent assortment of chromosomes during meiosis, as well as the combination of genetic material from two different gametes, as described in Concept 7.4. Sexual recombination generates an endless variety of genotype combinations that increase the evolutionary potential of populations—a long-term advantage of sex. Although some species may reproduce asexually most of the time, most asexual species have some means of achieving genetic recombination.

The evolution of meiosis and sexual recombination was a crucial event in the history of life. Exactly how these mechanisms arose is puzzling, however, because in the short term, sex has at least three striking disadvantages:

- Recombination breaks up adaptive combinations of genes.
- Sex reduces the rate at which females pass genes on to their offspring.
- Dividing offspring into separate genders greatly reduces the overall reproductive rate.

To see why this last disadvantage exists, consider an asexual female that produces the same number of offspring as a sexual female. Assume that both females produce two offspring, but that half of the sexual female's offspring are males. In the next (F_1) generation, then, each of the two asexual F_1 females will produce two more offspring—but there is only one sexual F_1 female to produce offspring. Thus, the effective reproductive rate of the asexual lineage is twice that of the sexual lineage. The evolutionary problem is to identify the advantages of sex that can overcome such short-term disadvantages.

A number of hypotheses have been proposed to explain the existence of sex, none of which are mutually exclusive. One is that sexual recombination facilitates repair of damaged DNA, because breaks and other errors in DNA on one chromosome can be repaired by copying the intact sequence from the homologous chromosome.

Another advantage of sexual reproduction is that it permits the elimination of deleterious mutations through recombination followed by selection. As Concept 9.2 described, DNA replication is not perfect, and many replication errors result in lower fitness. Meiotic recombination distributes these deleterious mutations unequally among gametes. Sexual reproduction

then produces some individuals with more deleterious mutations and some with fewer. The individuals with fewer deleterious mutations are more likely to survive. Therefore, sexual reproduction allows natural selection to eliminate particular deleterious mutations from the population over time.

In asexual reproduction, deleterious mutations can be eliminated only by the death of the lineage or by a rare back mutation (that is, when a subsequent mutation returns a mutated sequence to its original DNA sequence). Hermann J. Muller noted that deleterious mutations in a non-recombining genome accumulate—“ratchet up”—at each replication. Mutations occur and are passed on each time a genome replicates, and these mutations accumulate with each subsequent generation. This accumulation of deleterious mutations in lineages that lack genetic recombination is known as *Muller’s ratchet*.

Another explanation for the existence of sex is that the great variety of genetic combinations created in each generation can itself be advantageous. For example, genetic variation can be a defense against pathogens and parasites. Most pathogens and parasites have much shorter life cycles than their hosts and can rapidly evolve counteradaptations to host defenses. Sexual recombination might give the host’s defenses a chance to keep up.

Sexual recombination does not directly influence the frequencies of alleles. Rather, *it generates new combinations of alleles on which natural selection can act*. It expands variation in quantitative characters by creating new genotypes. That is why artificial selection for bristle number in *Drosophila* (see Figure 15.6) resulted in flies that had either more or fewer bristles than the flies in the initial population had.

Lateral gene transfer can result in the gain of new functions

The tree of life is usually visualized as a branching diagram, with each lineage diverging into two (or more) lineages over time, from one common ancestor to the millions of species that are alive today. Ancestral lineages divide into descendant lineages, and it is those speciation events that the tree of life captures. However, there are also processes of **lateral gene transfer**, which allow individual genes, organelles, or fragments of genomes to move horizontally from one lineage to another. Some species may pick up fragments of DNA directly from the environment. A virus may pick up some genes from one host and transfer them to a new host when the virus becomes integrated into the new host’s genome. Hybridization between species also results in the lateral transfer of large numbers of genes.

Lateral gene transfer can be highly advantageous to the species that incorporates novel genes from a distant relative. Genes that confer antibiotic resistance, for example, are commonly transferred among different species of bacteria. Lateral gene transfer is another way, in addition to mutation and recombination, that species can increase their genetic variation.

The degree to which lateral gene transfer events occur in various parts of the tree of life is a matter of considerable current investigation and debate. Lateral gene transfer appears to be relatively uncommon among most eukaryote lineages,

although the two major endosymbioses that gave rise to mitochondria and chloroplasts involved lateral transfers of entire bacterial genomes to the eukaryote lineage. Some groups of eukaryotes, most notably some plants, are subject to relatively high levels of hybridization among closely related species. Hybridization leads to the exchange of many genes among recently separated lineages of plants. The greatest degree of lateral transfer, however, appears to occur among bacteria. Many genes have been transferred repeatedly among bacteria, to the point that relationships and boundaries among species of bacteria are sometimes hard to decipher.

Many new functions arise following gene duplication

Gene duplication is yet another way in which genomes can acquire new functions. When a gene is duplicated, one copy of that gene is potentially freed from having to perform its original function. The identical copies of a duplicated gene can have any one of four different fates:

- Both copies of the gene may retain their original function (which can result in a change in the amount of gene product that is produced by the organism).
- Both copies of the gene may retain the ability to produce the original gene product, but the expression of the genes may diverge in different tissues or at different times in development.
- One copy of the gene may be incapacitated by the accumulation of deleterious mutations and become a functionless pseudogene.
- One copy of the gene may retain its original function while the second copy changes and evolves a new function.

How often do gene duplications arise, and which of these four outcomes is most likely? Investigators have found that rates of gene duplication are fast enough for a yeast or *Drosophila* population to acquire several hundred duplicate genes over the course of a million years. They have also found that most of the duplicated genes that are still present in these organisms are very young. Many duplicated genes are lost from a genome within 10 million years—an eyeblink on an evolutionary time scale.

Many gene duplications affect only one or a few genes at a time, but in some cases entire genomes may be duplicated. When all the genes are duplicated, there are massive opportunities for new functions to evolve. That is exactly what seems to have happened during the course of vertebrate evolution. The genomes of the jawed vertebrates have four diploid sets of many major genes, which leads biologists to conclude that two genome-wide duplication events occurred in the ancestor of these species. These duplications allowed considerable specialization of individual vertebrate genes, many of which are now highly tissue-specific in their expression.

LINK See Concept 14.4 for a discussion of the role of duplicated Hox genes in vertebrate evolution

FIGURE 15.22 A Globin Family Gene Tree This gene tree suggests that the α -globin and β -globin gene clusters diverged about 450 million years ago (open circle), soon after the origin of the vertebrates.

yourBioPortal.com

Go to WEB ACTIVITY 15.1
Gene Tree Construction

Several successive rounds of duplication and sequence evolution may result in a *gene family*, a group of homologous genes with related functions, often arrayed in tandem along a chromosome. An example of this process is provided by the globin gene family (FIGURE 15.22). Comparisons of the amino acid sequences among globins strongly suggest that this family of proteins arose via gene duplications.

Hemoglobin is a tetramer (four-subunit molecule) consisting of two α -globin and two β -globin polypeptide chains. It carries oxygen in the blood. Myoglobin, a monomer, is the primary O_2 storage protein in muscle. Myoglobin's affinity for O_2 is much higher than that of hemoglobin, but hemoglobin has evolved to be more diversified in its role. Hemoglobin binds O_2 in the lungs or gills, where the O_2 concentration is relatively high, transports it to deep body tissues, where the O_2 concentration is low, and releases it in those tissues. With its more complex tetrameric structure, hemoglobin is able to carry four molecules of O_2 , as well as hydrogen ions and carbon dioxide, in the blood. Hemoglobin and myoglobin are estimated to have arisen through gene duplication about 500 million years ago.

Do You Understand Concept 15.6?

- What are some of the potential advantages of lateral gene transfer to the organisms that gain new genes by this mechanism?
- Why is gene duplication considered important for long-term evolutionary change?
- Why is sexual reproduction so prevalent in nature, despite its having at least three short-term evolutionary disadvantages?

The development of evolutionary theory has helped reveal how biological molecules function, how genetic diversity is created and maintained, and how organisms develop new features. Next we will see how biologists put this theory into practice.

concept 15.7 Evolutionary Theory Has Practical Applications

Evolutionary theory has many practical applications across biology, and new ones are being developed every day. Here we'll discuss a few of these applications to fields such as agriculture, industry, and medicine.

Knowledge of gene evolution is used to study protein function

Earlier in this chapter we discussed the ways in which biologists can detect codons or genes that are under positive selection for change. These methods have greatly increased our

understanding of the functions of many genes. Consider, for example, the gated sodium channel genes. Sodium channels have many functions, including the control of nerve impulses in the nervous system (see Concept 34.2). Sodium channels can become blocked when they bind certain toxins, one of which is the tetrodotoxin (TTX) present in puffer fishes and many other animals. A human who eats puffer fish tissues that contain TTX can become paralyzed and die because the toxin-blocked sodium channels prevent nerves and muscles from functioning properly.

But puffer fish themselves have sodium channels, so why doesn't the TTX in their system paralyze them? Nucleotide substitutions in the puffer fish genome have resulted in structural changes in the proteins that form the sodium channels, and those changes prevent TTX from binding to the channel pore. Several different substitutions that result in such resistance have evolved in the various duplicated sodium channel genes of the many species of puffer fish. Many other changes that have nothing to do with the evolution of tetrodotoxin resistance have occurred in these genes as well.

So how does what we have learned about the evolution of TTX-resistant sodium channels affect our lives? Mutations in human sodium channel genes are responsible for a number of neurological pathologies. By studying the function of sodium channels and understanding which changes have produced tetrodotoxin resistance, we are learning a great deal about how these crucial channels work and how various mutations affect them. Biologists do this by comparing rates of synonymous and nonsynonymous substitutions across sodium channel genes in various animals that have evolved TTX resistance. In a similar manner, molecular evolutionary principles are used to understand function and diversification of function in many other proteins.

In vitro evolution produces new molecules

Living organisms produce thousands of compounds that humans have found useful. The search for naturally occurring compounds that can be used for pharmaceutical, agricultural, or industrial purposes has been termed *bioprospecting*. These compounds are the result of millions of years of molecular evolution across millions of species of living organisms. Yet biologists can imagine molecules that could have evolved but have not, in the absence of the right combination of selection pressures and opportunities.

For instance, we might want to find a molecule that binds a particular environmental contaminant so that the contaminant can be isolated and extracted from the environment. But if the contaminant is synthetic (not produced naturally), then it is unlikely that any living organism would have evolved a molecule with the function we desire. This problem was the inspiration for the field of **in vitro evolution**, in which new molecules are produced in the laboratory to perform novel and useful functions.

The principles of in vitro evolution are based on principles of molecular evolution that we have learned from the natural world. Consider a new RNA molecule that was produced in

the laboratory using the principles of mutation and selection. The new molecule's intended function was to join two other RNA molecules (acting as a ribozyme with a function similar to that of the naturally occurring DNA ligase described in Concept 9.2, but for RNA molecules). The process started with a large pool of random RNA sequences (10^{15} different sequences, each about 300 nucleotides long), which were then selected for displaying any ligase activity (**FIGURE 15.23**). None were very effective ligases, but some were slightly better than others. The most functional of the ribozymes were selected and reverse-transcribed into cDNA (using the enzyme reverse transcriptase). The cDNA molecules were then amplified using the polymerase chain reaction (PCR; see Figure 9.15). PCR amplification is not perfect, and it introduced many new mutations

FIGURE 15.23 In Vitro Evolution Starting with a large pool of random RNA sequences, David Bartel and Jack Szostak of Massachusetts General Hospital produced a new ribozyme through rounds of mutation and selection for the ability to ligate RNA sequences.

into the pool of RNA sequences. These sequences were then transcribed back into RNA molecules using RNA polymerase, and the process was repeated.

The ligase activity of the RNAs evolved quickly; after 10 rounds of *in vitro* evolution, it had increased by about 7 million times. Similar techniques have been used to create a wide variety of molecules with novel enzymatic and binding functions.

FRONTIERS *In vitro* evolution of a bacterial enzyme has identified molecular changes that give rise to antibiotic resistance in bacteria. This research may lead to the design of new antibiotics that are harder for bacteria to evolve resistance against. Developing new, effective antibiotics is critical to human health, since many of the existing antibiotic drugs are rapidly losing their effectiveness against bacterial pathogens.

Evolutionary theory provides multiple benefits to agriculture

Well before humans had a clear understanding of evolution, they were selecting beneficial traits in the plants and animals they used for food. Modern agricultural practices have benefited from a clearer understanding of evolutionary principles. Agriculturists have also used knowledge of evolutionary relationships and principles to incorporate beneficial genes into our food crops from many wild species.

Evolutionary theory has also proved important for understanding how to reduce the threats of pesticide and herbicide resistance. When farmers use the same pesticide over many seasons, the pests they are trying to kill gradually evolve resistance to the pesticide. Each year, a few pest individuals are slightly better at surviving in the presence of the pesticide, and those individuals produce most of the next generation of crop pests. Because their genes allow them to survive at a higher rate, and because they pass these resistant genes on to their offspring, pesticide resistance quickly evolves in the entire population. To combat this problem, evolutionary biologists have devised pesticide application and rotation schemes to reduce the rate of evolution of pesticide resistance, thus allowing farmers to use pesticides more effectively for longer periods of time.

Knowledge of molecular evolution is used to combat diseases

Many of the most problematic human diseases are caused by living, evolving organisms that present a moving target for modern medicine, as we described for influenza at the start of this chapter. The control of these and many other human diseases depends on techniques that can track the evolution of pathogenic organisms over time.

During the past century, transportation advances have allowed humans to move around the world with unprecedented speed and increasing frequency. Unfortunately, this mobility has increased the rate at which pathogens are transmitted among human populations, leading to the global emergence of many “new” diseases. Most of these emerging diseases are

caused by viruses, and virtually all new viral diseases have been identified by evolutionary comparison of their genomes with those of known viruses. In recent years, rodent-borne hantaviruses have been identified as the source of widespread respiratory illnesses, and the virus that causes sudden acute respiratory syndrome (SARS) has been identified, as has its host, using evolutionary comparisons of genes. Studies of the origins, timing of emergence, and global diversity of many human pathogens (including HIV, the human immunodeficiency virus) depend on evolutionary principles and methods, as do efforts to develop effective vaccines against these pathogens.

At present, it is difficult to identify many common infections (the viral strains that cause “colds,” for instance). As genomic databases increase, however, automated methods of sequencing and making evolutionary comparisons of sequences will allow us to identify and treat a much wider array of human (and other) diseases. Once biologists have collected genome data for enough infectious organisms, it will be possible to identify an infection by sequencing a portion of the pathogen’s genome and comparing this sequence with other sequences on an evolutionary tree.

Do You Understand Concept 15.7?

- How can gene evolution be used to study protein function?
- How are principles of evolutionary biology used to identify emerging diseases?
- What are the key elements of *in vitro* evolution, and how do these elements correspond to natural evolutionary processes?

The mechanisms of evolution have produced a remarkable variety of organisms, some of which are adapted to most environments on Earth. In the next chapter, we will describe how biologists study the evolutionary relationships across the great diversity of life.

How do biologists use evolutionary theory to develop better flu vaccines?

ANSWER Many different strains of influenza virus circulate among human populations and other vertebrate hosts each year, but only a few of those strains survive to leave descendants. Selection among these circulating influenza strains results in rapid evolution of the viral genome. One of the ways that influenza strains differ is in the configuration of proteins on their surface. These surface proteins are the targets of recognition by the host immune system (**FIGURE 15.24**).

When changes occur in the surface proteins of an influenza virus, the host immune system may no longer detect the invading virus, so the virus is more likely to replicate

A vaccine stimulates our immune system to produce antibodies that recognize these proteins on the surface of the H1N1 virus.

FIGURE 15.24 Evolutionary Analysis of Surface Proteins Leads to Improved Flu Vaccines This computer-generated image is of the H1N1 virus that was the target of a 2009–2010 flu vaccine. Rapidly evolving surface proteins (“spikes” in this illustration) allow flu viruses to escape detection by the host’s immune system. Analyzing the surface proteins among current strains of the virus can help biologists anticipate which strains are most likely to be the cause of future epidemics.

successfully. The viral strains with the greatest number of changes to their surface proteins are most likely to escape detection by the host immune system, and are therefore most likely to spread among the host population and result in future flu epidemics. In other words, there is positive selection for change in the surface proteins of influenza.

By comparing the survival and proliferation rates of virus strains that have different gene sequences coding for their surface proteins, biologists can study adaptation of the viruses over time (Concept 15.2). If biologists can predict which of the currently circulating flu virus strains are most likely to escape host immune detection, then they can identify the strains of that are most likely to be involved in upcoming influenza epidemics and can target those strains for vaccine production.

How can biologists make such predictions? By examining the ratio of synonymous to nonsynonymous substitutions in genes that encode viral surface proteins, biologists can detect which codon changes (i.e., mutations) are under positive selection (Concept 15.5). They can then assess which of the currently circulating flu strains show the greatest number of changes in these positively selected codons. It is these flu strains that are most likely to survive and lead to the flu epidemics of the future, so they are the best targets for new vaccines. This practical application of evolutionary theory leads to more effective flu vaccines—and thus fewer illnesses and influenza-related deaths each year.

15

SUMMARY

concept 15.1 Evolution Is Both Factual and the Basis of Broader Theory

- **Evolution** is genetic change in populations over time. Evolution can be observed directly in living populations as well as in the fossil record of life.
- **Evolutionary theory** refers to our understanding and application of the mechanisms of evolutionary change.
- Charles Darwin is best known for his ideas on the common ancestry of divergent species and on **natural selection** as a mechanism of evolution. See **ANIMATED TUTORIAL 15.1**
- Since Darwin’s time, many biologists have contributed to the development of evolutionary theory, and rapid progress in our understanding continues today. **Review Figure 15.2**

concept 15.2 Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution

- Mutation produces new genetic variants (**alleles**).
- Within populations, natural selection acts to increase the frequency of beneficial alleles and decrease the frequency of deleterious alleles.

- **Adaptation** refers both to a trait that evolves through natural selection and to the process that produces such traits.
- Migration or mating of individuals between populations results in **gene flow**.
- In small populations, **genetic drift**—the random loss of individuals and the alleles they possess—may produce large changes in allele frequencies from one generation to the next and greatly reduce genetic variation.
- **Population bottlenecks** occur when only a few individuals survive a random event, resulting in a drastic shift in allele frequencies within the population and the loss of variation. Similarly, a population established by a small number of individuals colonizing a new region may lose variation via a **founder effect**. **Review Figure 15.7**
- **Nonrandom mating** may result in changes in genotype frequencies in a population.
- **Sexual selection** results from differential mating success of individuals based on their phenotype. **Review Figure 15.9 and WORKING WITH DATA 15.1**

concept 15.3 Evolution Can Be Measured by Changes in Allele Frequencies

- Allele frequencies measure the amount of genetic variation in a population. Genotype frequencies show how a population's genetic variation is distributed among its members. Together, allele and genotype frequencies describe a population's **genetic structure**. **Review Figure 15.10 and INTERACTIVE TUTORIAL 15.1**
- **Hardy-Weinberg equilibrium** predicts genotype frequencies from allele frequencies in the absence of evolution. Deviation from these frequencies indicates that evolutionary mechanisms are at work. **Review Figure 15.11 and ANIMATED TUTORIAL 15.2**

concept 15.4 Selection Can Be Stabilizing, Directional, or Disruptive

- Natural selection can act on characters with quantitative variation in three different ways. **Review Figure 15.12**
- **Stabilizing selection** acts to reduce variation without changing the mean value of a trait.
- **Directional selection** acts to shift the mean value of a trait toward one extreme.
- **Disruptive selection** favors both extremes of trait values, resulting in a bimodal character distribution.

concept 15.5 Genomes Reveal Both Neutral and Selective Processes of Evolution

- **Nonsynonymous substitutions** of nucleotides result in amino acid replacements in proteins, but **synonymous substitutions** do not. **Review Figure 15.16**
- Rates of synonymous substitution are typically higher than rates of nonsynonymous substitution in protein-coding genes (a result of stabilizing selection). **Review Figure 15.17**
- Much of the change in nucleotide sequences over time is a result of neutral evolution. The rate of fixation of neutral mutations is independent of population size and is equal to the mutation rate.
- Positive selection for change in a protein-coding gene may be detected by a higher rate of nonsynonymous than synonymous substitution.

- Specific codons within a given gene sequence can be under different modes of selection. **Review Figure 15.19 and WORKING WITH DATA 15.2**
- The total size of genomes varies much more widely across multicellular organisms than does the number of functional genes. **Review Figures 15.20 and 15.21**
- Even though many noncoding regions of the genome may not have direct functions, these regions can affect the phenotype of an organism by influencing gene expression.
- Functionless **pseudogenes** can serve as the raw material for the evolution of new genes.

concept 15.6 Recombination, Lateral Gene Transfer, and Gene Duplication Can Result in New Features

- Despite its short-term disadvantages, sexual reproduction generates countless genotype combinations that increase genetic variation in populations.
- **Lateral gene transfer** can result in the rapid acquisition of new functions from distantly related species.
- **Gene duplications** can result in increased production of the gene's product, in divergence of the duplicated genes' expression, in pseudogenes, or in new gene functions. Several rounds of gene duplication can give rise to multiple genes with related functions, known as a gene family. **Review Figure 15.22 and WEB ACTIVITY 15.1**

concept 15.7 Evolutionary Theory Has Practical Applications

- Protein function can be studied by examining gene evolution. Detection of positive selection can be used to identify molecular changes that have resulted in functional changes.
- Agricultural applications of evolution include the development of new crop plants and domesticated animals, as well as a reduction in the rate of evolution of pesticide resistance.
- **In vitro evolution** is used to produce synthetic molecules with particular desired functions. **Review Figure 15.23**
- Many diseases are identified, studied, and combated through molecular evolutionary investigations.

Reconstructing and Using Phylogenies

16

Green fluorescent protein (GFP) was discovered in 1962 when Osamu Shimomura, an organic chemist and marine biologist, led a team that was able to purify the protein from the tissues of the bioluminescent jellyfish *Aequorea victoria*. Some 30 years after its initial discovery, Martin Chalfie had the idea (and the technology) to link the gene for GFP to other protein-coding genes, so that the expression of specific genes of interest could be visualized in glowing green within cells and tissues of living organisms (see Figure 13.6). This work was extended by Roger Tsien, who changed some of the amino acids within GFP to create proteins of several distinct colors. Different colored proteins meant that the expression of a number of different proteins could be visualized and studied in the same organism at the same time. These three scientists were awarded the 2008 Nobel Prize in Chemistry for the isolation and development of GFP for visualizing gene expression.

Although Tsien was able to produce different colored proteins, he could not produce a red protein. This was frustrating; a red fluorescent protein would be particularly useful to biologists because red light penetrates tissues more easily than do other colors. Tsien's work stimulated Mikhail Matz to look for new fluorescent proteins in corals (which are relatives of the jellyfishes). Among the different species he studied, Matz found coral proteins that fluoresced in various shades of green, cyan (blue-green)—and red.

How had fluorescent red pigments evolved among the corals, given that the necessary molecular changes had eluded Tsien? To answer this question, Matz sequenced the genes of the fluorescent proteins and used these sequences to reconstruct the

evolutionary history of the amino acid changes that produced different colors in different species of corals.

Matz's work showed that the ancestral fluorescent protein in corals was green, and that red fluorescent proteins evolved in a series of gradual steps. His analysis of evolutionary relationships allowed him to retrace these steps. Such an evolutionary history, as depicted in a tree of relationships among lineages, is called a phylogeny.

The evolution of many aspects of an organism's biology can be studied using phylogenetic methods. This information is used in all fields of biology to understand the structure, function, and behavior of organisms.

The reef-building coral *Acropora millepora* shows cyan and red fluorescence. This photograph was taken under a fluorescent microscope that affects the colors we see; the colors are perceived differently by marine animals in their natural environment.

How are phylogenetic methods used to resurrect protein sequences from extinct organisms?

KEY CONCEPTS

- 16.1** All of Life Is Connected through Its Evolutionary History

- 16.3** Phylogeny Makes Biology Comparative and Predictive
- 16.4** Phylogeny Is the Basis of Biological Classification

concept 16.1 All of Life Is Connected through Its Evolutionary History

The sequencing of complete genomes from many diverse species has confirmed what biologists have long suspected: all of life is related through a common ancestor. The common ancestry of life explains why the general principles of biology apply to all organisms. Thus we can learn much about how the human genome works by studying the biology of model organisms because we share a common evolutionary history with those organisms. The evolutionary history of these relationships is known as **phylogeny**, and a **phylogenetic tree** is a diagrammatic reconstruction of that history.

Phylogenetic trees are commonly used to depict the evolutionary history of species, populations, and genes. For many years such trees have been constructed based on physical structures, behaviors, and biochemical attributes. Now, as genomes are sequenced for more and more organisms, biologists are able to reconstruct the history of life in ever greater detail.

In Chapter 15, we discussed why we expect populations of organisms to evolve over time. Such a series of ancestor and descendant populations forms a **lineage**, which we can depict as a line drawn on a time axis:

What happens when a single lineage divides into two? For example, a geographic barrier may divide an ancestral population into two descendant populations that no longer interact with one another. We depict such an event as a split, or **node**, in a phylogenetic tree. Each of the descendant populations give rise to a new lineage, and as these independent lineages evolve, new traits arise in each:

As the lineages continue to split over time, this history can be represented in the form of a branching tree that can be used to trace the evolutionary relationships from the ancient common ancestor of a group of species, through the various lineage splits, up to the present populations of the organisms:

A phylogenetic tree may portray the evolutionary history of all life forms; of a major evolutionary group (such as the insects); of a small group of closely related species; or in some cases, even the history of individuals, populations, or genes within a species. The common ancestor of all the organisms in the tree forms the **root** of the tree. The depictions of phylogenetic trees in this book are rooted at the left, with time flowing from left (earliest) to right (most recent):

The timing of splitting events in lineages is shown by the position of nodes on a time axis. These splits represent events where one lineage diverged into two, such as a **speciation event** (for a tree of species), a **gene duplication event** (for a tree of genes), or a **transmission event** (for a tree of viral lineages transmitted through a host population). The time axis may have an explicit scale, or it may simply show the relative timing of divergence events.

In this book's illustrations, the order in which nodes are placed along the horizontal (time) axis has meaning, but the vertical

distance between the branches does not. Vertical distances have been adjusted for legibility and clarity of presentation; they do not correlate with the degree of similarity or difference between groups. Note too that lineages can be rotated around nodes in the tree, so the vertical order of lineages is also largely arbitrary:

Any group of species that we designate with a name is a **taxon** (plural *taxa*). Examples of familiar taxa include humans, primates, mammals, and vertebrates; in this series, each taxon is also a member of the next, more inclusive taxon. Any taxon that consists of all the evolutionary descendants of a common ancestor is called a **clade**. Clades can be identified by picking any point on a phylogenetic tree and from that point tracing all the descendant lineages to the tips of the terminal branches (**FIGURE 16.1**). Two species that are each other's closest relatives are called **sister species**; similarly, any two clades that are each other's closest relatives are **sister clades**.

Before the 1980s, phylogenetic trees tended to be seen only in the literature on evolutionary biology, especially in the area of **systematics**—the study and classification of biodiversity. But almost every journal in the life sciences published during the last few years contains phylogenetic trees. Trees are widely used in molecular biology, biomedicine, physiology, behavior, ecology, and virtually all other fields of biology. Why have phylogenetic studies become so widespread?

Phylogenetic trees are the basis of comparative biology

In biology, we study life at all levels of organization—from genes, cells, organisms, populations, and species to the major divisions of life. In most cases, however, no individual gene or organism (or other unit of study) is exactly like any other gene or organism that we investigate.

Consider the individuals in your biology class. We recognize each person as an individual human, but we know that no two are exactly alike. If we knew everyone's family tree in detail, the genetic similarity of any pair of students would be more predictable. We would find that more closely related students have many more traits in common (from the color of their hair to their susceptibility or resistance to diseases). Likewise, biologists use phylogenies to make comparisons and predictions about shared traits across genes, populations, and species.

The evolutionary relationships among species, as represented in the tree of life, form the basis for biological classification. Biologists estimate that there are tens of millions of species on Earth. So far, however, only about 1.8 million species have been *classified*—that is, formally described and named. New species are being

FIGURE 16.1 Clades Represent All the Descendants of a Common Ancestor All clades are subsets of larger clades, with all of life as the most inclusive taxon. In this example, the groups called mammals, amniotes, tetrapods, and vertebrates represent successively larger clades. Only a few species within each clade are represented on this tree.

discovered all the time and phylogenetic analyses are constantly reviewed and revised, so our knowledge of the tree of life is far from complete. Yet knowledge of evolutionary relationships is essential for making comparisons in biology, so biologists build phylogenies for groups of interest as the need arises. The tree of life's evolutionary framework allows us to make many predictions about the behavior, ecology, physiology, genetics, and morphology of species that have not yet been studied in detail.

When biologists compare species, they observe traits that differ within the group of interest and try to ascertain when these traits evolved. In many cases, investigators are interested in how the evolution of a trait relates to environmental conditions or selective pressures. For instance, scientists have used phylogenetic analyses to discover changes in the genome of human immunodeficiency virus that confer resistance to particular drug treatments. The association of a particular genetic change in HIV with a particular treatment provides a hypothesis about the evolution of resistance that can be tested experimentally.

Any features shared by two or more species that have been inherited from a common ancestor are said to be **homologous**. Homologous features may be any heritable traits, including DNA sequences, protein structures, anatomical structures, and even some behavior patterns. For example, all living vertebrates have a vertebral column, as did the ancestral vertebrate. Therefore, the vertebral column is judged to be homologous in all vertebrates.

Derived traits provide evidence of evolutionary relationships

In tracing the evolution of a character, biologists distinguish between *ancestral* and *derived* traits. Each character of an organism evolves from one condition (the **ancestral trait**) to another condition (the **derived trait**). Derived traits that are shared among a group of organisms and are also viewed as evidence of the common ancestry of the group are called **synapomorphies** (*syn*, “shared”; *apo*, “derived”; *morph*, “form,” referring to the “form” of a trait). Thus the vertebral column is considered a synapomorphy—a shared, derived trait—of the vertebrates. (The ancestral trait was an undivided supporting rod.)

Not all similar traits are evidence of relatedness. Similar traits in unrelated groups of organisms can develop for either of the following reasons:

- Superficially similar traits may evolve independently in different lineages, a phenomenon called **convergent evolution**. For example, although the *wing bones* of bats and birds are homologous, having been inherited from a common tetrapod ancestor, the *wings* of bats and birds are not homologous because they evolved independently from the forelimbs of different nonflying ancestors (**FIGURE 16.2**).
- A character may revert from a derived state back to an ancestral state in an event called an **evolutionary reversal**. For example, the derived limbs of terrestrial tetrapods evolved from the ancestral fins of their aquatic ancestors. Then, within the mammals, the ancestors of modern cetaceans (whales and dolphins) returned to the ocean, and cetacean

FIGURE 16.2 The Bones Are Homologous, the Wings Are Not The supporting bone structures of both bat wings and bird wings are derived from a common tetrapod (four-limbed) ancestor and are thus homologous. However, the wings themselves—an adaptation for flight—evolved independently in the two groups.

limbs evolved to once again resemble their ancestral state—fins. The superficial similarity of cetacean and fish fins does not suggest a close relationship between these groups; the similarity arises from evolutionary reversal.

Similar traits generated by convergent evolution and evolutionary reversals are called *homoplastic traits* or **homoplasies**.

A particular trait may be ancestral or derived, depending on our point of reference. For example, all birds have feathers. We infer from this that feathers (which are highly modified scales) were present in the common ancestor of modern birds. Therefore, we consider the presence of feathers to be an *ancestral* trait for any particular group of modern birds, such as the songbirds. However, feathers are not present in any other living animals. In reconstructing a phylogeny of all living vertebrates, the presence of feathers is a *derived* trait found only among birds, and thus is a synapomorphy of the birds.

Do You Understand Concept 16.1?

- What biological processes are represented in a phylogenetic tree?
- Why is it important to consider only homologous characters in reconstructing phylogenetic trees?
- What are some reasons that similar traits might arise independently in species that are only distantly related? Can you think of examples among familiar organisms?

Phylogenetic analyses of evolutionary history have become increasingly important to many types of biological research in recent years, and they are the basis for the comparative nature of biology. For the most part, however, evolutionary history cannot be observed directly. How, then, do biologists reconstruct the past?

concept 16.2 Phylogeny Can Be Reconstructed from Traits of Organisms

Consider the eight vertebrate animals listed in **TABLE 16.1**: lamprey, perch, salamander, lizard, crocodile, pigeon, mouse, and chimpanzee. To illustrate how the phylogenetic tree in **FIGURE 16.3** is constructed, we assume initially that a given derived trait arose only once during the evolution of these animals (there has been no convergent evolution), and that no derived traits were lost from any of the descendant groups (there has been no evolutionary reversal). For simplicity, we have selected traits that are either present (+) or absent (–).

In a phylogenetic study, the group of organisms of primary interest is called the **ingroup**. As a point of reference, an ingroup is compared with an **outgroup**: a species or group known to be closely related to but phylogenetically outside the group of interest. If the outgroup is known to have diverged before the ingroup, the outgroup can be used to determine which traits of the ingroup are derived (i.e., evolved within the

TABLE 16.1 Eight Vertebrates and the Presence or Absence of Some Shared Derived Traits

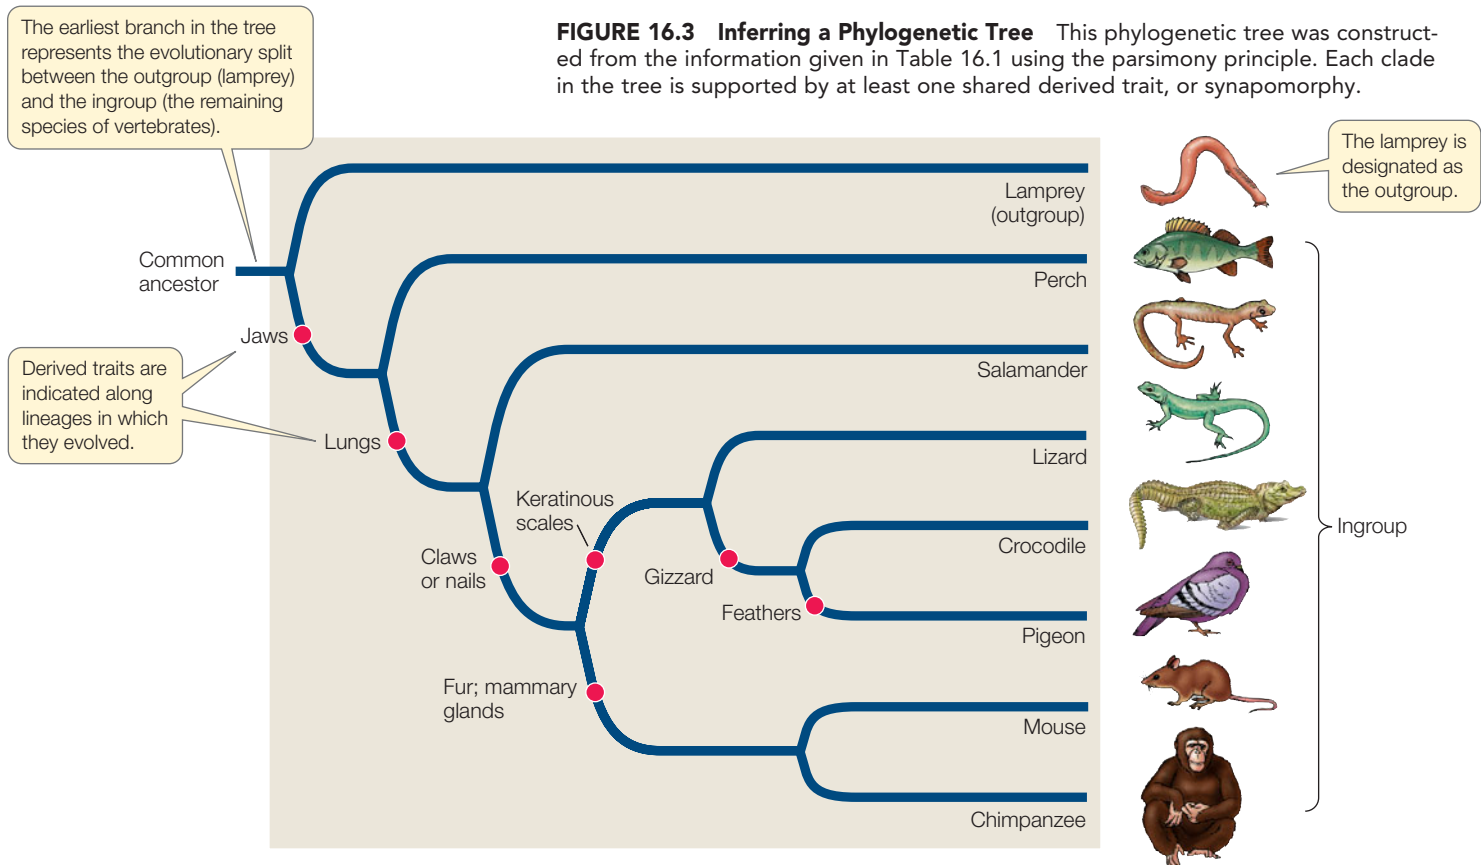

TAXON	DERIVED TRAIT							
	JAWS	LUNGS	CLAWS OR NAILS	GIZZARD	FEATHERS	FUR	MAMMARY GLANDS	KERATINOUS SCALES
Lamprey (outgroup)	-	-	-	-	-	-	-	-
Perch	+	-	-	-	-	-	-	-
Salamander	+	+	-	-	-	-	-	-
Lizard	+	+	+	-	-	-	-	+
Crocodile	+	+	+	+	-	-	-	+
Pigeon	+	+	+	+	+	-	-	+
Mouse	+	+	+	-	-	+	+	-
Chimpanzee	+	+	+	-	-	+	+	-

ingroup) and which are ancestral (i.e., evolved before the origin of the ingroup). The lamprey belongs to a group of jawless fishes thought to have separated from the lineage leading to the other vertebrates before the jaw arose. Therefore, we have specified the lamprey as the outgroup for our analysis. Because derived traits were acquired by other members of the vertebrate lineage *after* they diverged from the outgroup, any trait that is present in both the lamprey and the other vertebrates is judged to be ancestral.

We begin by noting that the chimpanzee and mouse share two traits—mammary glands and fur—that are absent in both

the outgroup and in the other species of the ingroup. Therefore, we infer that mammary glands and fur are derived traits that evolved in a common ancestor of chimpanzees and mice after that lineage separated from the lineages leading to the other vertebrates. These characters are synapomorphies that unite chimpanzees and mice (as well as all other mammals, although we have not included other mammalian species in

yourBioPortal.com
 Go to **WEB ACTIVITY 16.1**
 Constructing a Phylogenetic Tree

this example). By the same reasoning, we can infer that the other shared derived traits are synapomorphies for the various groups in which they are expressed. For instance, keratinous scales are a synapomorphy of the lizard, crocodile, and pigeon.

Table 16.1 also tells us that, among the animals in our group, the pigeon has a unique trait: the presence of feathers. Feathers are a synapomorphy of birds and their extinct relatives. However, because we only have one bird in this example, the presence of feathers provides no clues concerning relationships among these eight species of vertebrates. However, lizards are found in both birds and crocodiles, so this trait is evidence of a close relationship between birds and crocodilians.

By combining information about the various synapomorphies, we can construct the phylogenetic tree in Figure 16.3. We infer from our information that mice and chimpanzees—the only two animals that share fur and mammary glands—share a more recent common ancestor with each other than they do with pigeons and crocodiles. Otherwise, we would need to assume that the ancestors of pigeons and crocodiles also had fur and mammary glands but subsequently lost them; these additional assumptions are unnecessary in this case.

This particular tree was easy to construct because it is based on a very small sample of traits, and the derived traits we examined evolved only once and were never lost after they appeared. Had we included a snake in the group, our analysis would not have been as straightforward. We would need to examine additional characters to determine that snakes evolved from a group of lizards that had limbs. In an evolutionary

reversal, limbs were lost in the ancestors of snakes as an adaptation to a subterranean existence.

Typically, biologists construct phylogenetic trees using hundreds or thousands of traits. With larger data sets, we would expect to observe traits that have changed more than once, and thus would expect to see convergence and evolutionary reversal. How do we determine which traits are synapomorphies and which are homoplasies? One way is to invoke the principle of *parsimony*.

Parsimony provides the simplest explanation for phylogenetic data

In its most general form, the **parsimony principle** states that the preferred explanation of observed data is the simplest explanation. Applying the principle of parsimony to the reconstruction of phylogenies entails minimizing the number of evolutionary changes that need to be assumed over all characters in all groups in the tree. In other words, the best hypothesis under the parsimony principle is one that requires the fewest homoplasies. This application of parsimony is a specific case of a general principle of reasoning called *Occam's razor*: The best explanation is the one that best fits the data while making the fewest assumptions. More complicated explanations are accepted only when the evidence requires them. Phylogenetic trees represent our best estimates about evolutionary relationships, given the evidence available. As with all analyses in science, phylogenetic trees are continually modified as additional information is obtained.

APPLY THE CONCEPT

Phylogeny can be reconstructed from traits of organisms

The matrix below supplies data for seven land plants and an outgroup (an aquatic plant known as a stonewort). Each trait is scored as either present (+) or absent (–) in each of the plants. Use this data matrix to reconstruct the phylogeny of land plants and answer the questions.

1. Which two of these taxa are most closely related?

- Plants that produce seeds are known as seed plants. What is the sister group to the seed plants among these taxa?
- Which two traits evolved along the same branch of your reconstructed phylogeny?
- Are there any homoplasies in your reconstructed phylogeny?

TAXON	TRAIT						
	PROTECTED EMBRYOS	TRUE ROOTS	PERSISTENTLY GREEN SPOROPHYTE	VASCULAR CELLS	STOMATA	MEGAPHYLLS (TRUE LEAVES)	SEEDS
Stonewort (outgroup)	–	–	–	–	–	–	–
Liverwort	+	–	–	–	–	–	–
Pine tree	+	+	+	+	+	+	+
Bracken fern	+	+	+	+	+	+	–
Club moss	+	+	+	+	+	–	–
Sphagnum moss	+	–	–	–	+	–	–
Hornwort	+	–	+	–	+	–	–
Sunflower	+	+	+	+	+	+	+

Phylogenies are reconstructed from many sources of data

Naturalists have constructed various forms of phylogenetic trees for more than 150 years. In fact, the only figure in the first edition of Darwin's *Origin of Species* was a conceptual diagram of a phylogenetic tree. Phylogenetic tree construction has been revolutionized by the advent of computer software that allows us to consider far more data and analyze far more traits than could ever before be processed. Combining these advances in methodology with the massive comparative data sets being generated through genome sequencing and other molecular studies, biologists are learning details about the tree of life at a remarkable pace.

Any trait that is genetically determined—and therefore heritable—can be used in a phylogenetic analysis. Evolutionary relationships can be revealed through studies of morphology, development, the fossil record, behavioral traits, and molecular traits such as DNA and protein sequences.

yourBioPortal.com

Go to INTERACTIVE TUTORIAL 16.1
Phylogeny and Molecular Evolution

MORPHOLOGY An important source of phylogenetic information is *morphology*: the presence, size, shape, and other attributes of body parts. Since living organisms have been observed, depicted, and studied for millenia, we have a wealth of recorded morphological data as well as extensive museum and herbarium collections of organisms whose traits can be measured. New technological tools, such as the electron microscope and computed tomography (CT) scans, enable systematists to examine and analyze the structures of organisms at much finer scales than was formerly possible.

Most species are described and known primarily by their morphology, and morphology still provides the most comprehensive data set available for many taxa. The morphological features that are important for phylogenetic analysis are often specific to a particular group. For example, the presence, development, shape, and size of various features of the skeletal system are important in vertebrate phylogeny, whereas the structures of the floral organs (petals, carpels, stamens and sepals; see p. 557) are important for studying the relationships among flowering plants.

Reconstructing the evolutionary relationships of most extinct species depends almost exclusively on morphological comparisons. Fossils show us where and when organisms lived in the past and give us an idea of what they looked like. Fossils provide important evidence that helps distinguish ancestral from derived traits. The fossil record can also reveal when lineages diverged and began their independent evolutionary histories. Furthermore, in groups with few species that have survived to the present, information on extinct species is often critical to an understanding of the large divergences among the surviving species. The fossil record is limited, however; for some groups, few or no fossils have been found, and for others the fossil record is fragmentary.

Although useful, morphological approaches to phylogenetic analysis do have limitations. Some taxa exhibit little morphological diversity, despite great species diversity. For example, the

phylogeny of the leopard frogs of North and Central America would be difficult to infer from morphological differences alone, because the many species look very similar, despite important differences in their behavior and physiology. At the other extreme, few morphological traits can be compared across distantly related species (an earthworm and a mammal, for instance). Furthermore, some morphological variation has an environmental rather than a genetic basis and so must be excluded from phylogenetic analyses. For these reasons, an accurate phylogenetic analysis often requires information beyond that supplied by morphology.

DEVELOPMENT Observations of similarities in developmental patterns may reveal evolutionary relationships. Some organisms exhibit similarities in early developmental stages only. The larvae of marine creatures called sea squirts, for example, have a flexible gelatinous rod in the back—the *notochord*—that disappears as the larvae develop into adults. All vertebrate animals also have a notochord at some time during their development (**FIGURE 16.4**). This shared structure is one of the reasons for inferring that sea squirts are more closely related to vertebrates than would be suspected if only adult sea squirts were examined.

LINK For more on the role of developmental processes in evolution, see Concepts 14.4 and 14.5

BEHAVIOR Some behavioral traits are culturally transmitted (learned from other individuals); others have a genetic basis (see Chapter 41). If a particular behavior is culturally transmitted, it may not accurately reflect evolutionary relationships (but may nonetheless reflect cultural connections). Bird songs, for instance, are often learned and may be inappropriate traits for phylogenetic analysis. Frog calls, however, are genetically determined and appear to be acceptable sources of information for reconstructing phylogenies.

MOLECULAR DATA All heritable variation is encoded in DNA, and so the complete genome of an organism contains an enormous set of traits (the individual nucleotide bases of DNA) that can be used in phylogenetic analyses. In recent years, DNA sequences have become among the most widely used sources of data for constructing phylogenetic trees. Comparisons of nucleotide sequences are not limited to the DNA in the cell nucleus. Eukaryotes have genes in their mitochondria as well as in their nuclei; plant cells have genes in their chloroplasts as well.

The chloroplast genome (cpDNA) is used extensively in phylogenetic studies of plants because it has changed slowly over evolutionary time and can thus be used to study relatively ancient phylogenetic relationships. Most animal mitochondrial DNA (mtDNA) has changed more rapidly, so mitochondrial genes are used to study evolutionary relationships among closely related animal species (the mitochondrial genes of plants evolve more slowly). Many nuclear gene sequences are also commonly analyzed, and now that entire genomes have been sequenced from many species, they too are used to construct phylogenetic trees. Information on gene products (such as the amino acid sequences of proteins) is also widely used for phylogenetic analyses.

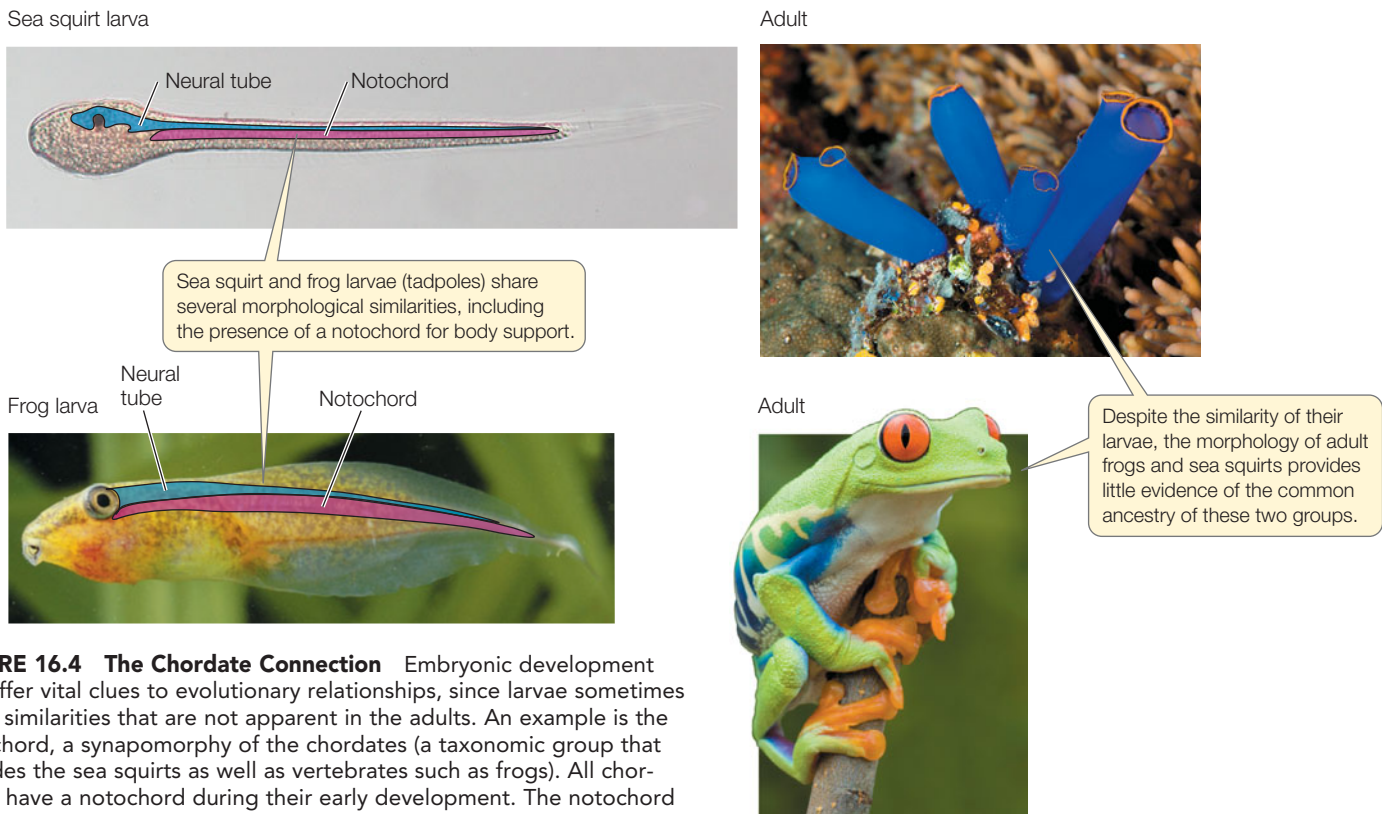

FIGURE 16.4 The Chordate Connection Embryonic development can offer vital clues to evolutionary relationships, since larvae sometimes share similarities that are not apparent in the adults. An example is the notochord, a synapomorphy of the chordates (a taxonomic group that includes the sea squirts as well as vertebrates such as frogs). All chordates have a notochord during their early development. The notochord is lost in adult sea squirts, whereas in adult frogs—as in all vertebrates—the vertebral column replaces the notochord as the body’s support structure.

Mathematical models expand the power of phylogenetic reconstruction

As biologists began to use DNA sequences to infer phylogenies, they developed explicit mathematical models describing how DNA sequences change over time. These models account for multiple changes at a given position in a DNA sequence. They also take into account different rates of change at different positions in a gene, at different positions in a codon, and among different nucleotides. For example, *transitions* (changes between two purines or between two pyrimidines) are usually more likely than are *transversions* (changes between a purine and pyrimidine).

Mathematical models can be used to compute how a tree might evolve given the observed data. A **maximum likelihood** method will identify the tree that most likely produced the observed data, given the assumed model of evolutionary change. Maximum likelihood methods can be used for any kind of characters, but they are most often used with molecular data, for which explicit mathematical models of evolutionary change are easier to develop. The principal advantages to maximum likelihood analyses are that they incorporate more information about evolutionary change than do parsimony methods, and they are easier to treat in a statistical framework. The principal disadvantages are that they are computationally intensive and require explicit models of evolutionary change (which may not be available for some kinds of character change).

The accuracy of phylogenetic methods can be tested

If phylogenetic trees represent reconstructions of past events, and if many of these events occurred before any humans were around to witness them, how can we test the accuracy of phylogenetic methods? Biologists have conducted experiments both in living organisms and with computer simulations that have demonstrated the effectiveness and accuracy of phylogenetic methods.

In one experiment designed to test the accuracy of phylogenetic analysis, a single viral culture of bacteriophage T7 was used as a starting point, and lineages were allowed to evolve from this ancestral virus in the laboratory (**FIGURE 16.5**). The initial culture was split into two separate lineages, one of which became the ingroup for analysis and the other of which became the outgroup for rooting the tree. The lineages in the ingroup were split in two after every 400 generations, and samples of the virus were saved for analysis at each branching point. The lineages were allowed to evolve until there were eight lineages in the ingroup. Mutagens were added to the viral cultures to increase the mutation rate so that the amount of change and the degree of homoplasy would be typical of the organisms analyzed in average phylogenetic analyses. The investigators then sequenced samples from the end points of the eight lineages, as well as from the ancestors at the branching points. They then gave the sequences from the end points of the lineages to other

INVESTIGATION

FIGURE 16.5 The Accuracy of Phylogenetic Analysis
To test whether analysis of gene sequences can accurately reconstruct evolutionary phylogeny, we must have an unambigu-

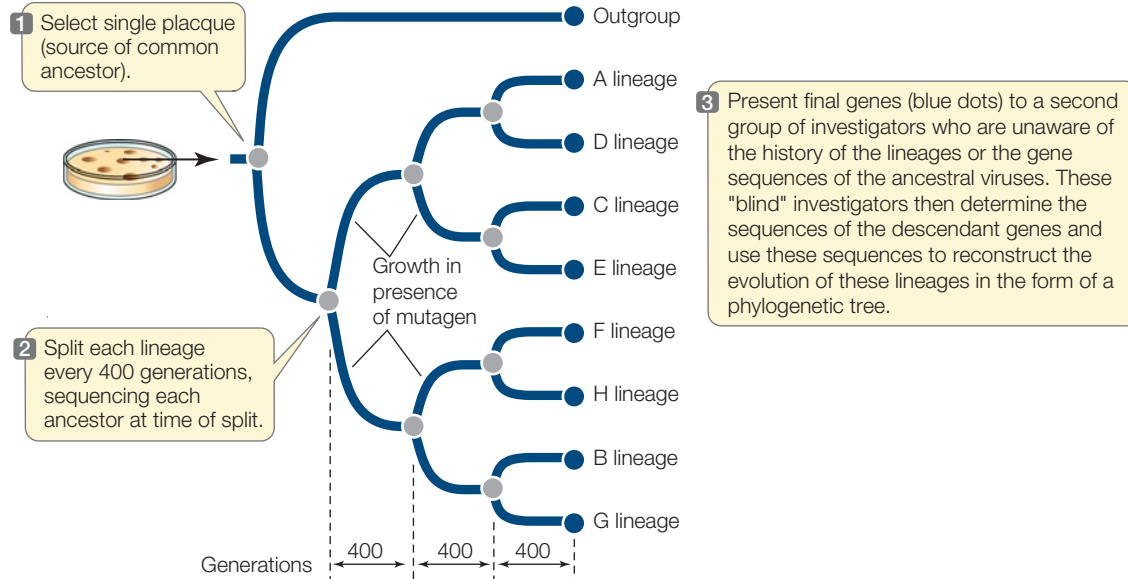

ously known phylogeny to compare against the reconstruction. Will the observed phylogeny match the reconstruction?

HYPOTHESIS

A phylogeny reconstructed from analysis of the DNA sequences of living organisms can accurately match the known evolutionary history of the organisms.

METHOD

In the laboratory, one group of investigators produced an unambiguous phylogeny of 9 viral lineages, enhancing the mutation rate to increase variation among the lineages.

RESULTS

The true phylogeny and ancestral DNA sequences were accurately reconstructed solely from the DNA sequences of the viruses at the tips of the tree.

CONCLUSION

Phylogenetic analysis of DNA sequences can accurately reconstruct evolutionary history.

ANALYZE THE DATA

The full DNA sequences for the T7 strains in this experiment are thousands of nucleotides long. The nucleotides ("characters") at 23 DNA positions are given in the table.

	Character at position

investigators to analyze, without revealing the known history of the lineages or the sequences of the ancestral viruses.

After the phylogenetic analysis was completed, the investigators asked two questions. Did phylogenetic methods reconstruct the known history correctly? And, were the sequences of the ancestral viruses reconstructed accurately? The answer in both cases was “yes.” The branching order of the lineages was reconstructed exactly as it had occurred; more than 98% of the nucleotide positions of the ancestral viruses were reconstructed correctly; and 100% of the amino acid changes in the viral proteins were reconstructed correctly.

Using Phylogenetic Analysis to Reconstruct
Evolutionary History

The experiment shown in Figure 16.5 demonstrated that phylogenetic analysis was accurate under the conditions tested, but it did not examine all possible conditions. Other experimental studies have taken other factors into account, such as the sensitivity of phylogenetic analysis to convergent environments and highly variable rates of evolutionary change. In addition, computer simulations based on evolutionary models have been used extensively to study the effectiveness of phylogenetic analysis. These studies have also confirmed the accuracy of phylogenetic methods and have been used to refine those methods and extend them to new applications.

Do You Understand Concept 16.2?

- How is the parsimony principle used in reconstructing evolutionary history?
- Why is it useful to consider the entire life cycle when reconstructing an organism’s evolutionary history?
- What are some comparative advantages and disadvantages of morphological and molecular approaches for reconstructing phylogenetic trees?
- Contrast experimental and simulation approaches for testing the accuracy of phylogenetic reconstructions of evolutionary history. Can you think of some aspects of phylogenetic accuracy that might be more practical to test using computer simulation than with experimental studies of viruses?

Why do biologists expend the time and effort necessary to reconstruct phylogenies? In fact, information about the evolutionary relationships among organisms is a useful source of data for scientists investigating a wide variety of biological questions. Next we will describe how phylogenetic trees are used to answer questions about the past, and to predict and compare traits of organisms in the present.

concept 16.3 Phylogeny Makes Biology Comparative and Predictive

Once a phylogeny is reconstructed, what do we do with it? What beyond an understanding of evolutionary history does phylogeny offer us?

Reconstructing the past is important for understanding many biological processes

Phylogeny often clarifies the origin and evolution of traits that are of great interest in understanding fundamental biological processes. This information is then widely applied in diverse fields in the life sciences, including agriculture and medicine.

SELF-COMPATIBILITY Like most animals, flowering plants (angiosperms) often reproduce by mating with another individual of the same species. But in many angiosperm species, the same individual produces both male and female gametes (contained within pollen and ovules, respectively). *Self-incompatible* species have mechanisms to prevent fertilization of the ovule by the individual’s own pollen, and so must reproduce by *outcrossing* with another individual. Individuals of some species, however, regularly fertilize their ovules using their own pollen; they are self-fertilizing or *selfing* species, and their gametes are *self-compatible*.

The evolution of angiosperm fertilization mechanisms was examined in *Leptosiphon*, a genus in the phlox family that exhibits a diversity of mating systems and pollination mechanisms. The self-incompatible (outcrossing) species of *Leptosiphon* have long petals and are pollinated by long-tongued flies. In contrast, self-pollinating species have short petals and do not require insect pollinators to reproduce successfully. Using nuclear ribosomal DNA sequences, investigators reconstructed a phylogeny this genus (**FIGURE 16.6**). They then determined whether each species was self-compatible by artificially pollinating flowers with the plant’s own pollen or with pollen from other individuals and observing whether viable seeds formed.

The reconstructed phylogeny suggests that self-incompatibility is the ancestral state and that self-compatibility evolved three times within this group of *Leptosiphon*. The change to self-compatibility eliminated the plants’ dependence on an outside pollinator and has been accompanied by the evolution of reduced petal size. Indeed, the striking morphological similarity of the flowers in the self-compatible groups once led to their being classified as members of a single species. Phylogenetic analysis, however, shows them to be members of three distinct lineages.

LINK Some mechanisms of self-incompatibility are discussed in Concept 27.1

ZOO NOTIC DISEASES Many infectious pathogens, particularly viruses, affect individuals of only one species. However, *zoonotic diseases*, or *zoonoses*, are caused by infectious organisms transmitted from an infected animal of a different species. Approximately 150 zoonotic diseases are known to affect humans;

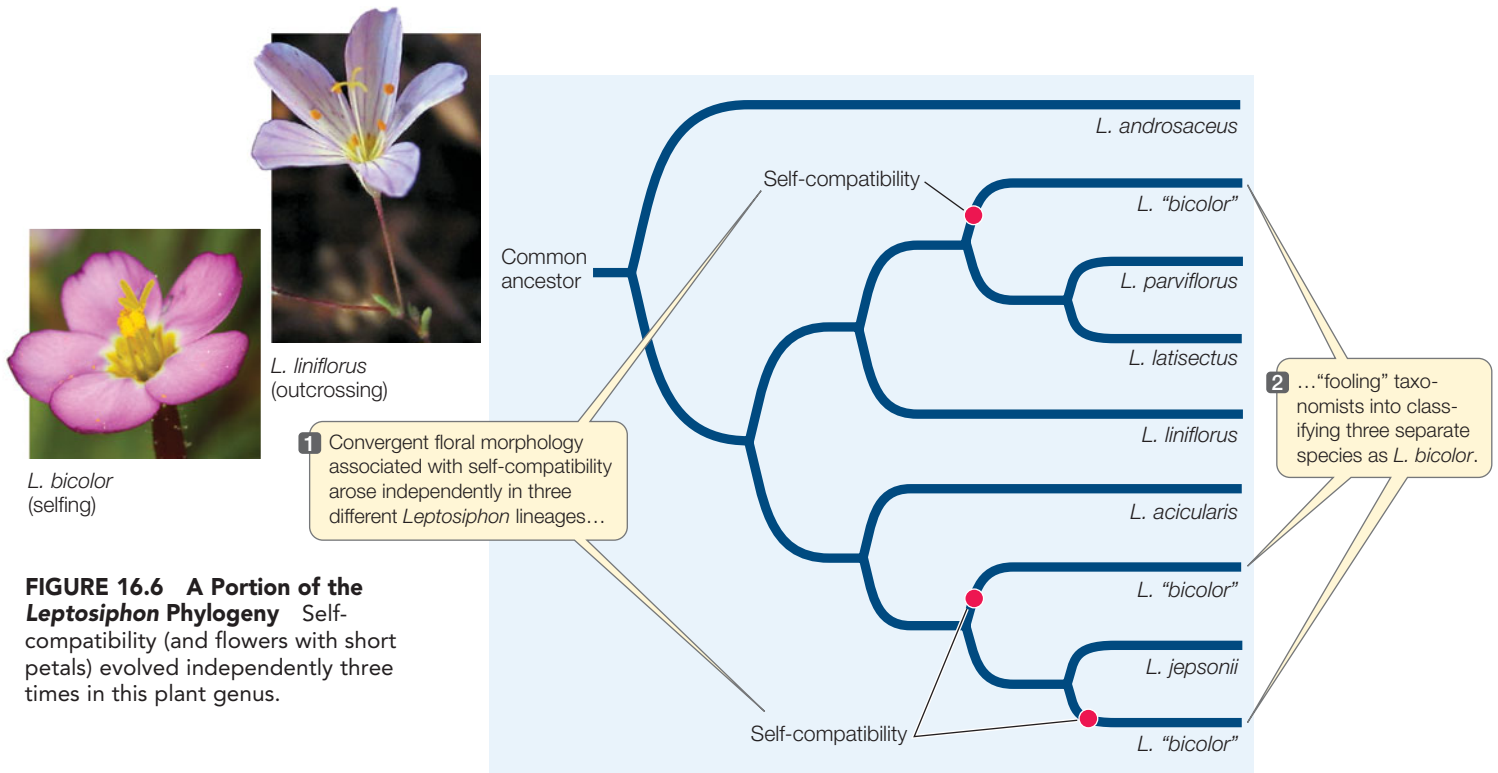

FIGURE 16.6 A Portion of the *Leptosiphon* Phylogeny Self-compatibility (and flowers with short petals) evolved independently three times in this plant genus.

rabies and bubonic plague are historically well-known examples. Lyme disease and acquired immunodeficiency syndrome (AIDS) are more recent examples of zoonotic transfers.

In dealing with zoonotic diseases, it is important to understand when, where, and how the disease first entered a human population. Phylogenetic analyses have become important for studying the transmission of zoonotic pathogens, including the human immunodeficiency virus (HIV) that causes AIDS. Phylogenies are also important for understanding the present global diversity of HIV and for determining the virus's origins in human populations. A broader phylogenetic analysis of immunodeficiency viruses shows that humans acquired these viruses from two different hosts: HIV-1 from chimpanzees, and HIV-2 from sooty mangabeys (FIGURE 16.7).

HIV-1 is the common form of the virus in human populations in central Africa, where chimpanzees are hunted for food. HIV-2 is the common form in human populations in western Africa, where sooty mangabeys are hunted for food. These viruses apparently entered human populations through hunters who cut themselves while skinning their primate prey. The

relatively recent global pandemic of AIDS occurred when these infections in local African populations spread through human populations around the world. By understanding how such viruses first entered human populations, health care workers can know what steps need to be taken to prevent other zoonotic diseases from spreading into human populations.

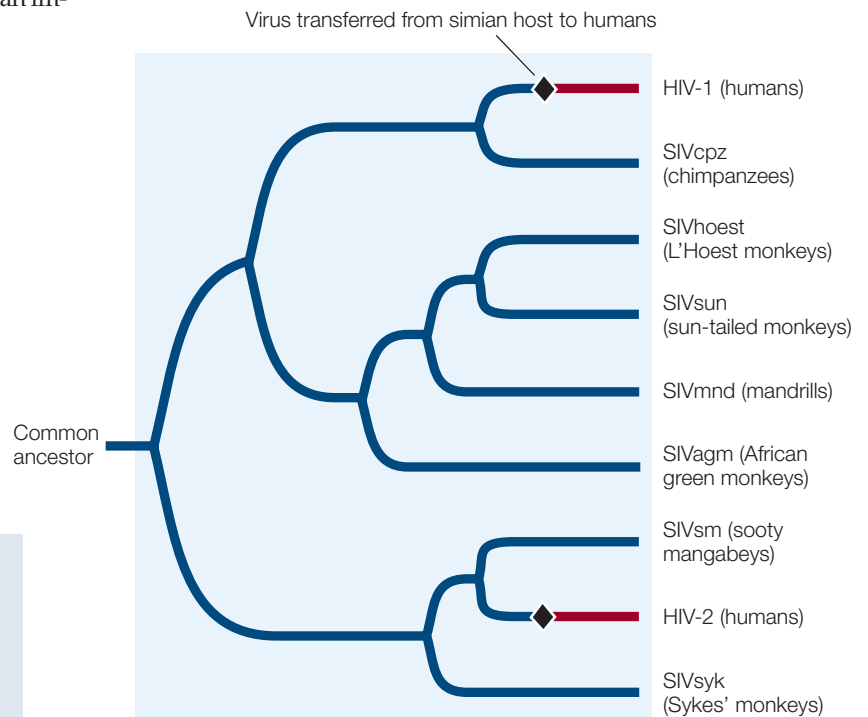

FIGURE 16.7 Phylogenetic Tree of Immunodeficiency Viruses Immunodeficiency viruses have been transmitted to humans from two different simian hosts: HIV-1 from chimpanzees and HIV-2 from sooty mangabeys. SIV stands for “simian immunodeficiency virus.”

FRONTIERS Using phylogenetics, it is often possible to trace rare viral infections in humans from specific sources, as in cases of forensic investigations of rape, aggravated assault, and even attempted murder. Biologists are now considering the possibility of tracing the transmission paths of common viral diseases among individuals. This information would allow epidemiologists to identify how these diseases spread, which could lead to prevention of future epidemics.

Understanding and developing new treatments for many viral diseases depends in large part on information from phylogenetic analyses. Different strains of dengue virus require different forms of treatment, but the virus changes quickly and new variants are found on a regular basis. Phylogenetic analyses show the relationships of a new dengue variant to known strains, which is an effective way to predict the most effective treatment.

Phylogenies allow us to understand the evolution of complex traits

Biologists are constantly confronted with evolutionary adaptations that at first seem puzzling, and many of these have to do with mating behavior and *sexual selection*. The tails of male widowbirds (see Figure 15.8) are one of many examples; another is found among the swordtail fishes.

Male swordtail fishes have a long, colorful tail extension, and their reproductive success is closely associated with this appendage. Males with a long sword are more likely to mate successfully than are males with a short sword. Several explanations have been advanced for the evolution of this structure, including the hypothesis that the sword exploits a preexisting bias in the sensory system of the female fish. This *sensory exploitation hypothesis* suggests that female swordtails had a bias to prefer males with long tails even before this trait evolved (perhaps because females assess the size of males by their total body length—including the tail—and prefer larger males).

To test the sensory exploitation hypothesis, phylogenetic analysis identified the swordtail relatives that had split most recently from their lineage before the evolution of sword extensions. These closest relatives turned out to be the platyfishes. Even though male platyfishes do not normally have swords, when researchers attached artificial swordlike structures to the tails of some male platyfishes and not others, female platyfishes preferred the males with artificial swords, thus providing support for the hypothesis that female swordtails had a preexisting sensory bias favoring tail extensions even before the trait evolved (FIGURE 16.8). Thus, a long tail became a sexually selected trait because of the preexisting preference of the females.

Ancestral states can be reconstructed

In addition to using phylogenetic methods to infer evolutionary relationships, biologists can use these techniques to reconstruct the morphology, behavior, or nucleotide and amino acid sequences of ancestral species (as was demonstrated for the ancestral sequence of bacteriophage T7 in Figure 16.5). For instance, a phylogenetic analysis was used to reconstruct an opsin protein in the ancestral archosaur (the most recent common ancestor of birds, dinosaurs, and crocodiles).

Opsins are pigment proteins involved in vision; different opsins (with different amino acid sequences) are excited by different wavelengths of light (see Figure 35.17). Investigators used phylogenetic analysis of opsin from living vertebrates to predict the amino acid sequence of the visual pigment that existed in the ancestral archosaur. A protein with the predicted sequence was then constructed in the laboratory. Investigators tested the reconstructed opsin and found a significant shift toward the red end of the spectrum in the light sensitivity of this protein compared with that of most modern opsins. Modern species that exhibit similar red (and infrared) sensitivity are adapted for nocturnal vision; thus the investigators inferred that the ancestral archosaur was likely to have been active at night. These findings may remind you of the movie *Jurassic Park*, although here the extinct species are being “brought back to life” one protein at a time.

Molecular clocks help date evolutionary events

For many applications, biologists want to know not only the order in which evolutionary lineages split but also the timing of those splits. In 1965, Emile Zuckerkandl and Linus Pauling hypothesized that rates of molecular change were constant enough that they could be used to predict evolutionary divergence times—an idea that has become known as the *molecular clock hypothesis*.

Different genes evolve at different rates. In addition, there are differences in evolutionary rates among species related to differing generation times, environments, efficiencies of DNA repair systems, and other biological factors. Nonetheless, among closely related species, a given gene usually evolves at

FIGURE 16.8 The Origin of a Sexually Selected Trait The large tail of male swordtail fishes (genus *Xiphophorus*) apparently evolved through sexual selection, with females mating preferentially with males with a longer “sword.” Phylogenetic analysis reveals that the platyfishes split from the swordtails before the evolution of the sword. The independent finding that female platyfishes prefer males with an artificial sword further supports the idea that this appendage evolved as a result of a preexisting preference in the females.

FIGURE 16.9 A Molecular Clock of the Protein Hemoglobin

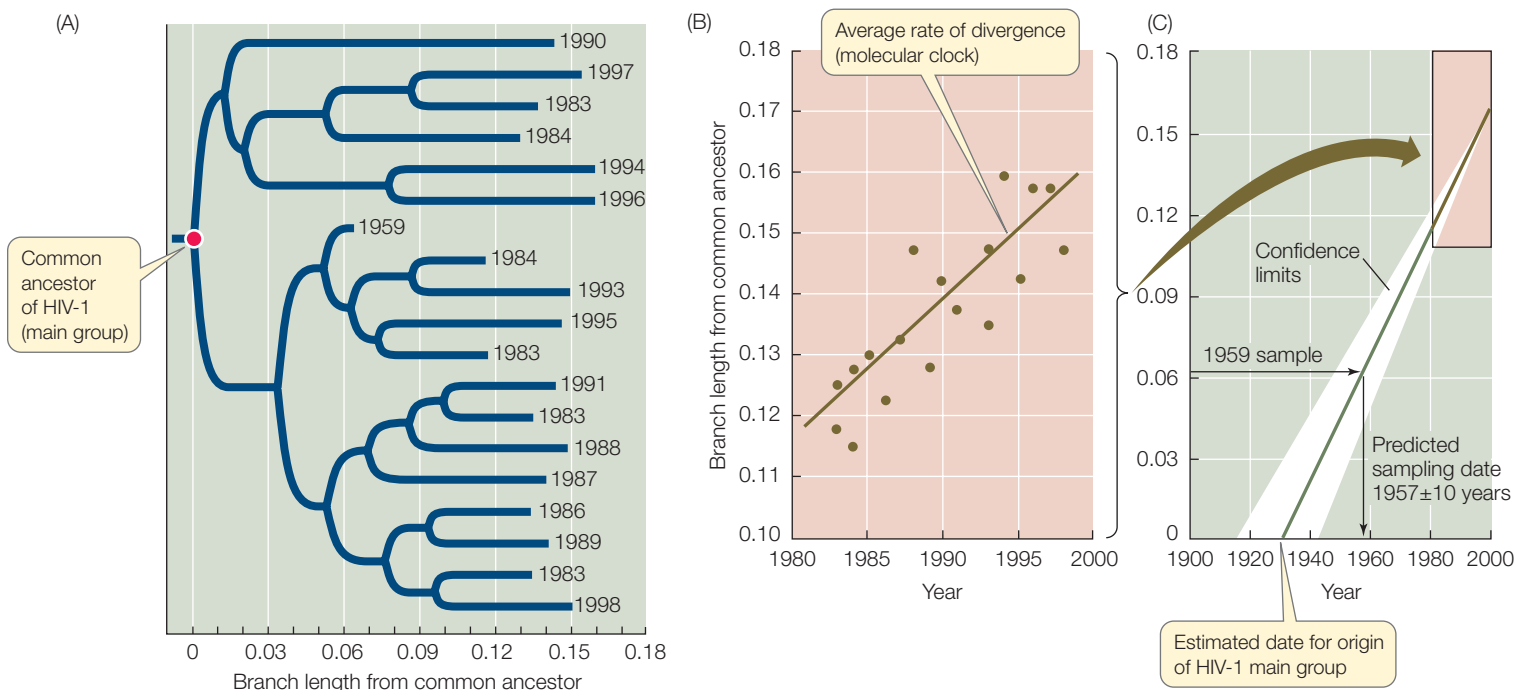

Amino acid replacements in hemoglobin have occurred at a relatively constant rate over nearly 500 million years of evolution. The graph shows the relationship between time of divergence and proportion of amino acid change for 13 pairs of vertebrate hemoglobin proteins. The average rate of change represents the molecular clock for hemoglobin in vertebrates.

a reasonably constant rate. Therefore, the protein encoded by the gene accumulates amino acid replacements at a relatively constant rate (FIGURE 16.9). A **molecular clock** uses the average rate at which a given gene or protein accumulates changes to gauge the time of divergence for a particular split in the phylogeny. Molecular clocks must be calibrated using independent data such as the fossil record (see Concept 18.1), known times of divergence, or biogeographic dates (e.g., the time of separations of continents; see Concept 18.3). Using such calibrations, times of divergence have been estimated for many groups of species that have diverged over millions of years.

Besides being useful for dating ancient events, molecular clocks can also be used to study the timing of comparatively recent events. Although HIV-1 samples have generally been collected from humans only since the early 1980s, a few isolates from medical biopsies are available from as early as the 1950s. But biologists can use the observed changes in HIV-1 over the past three decades to project back to the common ancestor of all HIV-1 isolates, and thus can estimate when HIV-1 first entered human populations from chimpanzees (FIGURE 16.10). The clock can be calibrated using the samples from the 1980s and 1990s, then tested using the samples from the 1950s. As shown in Figure 16.10C, a sample from a 1959 biopsy is dated by molecular clock analysis at 1957 ± 10 years. The molecular clock was also used to project back to the common ancestor of this group of HIV-1 samples. Extrapolation suggests a date of origin for this group of viruses of about 1930. Although AIDS was unknown to Western medicine until the 1980s, this analysis shows that HIV-1 was present (probably at very low frequency) in human populations in Africa for at least 50 years before its emergence as a global pandemic. Biologists have used similar analyses to conclude that immunodeficiency viruses have been transmitted repeatedly into human populations from multiple primates for more than a century.

FIGURE 16.10 Dating the Origin of HIV-1 in Human Populations

(A) A phylogenetic analysis of the main group of HIV-1 viruses. The dates indicate the years in which samples were taken. (For clarity, only a small fraction of the samples that were examined in the original study are shown.) (B) A plot of year of isolation versus genetic divergence from the common ancestor provides an average rate of divergence, or a molecular clock. (C) The molecular clock is used to date a sample taken in 1959 (as a test of the clock) and the unknown date of origin of the HIV-1 main group (about 1930).

Do You Understand Concept 16.3?

- How can phylogenetic trees help determine the number of times a particular trait evolved?
- How does the reconstruction of ancestral traits help biologists explain the biology of extinct species?
- What is the importance of adding a time dimension to phylogenetic trees, and how do biologists accomplish this?

All of life is connected through evolutionary history, and the relationships among organisms provide a natural basis for making biological comparisons. For these reasons, biologists use phylogenetic relationships as the basis for organizing life into a coherent classification system.

concept 16.4 Phylogeny Is the Basis of Biological Classification

The biological classification system in widespread use today is derived from that developed by the Swedish biologist Carolus Linnaeus in the mid-1700s. Linnaeus developed a system of **binomial nomenclature**. Linnaeus gave each species two names, one identifying the species itself and the other the group of closely related species, or **genus** (plural, *genera*) to which it belongs. Optionally, the name of the taxonomist who first proposed the species name may be added at the end. Thus *Homo sapiens* Linnaeus is the name of the modern human species. *Homo* is the genus, *sapiens* identifies the particular species in the genus *Homo*, and Linnaeus is the person who proposed the name *Homo sapiens*.

You can think of *Homo* as equivalent to your surname and *sapiens* as equivalent to your first name. The first letter of the genus name is capitalized, and the specific name is lowercase. Both of these formal designations are italicized. Rather than repeating the name of a genus when it is used several times in the same discussion, biologists often spell it out only once and abbreviate it to the initial letter thereafter (e.g., *D. melanogaster* rather than *Drosophila melanogaster*).

FIGURE 16.11 Monophyletic, Polyphyletic, and Paraphyletic Groups Monophyletic groups are the basis of biological taxa in modern classifications. Polyphyletic and paraphyletic groups do not accurately reflect evolutionary history.

Go to WEB ACTIVITY 16.2
Types of Taxa

As we noted earlier, any group of organisms that is treated as a unit in a biological classification system, such as all species in the genus *Drosophila*, or all insects, or all arthropods, is called a *taxon*. In the Linnaean system, species and genera are further grouped into a hierarchical system of higher taxonomic categories. The taxon above the genus in the Linnaean system is the **family**. The names of animal families end in the suffix “-idae.” Thus Formicidae is the family that contains all ant species, and the family Hominidae contains humans and our recent fossil relatives, as well as our closest living relatives, the chimpanzees and gorillas. Family names are based on the name of a member genus; Formicidae is based on the genus *Formica*, and Hominidae is based on *Homo*. The same rules are used in classifying plants, except that the suffix “-aceae” is used for plant family names instead of “-idae.” Thus Rosaceae is the family that includes the genus *Rosa* (roses) and its relatives.

In the Linnaean system, families are grouped into **orders**, orders into **classes**, and classes into **phyla** (singular *phylum*), and phyla into **kingdoms**. However, the ranking of taxa within Linnaean classification is subjective. Whether a particular taxon is considered, say, an order or a class is informative only with respect to the *relative* ranking of other related taxa. Although families are always grouped within orders, orders within classes, and so forth, there is nothing that makes a “family” in one group equivalent (in number of genera or in evolutionary age, for instance) to a “family” in another group.

Today, the Linnaean terms above the genus level are used largely for convenience. Linnaeus recognized the overarching hierarchy of life, but he developed his system before evolutionary thought had become widespread. Biologists today recognize the tree of life as the basis for biological classification and often name taxa without placing them into the various Linnaean ranks. But, regardless of whether they rank organisms into Linnaean categories or use unranked taxon names,

modern biologists use evolutionary relationships as the basis for distinguishing, naming, and classifying biological groups.

Evolutionary history is the basis for modern biological classification

Today's biological classifications express the evolutionary relationships of organisms. Taxa are expected to be **monophyletic**, meaning that the taxon contains an ancestor and all descendants of that ancestor, and no other organisms. In other words, a *monophyletic taxon* is a historical group of related species, or a complete branch on the tree of life. As noted earlier, this is also the definition of a *clade*. A true monophyletic group can be removed from a phylogenetic tree by a single "cut" in the tree, as shown in **FIGURE 16.11**.

Note that there are many monophyletic groups on any phylogenetic tree, and that these groups are successively smaller subsets of larger monophyletic groups. This hierarchy of biological taxa, with all of life as the most inclusive taxon and many smaller taxa within larger taxa, down to the individual species, is the modern basis for biological classification.

Although biologists seek to describe and name only monophyletic taxa, the detailed phylogenetic information needed to do so is not always available. A group that does not include its common ancestor is **polyphyletic**; a group that does not include all the descendants of a common ancestor is referred to as **paraphyletic** (see Figure 16.11). Virtually all taxonomists now agree that polyphyletic and paraphyletic groups are inappropriate as taxonomic units because they do not correctly reflect evolutionary history. Some classifications still contain such groups because some organisms have not been evaluated phylogenetically. As mistakes in prior classifications are detected, taxonomic names are revised and polyphyletic and paraphyletic groups are eliminated from the classifications.

Several codes of biological nomenclature govern the use of scientific names

Several sets of explicit rules govern the use of scientific names. Biologists around the world follow these rules voluntarily to facilitate communication and dialogue. There may be dozens of common names for an organism in many different languages, and the same common name may refer to more than one species (**FIGURE 16.12**). The rules of biological nomenclature are designed so that there is only one correct scientific name for any single recognized taxon and (ideally) a given scientific name applies only to a single taxon (that is, each scientific name is unique). Sometimes the same species is named more than once (when more than one taxonomist has taken up the task); the rules specify that the valid name is the first name that was proposed. If the same name is inadvertently given to two different species, then a replacement name must be given to the species that was named second.

Because of the historical separation of the fields of zoology, botany (which originally included mycology, the study of

(A) *Asclepias tuberosa*

(B) *Castilleja coccinea*

(C) *Hieracium aurantiacum*

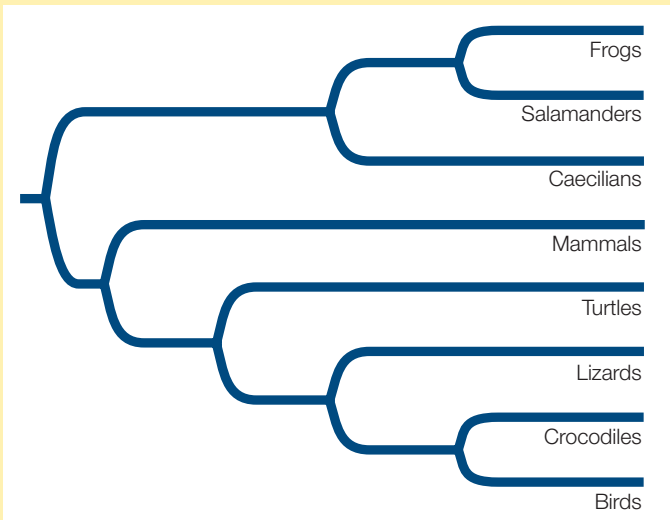

FIGURE 16.12 Same Common Name, Not the Same Species All three of these distinct plant species are commonly called "Indian paintbrush" in North America. Unique scientific binomials allow biologists to communicate clearly about each species. (A) *Asclepias tuberosa* is a perennial milkweed native to eastern North America. (B) *Castilleja coccinea* is also native to eastern North America, but is a member of a very different group of plants called scrophs. (C) *Hieracium aurantiacum* is a European species of aster that has been widely introduced into North America.

fungi), and microbiology, different sets of taxonomic rules were developed for each of these groups. Yet another set of rules emerged later for classifying viruses. This separation of fields resulted in duplicated taxon names in groups governed by the different sets of rules; *Drosophila*, for instance, is both a genus of fruit flies and a genus of fungi, and some species in both groups have identical names. Until recently these duplicated

FRONTIERS Biologists are working on a universal code of nomenclature that can be applied to all organisms, so that every species will have a unique identifying name or registration number. This will assist efforts to build an online *Encyclopedia of Life* that links all the information for all the world's species.

APPLY THE CONCEPT

Phylogeny is the basis of biological classification

Consider the above phylogeny and three possible classifications of the living taxa.

1. Which of these classifications contains a paraphyletic group?
2. Which of these classifications contains a polyphyletic group?

Classification One:

Named group	Included taxa
Amphibia	Frogs, salamanders, and caecilians
Mammalia	Mammals
Reptilia	Turtles, lizards, and crocodiles
Aves	Birds

Classification Two:

Named group	Included taxa
Amphibia	Frogs, salamanders, and caecilians
Mammalia	Mammals
Reptilia	Turtles, lizards, crocodiles, and birds

Classification Three:

Named group	Included taxa
Amphibia	Frogs, salamanders, and caecilians
Homothermia	Mammals and birds
Reptilia	Turtles, lizards, and crocodiles

3. Which of these classifications is consistent with the goal of including only monophyletic groups in a biological classification?
4. Starting with the classification you named in Question 3, how many additional group names would you need to include all the clades shown in this phylogenetic tree?

names caused little confusion, since traditionally biologists who studied fruit flies were unlikely to read the literature on fungi (and vice versa). Today, given the prevalence of large, universal biological databases (such as GenBank, which includes DNA sequences from across all life), it is increasingly important that each taxon have a unique and unambiguous name.

Do You Understand Concept 16.4?

- What is the difference between monophyletic, paraphyletic, and polyphyletic groups?
- Why do biologists prefer monophyletic groups in formal classifications?
- What advantages or disadvantages do you see to having separate sets of taxonomic rules for animals, plants, bacteria, and viruses?

Having described some of the mechanisms by which evolution occurs and how phylogenies can be used to study evolutionary relationships, we are now ready to consider the subject of speciation. Speciation is the process that leads to the splitting events (nodes) on the tree of life and eventually results in the millions of distinctive species that constitute Earth's biodiversity.

How are phylogenetic methods used to resurrect protein sequences from extinct organisms in the laboratory?

ANSWER Most genes and proteins of organisms that lived millions of years ago have decomposed in the fossil remains of these species. Nonetheless, sequences of many ancient genes and proteins can be reconstructed. As we discussed in Concept 16.3, just as we can reconstruct the morphological features of a clade's ancestors, we can also reconstruct their DNA and protein sequences—if we have enough information about the genomes of their descendants.

Biologists have now reconstructed gene sequences from many species that have been extinct for millions of years. Using this information, a laboratory can reconstruct real proteins that correspond to the proteins that were present in long-extinct species. This is how Mikhail Matz and his colleagues were able to resurrect fluorescent proteins from the extinct ancestors of modern corals and then visualize the colors produced by these proteins in the laboratory and recreate the probable evolutionary path of the different pigments (**FIGURE 16.13**).

Biologists have even used phylogenetic analysis to reconstruct some protein sequences that were present in the

FIGURE 16.13 Evolution of Fluorescent Proteins of Corals Mikhail Matz and his colleagues used phylogenetic analysis to reconstruct the sequences of extinct fluorescent proteins that were present in the ancestors of modern corals. They then expressed these proteins in bacteria and plated the bacteria in the form of a phylogenetic tree to show how the colors evolved over time.

common ancestor of life described in Concept 16.1. These hypothetical protein sequences can then be resurrected into actual proteins in the laboratory. When biologists measured the temperature optima for these resurrected proteins, they found the proteins functioned best in the range of 55°C–65°C. This analysis is consistent with hypotheses that life evolved in a high-temperature environment.

To reconstruct protein sequences from species that have been extinct for millions or even billions of years, biologists use detailed mathematical models that take into account much of what we have learned of molecular evolution, as described in Concept 16.2. These models incorporate information on rates of replacement among different amino acid residues in proteins, information on different substitution rates among nucleotides, and changes in the rate molecular evolution among the major lineages of life.

16

SUMMARY

concept 16.1 All of Life Is Connected through Its Evolutionary History

- **Phylogeny** is the history of descent of organisms from their common ancestor. Groups of evolutionarily related species are represented as related branches in a **phylogenetic tree**.
- A group of species that consists of a common ancestor and all its evolutionary descendants is called a **clade**. Named clades and species are called **taxa**. **Review Figure 16.1**
- **Homologies** are similar traits that have been inherited from a common ancestor.
- A trait that is shared by two or more taxa and is derived through evolution from a common ancestral form is called a **synapomorphy**.
- Similar traits may occur among species that do not result from common ancestry. **Convergent evolution** and **evolutionary reversals** can give rise to such traits, which are called **homoplasies**. **Review Figure 16.2**

concept 16.2 Phylogeny Can Be Reconstructed from Traits of Organisms

- Phylogenetic trees can be inferred from synapomorphies and using the **parsimony principle**. **Review Figure 16.3 and WEB ACTIVITY 16.1**
- Sources of phylogenetic information include morphology, patterns of development, the fossil record, behavioral traits, and molecular traits such as DNA and protein sequences. **Review INTERACTIVE TUTORIAL 16.1**
- Phylogenetic trees can be inferred with **maximum likelihood** methods, which calculate the probability that a particular tree

will have generated the observed data. **See WORKING WITH DATA 16.1 and ANIMATED TUTORIAL 16.1**

concept 16.3 Phylogeny Makes Biology Comparative and Predictive

- Phylogenetic trees are used to reconstruct the past and understand the origin of traits. **Review Figure 16.6**
- Phylogenetic trees are used to make appropriate evolutionary comparisons among living organisms.
- Biologists can use phylogenetic trees to reconstruct ancestral states. **Review Figure 16.7**
- Phylogenetic trees may include estimates of times of divergence of lineages determined by **molecular clock** analysis. **Review Figure 16.10**

concept 16.4 Phylogeny Is the Basis of Biological Classification

- Taxonomists organize biological diversity on the basis of evolutionary history.
- Taxa in modern classifications are expected to be clades, or **monophyletic** groups. **Paraphyletic** and **polyphyletic** groups are not considered appropriate taxonomic units. **Review Figure 16.11 and WEB ACTIVITY 16.2**
- Several sets of rules govern the use of scientific names, with the goal of providing unique and universal names for biological taxa.

Speciation

17

Not quite 2 million years ago, a tectonic split in the Great Rift Valley of East Africa led to the formation of Lake Malawi, which lies between the modern countries of Malawi, Tanzania, and Mozambique. A few fish species entered the new lake, including a type known as a haplochromine cichlid. Today the descendants of this early invader include nearly a thousand species of haplochromine cichlids. All of them are *endemic* to Lake Malawi—they are found nowhere else. This vast array of cichlid species makes this the most diverse lake in the world in terms of its fish fauna. How did so many different species arise from a single ancestral species in less than 2 million years?

As we noted in Chapter 16, *speciation* is the process that produces the splits among lineages in the tree of life. Biologists have studied the history and timing of speciation events in Lake Malawi and have pieced together some of the processes that led to so many cichlid species. The earliest haplochromine cichlids to enter the new lake encountered diverse habitats in Lake Malawi, as some shores were rocky and others were sandy. Cichlid populations quickly adapted to these distinct habitat types. Fish in rocky habitats adapted to breeding and living in rocky conditions, and those in sandy habitats evolved specializations for life over sand. These changes resulted in an early speciation event.

Within each of these major habitat types, there were numerous opportunities for diet specialization. Various populations of cichlids became rock scrapers, bottom feeders, fish predators, scale biters, pelagic zooplankton eaters, and plant specialists. Each of these feeding specializations requires different mouth morphology. The offspring of fish that bred with fish of similar morphology were more

likely to survive than were fish with two very different parents. These differences in fitness led to the formation of many more new species, each adapted to a different feeding mode.

But still the Lake Malawi cichlids continued to diverge and form new species. Male cichlids compete for the attention of females through their bright body colors. Diversification of the body colors of males, and of the preferences of females for different body colors, led to many more new species of cichlids, each isolated from the other by their sexual preferences. Now biologists are studying the genomes of these Lake Malawi cichlids to understand the details of the genetic changes that have given rise to so many species over so little time.

This composite photograph shows several of the hundreds of species of diverse haplochromine cichlids that are endemic to Lake Malawi.

Can biologists study the process of speciation in the laboratory?

KEY CONCEPTS

- 17.1** Species Are Reproductively Isolated Lineages on the Tree of Life
- 17.2** Speciation Is a Natural Consequence of Population Subdivision
- 17.3** Speciation May Occur through Geographic Isolation or in Sympatry
- 17.4** Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

concept
17.1 Species Are Reproductively Isolated Lineages on the Tree of Life

Although “species” is a useful and common term in biology, its usage varies among biologists who are interested in different aspects of **speciation**—the divergence of biological lineages and the emergence of reproductive isolation between lineages. Different biologists think about species differently because they ask different questions: How can we recognize and identify species? How do new species arise? How do different species remain separate? Why do rates of speciation differ among groups of organisms? In answering these questions, biologists focus on different attributes of species, leading to several different ways of thinking about what species are and how they form. Most of the various *species concepts* proposed by biologists are simply different ways of approaching the question “What are species?”

We can recognize many species by their appearance

Biological diversity does not vary in a smooth, incremental way. People have long recognized groups of similar organisms that mate with one another, and they have noticed that there are usually distinct morphological breaks between these groups. Groups of organisms that mate with one another are commonly called *species* (note that this is both the plural and singular form of the word). Someone who is knowledgeable about a group of organisms, such as birds or flowering plants, can usually distinguish the different species found in a particular area simply by looking at them. Standard field guides to birds, mammals, insects, and wildflowers are possible only because many species change little in appearance over large geographic distances (**FIGURE 17.1A**).

More than 250 years ago, Carolus Linnaeus developed the system of binomial nomenclature by which species are named today

(see Concept 16.4). Linnaeus described and named thousands of species, but because he knew nothing about genetics or the mating behavior of the organisms he was naming, he classified them on the basis of their appearance alone. In other words, Linnaeus used a **morphological species concept**, a construct that assumes a species comprises individuals that “look alike,” and that individuals that do not look alike belong to different species. Although Linnaeus did not know it, the members of most of the groups he classified as species look alike because they share many alleles of genes that code for morphological features.

Using morphology to define species has limitations. Members of the same species do not always look alike. For example, males, females, and young individuals do not always resemble one another closely (**FIGURE 17.1B**). Furthermore, morphology is of little use in the case of *cryptic species*—instances in which two or more species are morphologically indistinguishable but do not interbreed (**FIGURE 17.2**). Biologists therefore cannot rely on appearance alone in determining whether individual organisms are members of the same or different species. Today, biologists use several additional types of information—especially behavioral and genetic data—to differentiate species.

Reproductive isolation is key

The most important factor in the long-term isolation of sexually reproducing lineages from one another is the evolution of **reproductive isolation**, a state in which two groups of organisms can no longer exchange genes. If individuals of group “A” mate and reproduce only with one another, group “A” constitutes a distinct species within which genes recombine. In other words, group “A” is an independent evolutionary lineage—a separate branch on the tree of life.

It was his recognition of the importance of reproductive isolation that brought Ernst Mayr to propose the **biological species concept**: “Species are groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.” The phrase “actually or potentially” is an important

FIGURE 17.1 Members of the Same Species Look Alike—or Not (A) It is easy to identify these two male wood ducks as members of the same species, even though they are found on opposite coasts 2,000 miles apart. Despite their geographic separation, the two individuals are morphologically very similar. (B) Wood ducks are sexually dimorphic, which means the female’s appearance is quite different from that of the male.

FIGURE 17.2 Cryptic Species Look Alike but Do Not Interbreed These two species of gray treefrogs (*Hyla versicolor* and *H. chrysoscelis*) cannot be distinguished by their external morphology, but they do not interbreed even when they occupy the same geographic range. *Hyla versicolor* is a tetraploid species, whereas *H. chrysoscelis* is diploid. Although they look alike, the males have distinctive mating calls, and based on these calls, the females recognize and mate with males of their own species.

element of this definition. “Actually” says that the individuals live in the same area and interbreed with one another. “Potentially” says that even though the individuals do not live in the same area, and therefore do not interbreed, other information suggests that they *would* do so if they were able to get together. This widely used species concept does not apply to organisms that reproduce asexually, and it is limited to a single point in evolutionary time.

The lineage approach takes a long-term view

Evolutionary biologists often think of species as branches on the tree of life. This idea can be termed a **lineage species concept**. In this framework for thinking about species, one species splits into two or more daughter species, which thereafter evolve as distinct lineages. A lineage concept allows biologists to consider species over evolutionary time.

Recall from Chapter 16 that a *lineage* is an ancestor–descendant series of populations followed over time. Each species has a history that starts with a speciation event by which one lineage on the tree is split into two, and ends either at extinction or at another speciation event, at which time the species produces two daughter species. The process of lineage splitting may be gradual, taking thousands of generations to complete. At the other extreme, an ancestral lineage may be split in two within a few generations (as happens with polyploidy, which we’ll discuss in Concept 17.3). The gradual nature of some splitting events means that at a single point in time, the final outcome of the process may not be clear. In these cases, it may be difficult to predict whether the incipient species will continue to diverge and become fully isolated from its sibling species, or if they will merge again in the future.

The different species concepts are not mutually exclusive

Many named variants of these three major classes of species concepts exist. The various concepts are not entirely

incompatible; they simply emphasize different aspects of species or speciation. Morphological species concepts emphasize the practical aspects of recognizing species, although sometimes underestimating or overestimating the actual number of species. Mayr’s biological species concept emphasizes that reproductive isolation is what allows sexual species to evolve independently of one another. Lineage species concepts embrace the idea that sexual species are maintained by reproductive isolation, but extend the concept of a species as a lineage over evolutionary time. The species-as-lineage concept is also able to accommodate species that reproduce asexually.

Virtually all species exhibit some degree of genetic recombination among individuals, even if recombination events are relatively rare. Significant reproductive isolation between species is therefore necessary for lineages to remain distinct over evolutionary time. Furthermore, reproductive isolation is responsible for the morphological distinctiveness of most species, because mutations that result in morphological changes cannot spread between reproductively isolated species. Therefore, no matter which species concept we emphasize, the evolution of reproductive isolation is important for understanding the origin of species.

Do You Understand Concept 17.1?

- Why do different biologists emphasize different attributes of species in formulating species concepts?
- What makes reproductive isolation such an important component of each of the species concepts discussed here?
- Why is the biological species concept not applicable to asexually reproducing organisms? Do you think this limits its applicability?

Although Charles Darwin titled his groundbreaking book *The Origin of Species*, in fact it included very little about speciation

as we understand it today. Darwin devoted most of his attention to demonstrating that individual species are altered over time by natural selection. The remaining sections discuss the many aspects of speciation that biologists have learned about since Darwin's time.

concept 17.2 Speciation Is a Natural Consequence of Population Subdivision

Not all evolutionary changes result in new species. A single lineage may change over time without giving rise to a new species. Speciation requires the interruption of gene flow within a species whose members formerly exchanged genes. But if a genetic change prevents reproduction between individuals of a species, how can such a change spread through a species in the first place?

Incompatibilities between genes can produce reproductive isolation

If a new allele that causes reproductive incompatibility arises in a population, it cannot spread through the population because no other individuals will be reproductively compatible with the individual that carries the new allele. So how can one reproductively cohesive lineage ever split into two reproductively isolated species? Several early geneticists, including Theodosius Dobzhansky and Hermann Joseph Muller, developed a genetic model to explain this apparent conundrum (FIGURE 17.3).

The Dobzhansky–Muller model is quite simple. First, assume that a single ancestral population is subdivided into two

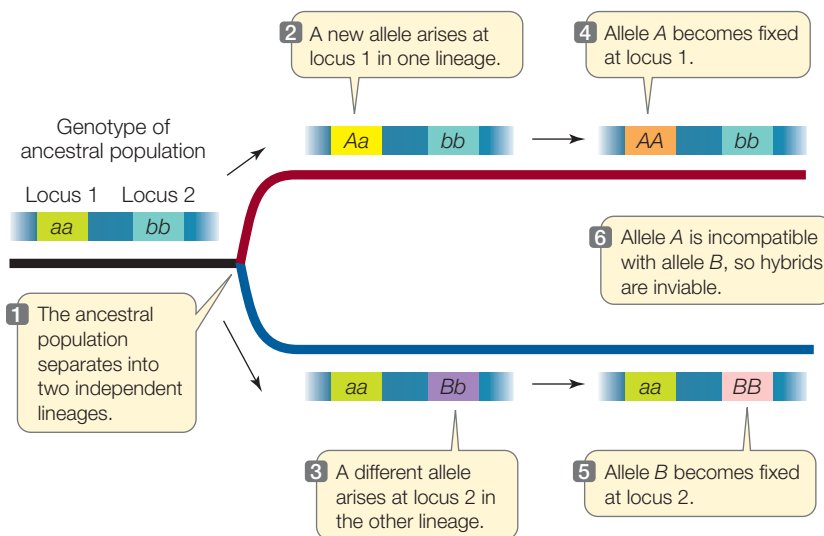

FIGURE 17.3 The Dobzhansky–Muller Model In this simple two-locus version of the model, two lineages from the same ancestral population become separated from each other and evolve independently. A new allele becomes fixed in each descendant lineage, but at two different genes. Neither of the new alleles is incompatible with the ancestral alleles, but the two new alleles in the two different genes are incompatible with each other. Thus the two descendant lineages are reproductively incompatible.

daughter populations (by the formation of a new mountain range, for instance), which then evolve as independent lineages. In one of the descendant lineages, a new allele (A) arises and becomes fixed (see Figure 17.3). In the other population, another new allele (B) becomes fixed at a different gene locus. Neither new allele at either locus results in any loss of reproductive compatibility. However, the two new forms of these two different genes have never occurred together in the same individual or population. Recall that the products of many genes must work together in an organism. It is possible that the new protein forms encoded by the two new alleles will not be compatible with each other. If individuals from the two lineages come back together after these genetic changes, they may still be able to interbreed, or *hybridize*. However, the hybrid offspring may have a new combination of genes that is functionally inferior, or even lethal. This will not happen with all new combinations of genes, but over time, isolated lineages will accumulate many allele differences at many gene loci. Some combinations of these differentiated genes will not function well together in hybrids. Thus genetic incompatibility between the two isolated populations will develop over time.

FRONTIERS Although the Dobzhansky–Muller model is based on a minimum of two gene loci, reproductive incompatibility between pairs of closely related species may involve many more genes. The number of genes involved in known cases of reproductive incompatibility has been estimated for more than 20 such species pairs and ranges from 2 to nearly 200 genes.

Many empirical examples support the Dobzhansky–Muller model. This model works not only for pairs of individual genes but also for some kinds of chromosomal rearrangements. Bats of the genus *Rhogeessa*, for example, exhibit considerable variation in *centric fusions* of their chromosomes. The chromosomes of the various species contain the same basic chromosomal arms, but in some species two *acrocentric* (one-armed) chromosomes have fused at the centromere to form larger, *metacentric* (two-armed) chromosomes. A polymorphism in centric fusion causes few, if any, problems in meiosis because the respective chromosomes can still align and assort normally. Therefore, a given centric fusion can become fixed in a lineage. However, if a different centric fusion becomes fixed in a second lineage, then hybrids between individuals of each lineage will not be able to produce normal gametes in meiosis (FIGURE 17.4). Most of the closely related species of *Rhogeessa* display different combinations of these centric fusions and are thereby reproductively isolated from one another.

Go to INTERACTIVE TUTORIAL 17.1
Speciation: Trends

*Rhogeessa tumida*

FIGURE 17.4 Speciation by Centric Fusion In this chromosomal version of the Dobzhansky–Muller model, two independent centric fusions of one-armed chromosomes occur in two sister lineages of the bat genus *Rhogeessa*. Neither centric fusion by itself results in difficulties at meiosis, whether the fusion is found in just one or in both pairs of chromosomes. After fixation of the respective fusions in each lineage, however, F_1 hybrids between the two lineages are sterile, because the three different chromosomes involved in these centric fusions cannot pair normally at meiosis in hybrids. Most of the species in the bat genus *Rhogeessa* differ from one another by such centric fusions.

Reproductive isolation develops with increasing genetic divergence

As pairs of species diverge genetically, they become increasingly reproductively isolated (**FIGURE 17.5**). Both the rate at which reproductive isolation develops and the mechanisms that produce it vary from group to group. Reproductive incompatibility has been shown to develop gradually in many groups of plants, animals, and fungi, reflecting the slow pace at which incompatible genes accumulate in each lineage. In some cases, complete reproductive isolation may take millions of years. In other cases (as with the chromosomal fusions of *Rhogeessa* described above), reproductive isolation can develop over just a few generations.

Partial reproductive isolation has evolved in strains of *Phlox drummondii* artificially isolated by humans. In 1835, Thomas Drummond, after whom this species of garden plant is named, collected seeds in Texas and distributed them to nurseries in Europe. The European nurseries established more than 200 true-breeding strains of *P. drummondii* that differed in flower size, flower color, and plant growth form. The breeders did not select directly for reproductive incompatibility between strains, but in subsequent experiments in which strains were crossed and seed production was measured and compared,

FIGURE 17.5 Reproductive Isolation Increases with Genetic Divergence Among pairs of *Drosophila* species, the more the species differ genetically, the greater their reproductive isolation from each other. Each dot represents a comparison of one species pair. Such positive relationships between genetic distance and reproductive isolation have been observed in many groups of plants, animals, and fungi.

biologists found that reproductive compatibility between strains had been reduced by 14 to 50 percent, depending on the cross—even though the strains had been isolated from one another for less than two centuries.

Do You Understand Concept 17.2?

- The Dobzhansky–Muller model suggests that divergence among alleles at *different* gene loci leads to genetic incompatibility between species. Why is genetic incompatibility between two alleles at the *same* locus considered less likely?
- Why do some combinations of chromosomal centric fusions cause problems in meiosis? Can you diagram what would happen at meiosis in a hybrid of the divergent lineages shown in Figure 17.4?
- Assume that the reproductive isolation seen in *Phlox* strains results from lethal combinations of incompatible alleles at several loci among the various strains. Given this assumption, why might the reproductive isolation seen among these strains be partial rather than complete?

We have now seen how splitting an ancestral population leads to genetic divergence in the two descendant lineages. Next we will consider ways in which the descendant lineages could have become separated in the first place.

concept 17.3 Speciation May Occur through Geographic Isolation or in Sympatry

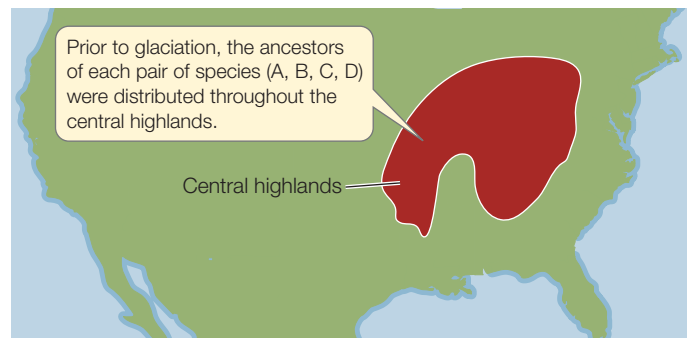

Many scientists who study speciation have concentrated on geographic processes that result in the splitting of an ancestral species. Splitting the range of a species is one obvious way of achieving such a division, but it is not the only way.

Physical barriers give rise to allopatric speciation

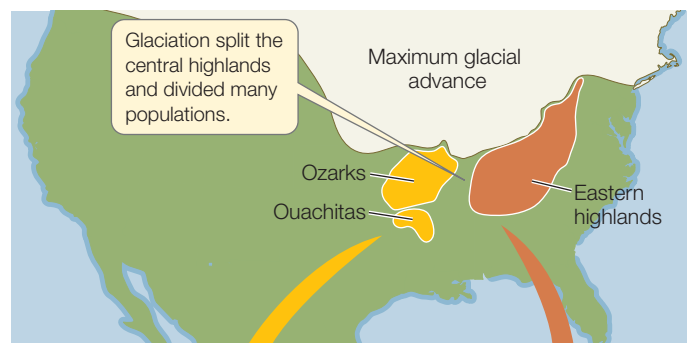

Speciation that results when a population is divided by a physical barrier is known as **allopatric speciation** (Greek *allos*, “other”; *patria*, “homeland”) or *geographic speciation* (FIGURE 17.6). Allopatric speciation is thought to be the dominant mode of speciation in most groups of organisms. The physical barrier that divides the range of a species may be a body of water, a mountain range, or other inhospitable habitat for terrestrial organisms, or dry land for aquatic organisms. Such barriers can form when continents drift, sea levels rise and fall, glaciers advance and retreat, or climates change. These processes continue to generate physical barriers today. The populations separated by such barriers are often, but not always, initially large. The lineages that descend from these founding populations evolve differences for a variety of reasons, including genetic drift and adaptation to the different environments in the two areas.

Allopatric speciation also may result when some members of a population cross an existing barrier and establish a new,

FIGURE 17.6 Allopatric Speciation Allopatric speciation may result when an ancestral population is divided into two separate populations by a physical barrier, and the lineages that descend from these populations then diverge. (A) Many species of freshwater stream fishes were distributed throughout the central highlands of North America in the Pliocene epoch (about 3–5 million years ago). (B) During the Pleistocene, glaciers advanced and isolated fish populations in the Ozark and Ouachita mountains to the west from fish populations in the highlands to the east. Numerous species diverged as a result of this separation, including the ancestors of the four species pairs shown here.

isolated population. The 14 species of finches found in the Galápagos, an archipelago some 1,000 km off the coast of Ecuador, are the result of this process. Darwin's finches (as they are usually called, because Darwin was the first scientist to study them) arose in the Galápagos from a single South American finch species that colonized the islands. Today the Galápagos species differ strikingly from their closest mainland relative and from one another (FIGURE 17.7). The islands of the archipelago are sufficiently far apart that the finches move among them only infrequently. In addition, environmental conditions differ widely from island to island. Some islands are relatively flat and arid; others have forested mountain slopes. Over millions of years, finch lineages on the different islands have differentiated to the point that when occasional immigrants arrive from other islands, they either do not breed with the residents or, if they do, the resulting offspring do not survive as well as the offspring of established residents. The genetic distinctness of each finch species from the others and the genetic cohesiveness of the individual species are thus maintained.

Founder Events and Allopatric Speciation

Sympatric speciation occurs without physical barriers

Although geographic isolation is usually required for speciation, under some circumstances speciation can occur in the absence of a physical barrier. Speciation without physical isolation is called **sympatric speciation** (Greek *sym*, "together with"). But how can such speciation happen? Given that speciation

is usually a gradual process, how can reproductive isolation develop when individuals have frequent opportunities to mate with one another?

Sympatric speciation may occur with some forms of disruptive selection (see Concept 15.4) in which individuals with certain genotypes have a preference for distinct microhabitats where mating takes place. For example, sympatric speciation via disruptive selection appears to be taking place in the apple maggot fly (*Rhagoletis pomonella*) of eastern North America. Until the mid-1800s, *Rhagoletis* flies courted, mated, and deposited their eggs only on hawthorn fruits. About 150 years ago, some flies began to lay their eggs on apples, which European immigrants had introduced into eastern North America. Apple trees are closely related to hawthorns, but the smell of the fruits differs, and the apple fruits appear earlier than those of hawthorns. Some early-emerging female *Rhagoletis* laid their eggs on apples, and over time, a genetic preference for the smell of apples evolved among early-emerging insects. When the offspring of these flies sought out apple trees for mating and egg deposition, they mated with other flies reared on apples, which shared the same preferences.

Today the two groups of *Rhagoletis pomonella* in the eastern U.S. appear to be on the way to becoming distinct species. One group mates and lays eggs primarily on hawthorn fruits, the other on apples. The incipient species are partially reproductively isolated because they mate primarily with individuals raised on the same fruit and because they emerge from their pupae at different times of the year. In addition, the apple-feeding flies now grow more rapidly on apples than they originally did. Sympatric speciation that arises from such host-plant specificity may be widespread among insects, many of which feed only on a single plant species.

APPLY THE CONCEPT

Speciation may occur through geographic isolation

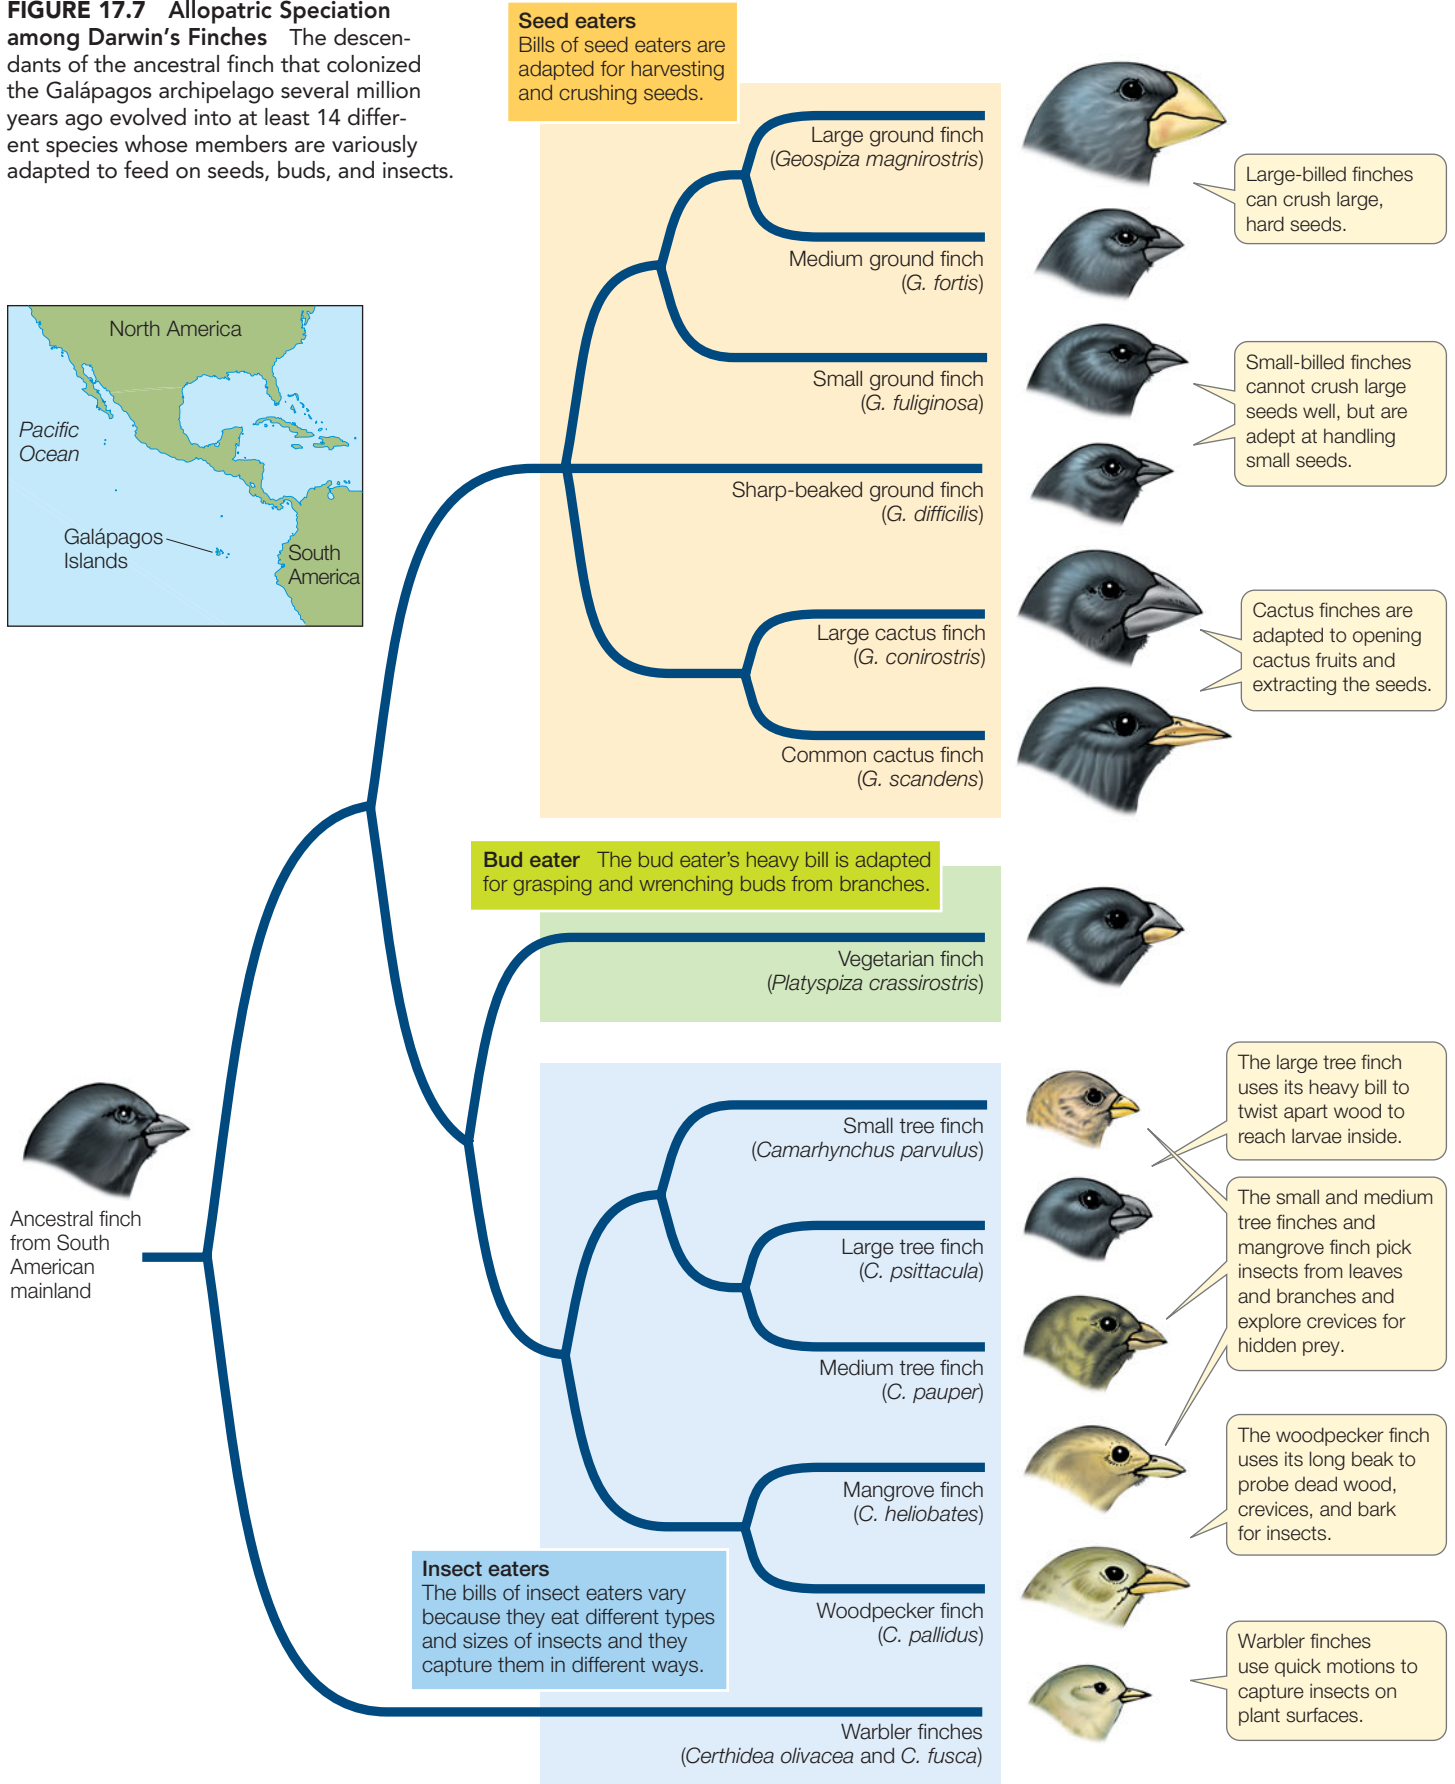

The different species of Darwin's finches shown in the phylogeny in Figure 17.7 have all evolved on islands of the Galápagos archipelago within the past 3 million years. Molecular clock analysis (see Concept 15.5) has been used to determine the dates of the various speciation events in that phylogeny. Geological techniques for dating rock samples (see Concept 18.1) have been used to determine the ages of the various Galápagos islands. The table shows the number of species of Darwin's finches and the number of islands that have existed in the archipelago at several times during the past 4 million years.

1. Plot the number of species of Darwin's finches and the number of islands in the Galápagos archipelago (dependent variables) against time (independent variable).
2. Are the data consistent with the hypothesis that isolation of populations on newly formed islands is related to speciation in this group of birds? Why or why not?

TIME (MYA)	NUMBER OF ISLANDS	NUMBER OF FINCH SPECIES
0.25	18	14
0.50	18	9
0.75	9	7
1.00	6	5
2.00	4	3
3.00	4	1
4.00	3	0

3. If no more islands form in the Galápagos archipelago, do you think that speciation by geographic isolation will continue to occur among Darwin's finches? Why or why not? What additional data could you collect to test your hypothesis (without waiting to see if speciation occurs)?

FIGURE 17.7 Allopatric Speciation among Darwin’s Finches The descendants of the ancestral finch that colonized the Galápagos archipelago several million years ago evolved into at least 14 different species whose members are variously adapted to feed on seeds, buds, and insects.

The most common means of sympatric speciation, however, is **polyploidy**, or the duplication of sets of chromosomes within individuals. Polyploidy can arise either from chromosome duplication in a single species (**autopolyploidy**) or from the combining of the chromosomes of two different species (**allopolyploidy**).

An autopolyploid individual originates when, for example, two accidentally unreduced diploid gametes (with two sets of chromosomes) combine to form a tetraploid individual (with four sets of chromosomes). Tetraploid and diploid individuals of the same species are reproductively isolated because their hybrid offspring are triploid. Even if these offspring survive, they are usually sterile; they cannot produce normal gametes because their chromosomes do not segregate evenly during meiosis. So a tetraploid individual cannot produce fertile offspring by mating with a diploid individual—but it *can* do so if it self-fertilizes or mates with another tetraploid. Thus polyploidy can result in complete reproductive isolation in two generations—an important exception to the general rule that speciation is a gradual process.

Allopolyploids may be produced when individuals of two different (but closely related) species interbreed. Such hybridization often disrupts normal meiosis, which can result in chromosomal doubling. Allopolyploids are often fertile because each of the chromosomes has a nearly identical partner with which to pair during meiosis.

Speciation by polyploidy has been particularly important in the evolution of plants, although it has contributed to speciation in animals as well (such as the example in Figure 17.2). Botanists estimate that about 70 percent of flowering plant species and 95 percent of fern species are the result of recent polyploidization. Some of these species arose from hybridization between two species followed by chromosomal duplication and self-fertilization. Other species diverged from polyploid ancestors, so that the new species shared their ancestors' duplicated sets of chromosomes. New species arise by polyploidy more easily among plants than among animals because plants of many species can reproduce by self-fertilization. In addition, if polyploidy arises in several offspring of a single parent, the siblings can fertilize one another.

Speciation Mechanisms

Do You Understand Concept 17.3?

- Explain how speciation via polyploidy can happen in only two generations.
- What are some obstacles to sympatric speciation?
- If allopatric speciation is the most prevalent mode of speciation, what do you predict about the geographic distributions of many closely related species? Does your answer differ for species that are sedentary versus species that are highly mobile?

Most populations separated by a physical barrier become reproductively isolated only slowly and gradually. If two incipient species once again come into contact with each other, what keeps them from merging back into a single species?

concept 17.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

As discussed in Concept 17.2, once a barrier to gene flow is established, reproductive isolation will begin to develop through genetic divergence. Over many generations, differences accumulate in the isolated lineages, reducing the probability that individuals from each lineage will mate successfully with one another when they come back into contact. In this way, reproductive isolation can evolve as a by-product of the genetic changes in the two diverging lineages.

Reproductive isolation may be incomplete when the incipient species come back into contact, however, in which case some hybridization will occur. If hybrid individuals are less fit than non-hybrids, selection favors parents that do not produce hybrid offspring. Under these conditions, selection results in strengthening, or **reinforcement**, of isolating mechanisms that prevent hybridization.

Mechanisms that prevent hybridization from occurring are called **prezygotic isolating mechanisms**. Mechanisms that reduce the fitness of hybrid offspring are called **postzygotic isolating mechanisms**. Postzygotic mechanisms result in selection against hybridization, which leads to the reinforcement of the prezygotic mechanisms.

FIGURE 17.8 Mechanical Isolation through Mimicry Many orchid species maintain reproductive isolation by means of flowers that look and smell like females of a specific bee or wasp species. Shown here are an Australian orchid (*Cryptostylis* sp.) and its pollinator, a male wasp of the genus *Lissopimpla*.

(A) Allopatric populations

(B) Sympatric populations

FIGURE 17.9 Temporal Isolation of Breeding Seasons (A) The peak breeding seasons of three species of *Rana* overlap when the species are physically separated (allopatry). (B) Where two or more species of *Rana* live together (sympatry), overlap between their peak

breeding seasons is greatly reduced or eliminated. Selection against hybridization in areas of sympatry helps reinforce this prezygotic isolating mechanism.

Prezygotic isolating mechanisms prevent hybridization between species

Prezygotic isolating mechanisms, which come into play before fertilization, can prevent hybridization in several ways.

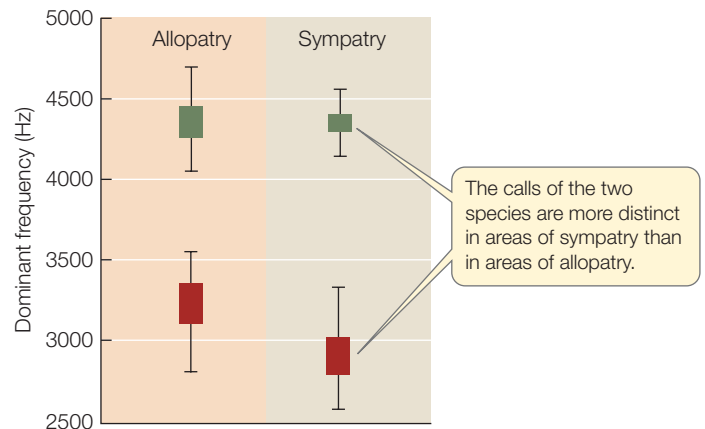

MECHANICAL ISOLATION Differences in the sizes and shapes of reproductive organs may prevent the union of gametes from different species. With animals, there may be a match between the shapes of the reproductive organs of males and females of the same species, so that reproduction between species with mismatched structures is not physically possible. In plants, mechanical isolation may involve a pollinator. For example, orchids of the genus *Cryptostylis* produce flowers that look and smell like the females of particular species of wasps (**FIGURE 17.8**). When a male wasp visits and attempts to mate with the flower (thinking it is a female wasp of his species), his mating behavior results in the transfer of pollen to and from his body by appropriately configured anthers and stigmas on the flower. Insects that visit the flower but do not attempt to mate with it do not trigger the transfer of pollen between the insect and the flower.

TEMPORAL ISOLATION Many organisms have distinct mating seasons. If two closely related species breed at different times of the year (or different times of day), they may never have an opportunity to hybridize. For example, in sympatric populations of three closely related leopard frog species, each species breeds at a different time of year (**FIGURE 17.9**). Although there is some overlap in the breeding seasons, the opportunities for hybridization are minimized.

BEHAVIORAL ISOLATION Individuals may reject, or fail to recognize, individuals of other species as potential mating partners. For example, the mating calls of male frogs of related species diverge quickly (**FIGURE 17.10**). Female frogs respond to mating calls from males of their own species but ignore the calls of other species, even closely related ones. The evolution of female preferences for certain male coloration patterns among the cichlids of Lake Malawi, described at the opening of this chapter, is another example of behavioral isolation.

Sometimes the mate choice of one species is mediated by the behavior of individuals of other species. For example, whether

Gastrophryne olivacea ■

Gastrophryne carolinensis ■

FIGURE 17.10 Behavioral Isolation in Mating Calls The males of most frog species produce species-specific calls. The calls of the two closely related frog species shown here differ in their dominant frequency (a high-frequency sound wave results in a high-pitched sound; a low frequency results in a low-pitched sound). Female frogs are attracted to the calls of males of their own species.

FIGURE 17.11 Floral Morphology Is Associated with Pollinator Morphology

(A) This hummingbird's morphology and behavior are adapted for feeding on nectar from flowers that are pendant. (B) The nectar-extracting proboscis of this hawkmoth is adapted to flowers that grow upright. (C) *Aquilegia formosa* flowers are normally pendant and are pollinated by hummingbirds. (D) Flowers of *A. pubescens* are normally upright and are pollinated by hawkmoths. In addition, their long floral spurs appear to restrict access by some other potential pollinators.

or not two plant species hybridize may depend on the food preferences of their pollinators. The floral traits of plants, including their color and shape, can enhance reproductive isolation either by influencing which pollinators are attracted to the flowers or by altering where pollen is deposited on the bodies of pollinators. A plant whose flowers are pendant (hanging downward; **FIGURE 17.11A**) will be pollinated by an animal with different physical characteristics than will a plant in which the flowers grow upright (**FIGURE 17.11B**). Because each pollinator prefers (and is adapted to) a different type of flower, the pollinators rarely transfer pollen from one plant species to the other.

Such isolation by pollinator behavior is seen in the mountains of California in two sympatric species of columbines (*Aquilegia*) that have diverged in flower color, structure, and orientation. *Aquilegia formosa* (**FIGURE 17.11C**) has pendant flowers with short spurs (spikelike, nectar-containing structures) and is pollinated by hummingbirds. *A. pubescens* (**FIGURE 17.11D**) has upright, lighter-colored flowers with long spurs and is pollinated by hawkmoths. The difference in pollinators means that these two species are effectively reproductively isolated even though they populate the same geographic range.

HABITAT ISOLATION When two closely related species evolve preferences for living or mating in different habitats, they may never come into contact during their respective mating periods.

The *Rhagoletis* flies discussed in Concept 17.3 experienced such habitat isolation, as did the cichlid fishes that first adapted to rocky and sandy habitats upon entering Lake Malawi, as described at the opening of this chapter.

LINK Some plants and their pollinators become so tightly adapted to each other that they develop mutually dependent relationships, as described in Concept 21.5

GAMETIC ISOLATION The sperm of one species may not attach to the eggs of another species because the eggs do not release the appropriate attractive chemicals, or the sperm may be unable to penetrate the egg because the two gametes are chemically incompatible. Thus, even though the gametes of two species may come into contact, the gametes never fuse into a zygote.

Gametic isolation is extremely important for many aquatic species that *spawn* (release their gametes directly into the environment); it has been extensively studied in sea urchins. A protein known as *bindin* is found in sea urchin sperm and functions in attaching (“binding”) the sperm to eggs. All sea urchin species studied produce this egg-recognition protein, but the *bindin* gene sequence diverges so rapidly that it becomes species-specific. Since sperm can only attach to eggs of the same species, no interspecific hybridization occurs.

Postzygotic isolating mechanisms result in selection against hybridization

Genetic differences that accumulate between two diverging lineages may reduce the survival and reproductive rates of hybrid offspring in any of several ways:

- *Low hybrid zygote viability.* Hybrid zygotes may fail to mature normally, either dying during development or developing phenotypic abnormalities that prevent them from becoming reproductively capable adults.
- *Low hybrid adult viability.* Hybrid offspring may have lower survivorship than non-hybrid offspring.
- *Hybrid infertility.* Hybrids may mature into infertile adults. For example, the offspring of matings between horses and donkeys—mules—are sterile; although otherwise healthy, they produce no descendants.

Natural selection does not directly favor the evolution of postzygotic isolating mechanisms. But if hybrids are less fit, individuals that breed only within their own species will leave more surviving offspring than will individuals that interbreed with another species. Therefore, individuals that can avoid interbreeding with members of other species will have a selective advantage, and any trait that contributes to such avoidance will be favored.

Donald Levin of the University of Texas has studied reinforcement of prezygotic isolating mechanisms in flowers of the genus *Phlox*. Levin noticed that individuals of *Phlox drummondii* in most of the range of the species in Texas usually have pink flowers. However, where *P. drummondii* is sympatric with its close relative the pink-flowered *P. cuspidata*, *P. drummondii* usually has red flowers. No other *Phlox* species has red flowers. Levin performed an experiment whose results showed that reinforcement may explain why red flowers are favored where the two species are sympatric (FIGURE 17.12).

Likely cases of reinforcement are often detected by comparing sympatric and allopatric populations of potentially hybridizing species, as in the case of *Phlox*. If reinforcement is occurring, then

INVESTIGATION

FIGURE 17.12 Flower Color and Reproductive Isolation Most *Phlox drummondii* individuals have pink flowers, but in regions where the species is sympatric with *P. cuspidata*—which is always pink—most *P. drummondii* individuals have red flowers. Most pollinators preferentially visit flowers of one color or the other. In this experiment, Donald Levin explored whether flower color acts as a prezygotic isolating mechanism that lessens the chances of hybridization between the two species.

HYPOTHESIS

Red-flowered *P. drummondii* are less likely to hybridize with *P. cuspidata* than are pink-flowered *P. drummondii*.

METHOD

1. Introduce equal numbers of red-flowered and pink-flowered *P. drummondii* individuals into an area where many pink-flowered *P. cuspidata* are growing.

2. After the flowering season ends, measure hybridization by assessing the genetic composition of the seeds produced by *P. drummondii* plants of both colors.

RESULTS

Of the seeds produced by pink-flowered *P. drummondii*, 38% were hybrids with *P. cuspidata*. Only 13% of the seeds produced by red-flowered *P. drummondii* were hybrids with *P. cuspidata*

CONCLUSION

P. drummondii and *P. cuspidata* are less likely to hybridize if the flowers of the two species differ in color.

ANALYZE THE DATA

Data from Levin's experiment show that the frequency of hybridization between *Phlox drummondii* and *P. cuspidata* was strongly dependent on the former's flower color.

<i>P. drummondii</i> flower color	Number of progeny (seeds)		
	<i>P. drummondii</i>	Hybrid	Total
Red	181 (87%)	27 (13%)	208
Pink	86 (62%)	53 (38%)	139

- A. The data reveal that red-flowered *P. drummondii* produced more seeds (208) than pink-flowered plants did (139), even though equal numbers of individuals of the two flower types were used. Does this difference influence your interpretation of Levin's results? Why or why not?
- B. How would you improve the experimental design of this study? Should replicate or control sites be added? What kinds of additional test sites and conditions would you add?

APPLY THE CONCEPT

Reproductive isolation is reinforced when diverging species come into contact

As shown in Figure 17.9, the leopard frogs *Rana berlandieri* and *R. sphenoccephala* usually have non-overlapping breeding seasons in areas of sympatry, but where the species are allopatric, both species breed in both spring and fall. But when new ponds are created where the ranges of the two species come close together, frogs from previously allopatric populations may colonize the new ponds and hybridize during their overlapping breeding seasons.

Imagine you have collected and tabulated data on hybridization between these two frog species. You have sampled various life stages of frogs and their tadpoles for two years after an initial spring breeding season at a newly established pond. Use the data (above right) to answer the following questions.

1. Create four pie charts (one for each life stage) showing the percentage of each species and the percentage of hybrids at each stage.

LIFE STAGE	<i>R. BERLANDIERI</i>	<i>R. SPHENOCEPHALA</i>	F ₁ HYBRIDS
Recently hatched tadpoles (spring, year 1)	155	125	238
Late-stage tadpoles (summer, year 1)	45	55	64
Newly metamorphosed froglets (fall, year 1)	32	42	15
Adult frogs (year 2)	10	15	1

2. What are some possible reasons for the differences in the percentages of hybrids found at each life stage? Suggest some postzygotic isolating mechanisms that are consistent with your data.
3. Over time, what changes might you expect in the breeding seasons of the two species at this particular pond, and why? How would future pie charts change if your predictions about breeding seasons are correct?

sympatric populations of closely related species are expected to evolve more effective prezygotic reproductive barriers than do allopatric populations of the same species. As Figure 17.8 shows, the breeding seasons of sympatric populations of different leopard frog species overlap much less than do those of the corresponding allopatric populations. Similarly, the frequencies of the frog mating calls illustrated in Figure 17.10 are more divergent in sympatric populations than in allopatric populations. In both cases, there appears to have been natural selection against hybridization in areas of sympatry.

Hybrid zones may form if reproductive isolation is incomplete

Unless reproductive isolation is complete, closely related species may hybridize in areas where their ranges overlap, resulting in the formation of a **hybrid zone**. When a hybrid zone first forms, most hybrids are offspring of crosses between purebred individuals of the two species. However, subsequent generations will include a variety of individuals with varying proportions of their genes derived from the original two species. Thus hybrid zones often contain recombinant individuals resulting from many generations of hybridization.

Detailed genetic studies can tell us much about why narrow hybrid zones may persist for long periods between the ranges of two species. In Europe, the hybrid zone between two toad species of the genus *Bombina* has been studied intensively. The fire-bellied toad (*B. bombina*) lives in eastern Europe; the closely related yellow-bellied toad (*B. variegata*) lives in western and southern Europe. The ranges of the two

FRONTIERS *Homo neanderthalensis* coexisted with modern *Homo sapiens* for tens of thousands of years before Neanderthals became extinct. Anthropologists have speculated as to whether the two groups, apparently genetically and morphologically quite distinct, were capable of interbreeding. Improvements in genome sequencing have now permitted biologists to sequence much of the Neanderthal genome from fossil remains, revealing that 1–4 percent of the genes present in modern European and Asian (but not African) human populations appears to have come from Neanderthals. This evidence suggests that *Homo sapiens* interbred with Neanderthals about 50,000 years ago in the Middle East—after humans left Africa but before they spread through the rest of the world.

species overlap in a long but very narrow zone stretching 4,800 kilometers from eastern Germany to the Black Sea (**FIGURE 17.13**). Hybrids between the two species suffer from a range of defects, many of which are lethal. Those hybrids that survive often have skeletal abnormalities, such as misshapen mouths, ribs that are fused to vertebrae, and a reduced number of vertebrae. By following the fates of thousands of toads from the hybrid zone, investigators found that a hybrid toad, on average, is only half as fit as a purebred individual of either species. The hybrid zone remains narrow because there is strong selection against hybrids and because adult toads do not move over long distances. The zone has persisted for hundreds of years, however, because individuals of both species continue to move short distances into it, continually replenishing the hybrid population.

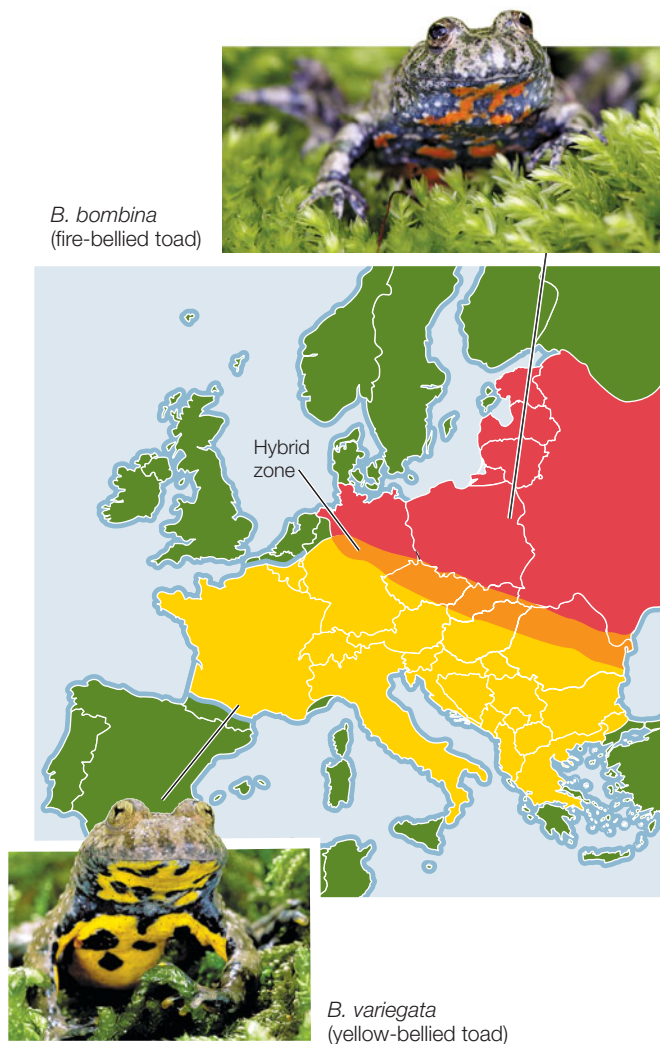

FIGURE 17.13 A Hybrid Zone The long, narrow zone where fire-bellied toads meet and hybridize with yellow-bellied toads has been stable for hundreds of years.

Do You Understand Concept 17.4?

- Why would reinforcement of prezygotic isolating mechanisms be expected even if postzygotic isolating mechanisms already exist?
- Why would you expect to find different types of prezygotic isolating mechanisms among different groups of organisms? Describe some specific examples.
- Why don't most narrow hybrid zones, such as the one between *Bombina orientalis* and *Bombina orientalis*, get wider over time?

The result of 4 billion of years of evolution has been many millions of species, each adapted to live in a particular environment and to use environmental resources in a particular way. In the next chapter we will describe how geological and biological processes interacted over the course of Earth's history to produce this vast biodiversity.

Can biologists study the process of speciation in the laboratory?

ANSWER Although speciation usually takes thousands or millions of years, and although it is typically studied in natural settings such as Lake Malawi, some aspects of speciation can be studied and observed in controlled laboratory experiments. Most such experiments use organisms with short generation times, in which evolution is expected to be relatively rapid.

William Rice and George Salt conducted an experiment in which fruit flies were allowed to choose food sources in different habitats, where mating also took place. The habitats were vials in different parts of an experimental cage (**FIGURE 17.14**). The vials differed in three environmental factors: (1) light; (2) the direction (up or down) in which the fruit flies had to move to reach food; and (3) the concentrations of two aromatic chemicals, ethanol and acetaldehyde. In just 35 generations, the two groups of flies that chose the most divergent habitats had become reproductively isolated from each other, having evolved distinct preferences for the different habitats.

The experiment by Rice and Salt demonstrated an example of habitat isolation evolving to function as a prezygotic isolating mechanism. Even though the different habitats were in the same cage, and individual fruit flies were capable of flying from one habitat to the other, habitat preferences were inherited by offspring from their parents, and populations from the two divergent habitats did not interbreed. Similar habitat selection is thought to have resulted in the early split in cichlids that preferred the rocky versus the sandy shores of Lake Malawi.

In controlled experiments like this one, biologists can observe many aspects of the process of speciation directly.

FIGURE 17.14 Evolution in the Laboratory For their experiments on the evolution of prezygotic isolating mechanisms in *Drosophila melanogaster*, Rice and Salt built an elaborate system of varying habitats contained within vials inside a large fly enclosure. Some groups of flies developed preferences for widely divergent habitats and became reproductively isolated within 35 generations.

17

SUMMARY

concept 17.1 Species Are Reproductively Isolated Lineages on the Tree of Life

- **Speciation** is the process by which one species splits into two or more daughter species, which thereafter evolve as distinct lineages.
- The **morphological species concept** distinguishes species on the basis of physical similarities; it often underestimates or overestimates the actual number of reproductively isolated species.
- The **biological species concept** distinguishes species on the basis of **reproductive isolation**.
- **Lineage species concepts**, which recognize independent evolutionary lineages as species, allow biologists to consider species over evolutionary time.

concept 17.2 Speciation Is a Natural Consequence of Population Subdivision

- Genetic divergence results from the interruption of gene flow within a population.
- The Dobzhansky–Muller model describes how reproductive isolation between two descendant lineages can develop through the accumulation of incompatible genes or chromosomal arrangements. **Review Figure 17.3 and INTERACTIVE TUTORIAL 17.1**
- Reproductive isolation increases with increasing genetic divergence between populations.

concept 17.3 Speciation May Occur through Geographic Isolation or in Sympatry

- **Allopatric speciation**, which results when populations are separated by a physical barrier, is the dominant mode of speciation. This type of speciation may follow founder events, in which some members of a population cross a barrier and found a new, isolated population. **Review Figure 17.6 and ANIMATED TUTORIAL 17.1**
- **Sympatric speciation** results when two species diverge in the absence of geographic isolation. It can result from disruptive selection in two or more distinct microhabitats.
- Sympatric speciation can occur within two generations via **polyploidy**, an increase in the number of chromosomes sets. Polyploidy may arise from chromosome duplications within a species (**autopolyploidy**) or from hybridization that combines the chromosomes of two species (**allopolyploidy**). **Review ANIMATED TUTORIAL 17.2**

concept 17.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

- **Prezygotic isolating mechanisms** prevent hybridization; **postzygotic isolating mechanisms** reduce the fitness of hybrids.
- Postzygotic isolating mechanisms lead to **reinforcement** of prezygotic isolating mechanisms by natural selection. **Review Figures 17.8 and 17.10**
- **Hybrid zones** may persist between species with incomplete reproductive isolation. **Review Figure 17.12 and WORKING WITH DATA 17.1**

See **WEB ACTIVITY 17.1** for a concept review of this chapter

The History of Life on Earth

18

Almost anyone who has spent time around freshwater ponds is familiar with dragonflies. Their bright colors and transparent wings stimulate our visual senses on bright summer afternoons as they fly about their business of devouring mosquitoes, mating, and laying their eggs. The largest dragonflies alive today have wingspans that can be covered by a human hand. Three hundred million years ago, however, dragonflies such as *Meganeuropsis permiana* had wingspans of more than 70 centimeters—well over 2 feet, matching or exceeding the wingspans of many modern birds of prey. These dragonflies were the largest flying predators of their time.

No flying insects alive today are anywhere near this size. But during the Carboniferous and Permian geological periods, 350–250 million years ago, many groups of flying insects contained gigantic members. *Meganeuropsis* probably ate huge mayflies and other giant flying insects that shared their home in the Permian swamps. These enormous insects were themselves eaten by giant amphibians.

None of these insects or amphibians would be able to survive on Earth today. The oxygen concentrations in Earth's atmosphere were about 50 percent higher than they are now, and those high oxygen concentrations are thought to have been necessary to support giant insects and their huge amphibian predators.

Paleontologists have uncovered fossils of *Meganeuropsis permiana* in the rocks of Kansas. How do we know the age of these fossils, and how can we know how much oxygen that long-vanished atmosphere contained? The layering of the rocks allows us to tell their ages relative to one another, but it does not by itself indicate a given layer's absolute age.

One of the remarkable achievements of twentieth-century scientists was the development of sophisticated techniques that use the decay rates of various radioisotopes, changes in Earth's magnetic field, and the ratios of certain molecules to infer conditions and events in the remote past and to date them accurately. It is those methods that allow us to age the fossils of *Meganeuropsis* and to calculate the concentration of oxygen in Earth's atmosphere at the time.

Earth is about 4.5 billion years old, and life has existed on it for about 3.8 billion of those years. That means human civilizations have occupied Earth for less than 0.0003 percent of the history of life. Discovering what happened before humans were around is an ongoing and exciting area of science.

Meganeuropsis permiana, shown in a reconstruction from fossils. Except for its size, this giant from the Permian period was similar to modern dragonflies (shown in the inset at the same scale).

Can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

KEY CONCEPTS

- 18.1** Events in Earth's History Can Be Dated
- 18.2** Changes in Earth's Physical Environment Have Affected the Evolution of Life
- 18.3** Major Events in the Evolution of Life Can Be Read in the Fossil Record

concept 18.1 Events in Earth's History Can Be Dated

Many evolutionary changes happen rapidly enough to be studied directly and manipulated experimentally. Plant and animal breeding by agriculturalists and evolution of resistance to pesticides are examples of rapid, short-term evolution that we saw in Chapter 15. Other evolutionary changes, such as the appearance of new species and evolutionary lineages, usually take place over much longer time scales.

To understand long-term patterns of evolutionary change, we must not only think in time scales spanning many millions of years, but also consider events and conditions very different from those we observe today. Earth of the distant past was so unlike our present Earth that it would seem like a foreign planet inhabited by strange organisms. The continents were not where they are now, and climates were sometimes dramatically different from those of today. We know this because much of Earth's history is recorded in its rocks.

We cannot tell the ages of rocks just by looking at them, but we can visually determine the ages of rocks *relative to one another*.

The first person to formally recognize this fact was the seventeenth-century Danish physician Nicolaus Steno. Steno realized that in undisturbed **sedimentary rocks** (rocks formed by the accumulation of sediments), the oldest layers of rock, or **strata** (singular *stratum*), lie at the bottom, and successively higher strata are progressively younger.

Geologists subsequently combined Steno's insight with their observations of fossils contained in sedimentary rocks. They developed the following principles of *stratigraphy*:

- Fossils of similar organisms are found in widely separated places on Earth.
- Certain fossils are always found in younger strata, and certain other fossils are always found in older strata.
- Organisms found in younger strata are more similar to modern organisms than are those found in older strata.

These patterns revealed much about the relative ages of sedimentary rocks and the fossils they contain, as well as patterns in the evolution of life. But the geologists still could not tell how old particular rocks were. A method of dating rocks did not become available until after radioactivity was discovered at the beginning of the twentieth century.

TABLE 18.1 Earth's Geological History

RELATIVE TIME SPAN	ERA	PERIOD	ONSET	MAJOR PHYSICAL CHANGES ON EARTH
	Cenozoic	Quaternary	2.6 mya	Cold/dry climate; repeated glaciations
		Tertiary	65 mya	Continents near current positions; climate cools
	Mesozoic	Cretaceous	145 mya	Northern continents attached; Gondwana begins to drift apart; meteorite strikes near present Yucatán Peninsula
		Jurassic	200 mya	Two large continents form: Laurasia (north) and Gondwana (south); climate warm
		Triassic	251 mya	Pangaea begins to slowly drift apart; hot/humid climate
Precambrian	Paleozoic	Permian	297 mya	Extensive lowland swamps; O ₂ levels 50% higher than present; by end of period continents aggregate to form Pangaea, and O ₂ levels begin to drop rapidly
		Carboniferous	359 mya	Climate cools; marked latitudinal climate gradients
		Devonian	416 mya	Continents collide at end of period; meteorite probably strikes Earth
		Silurian	444 mya	Sea levels rise; two large land masses emerge; hot/humid climate
		Ordovician	488 mya	Massive glaciation, sea level drops 50 meters
Precambrian		Cambrian	542 mya	O ₂ levels approach current levels
			900 mya	O ₂ level at ≈5% of current level
			1.5 bya	O ₂ level at ≈1% of current level
			3.8 bya	O ₂ first appears in atmosphere
		4.5 bya		

Note: mya, million years ago; bya, billion years ago.

Radioisotopes provide a way to date rocks

Radioactive isotopes of atoms—*radioisotopes*—decay in a predictable pattern over long periods. Over a specific time interval, known as a **half-life**, half of the atoms in a radioisotope decay to become a different, stable (nonradioactive) isotope (**FIGURE 18.1A**). The use of this knowledge to date fossils and rocks is known as **radiometric dating**.

To use a radioisotope to date a past event, we must know or estimate the concentration of that isotope at the time of that event, and we must know the radioisotope's half-life. In the case of carbon-14, a radioisotope of carbon, the production of new carbon-14 (^{14}C) in the upper atmosphere—by the reaction of neutrons with nitrogen-14—just balances the natural radioactive decay of ^{14}C into ^{14}N . Therefore, the ratio of ^{14}C to the more common stable isotope of carbon, carbon-12 (^{12}C), is relatively constant in living organisms and in their environment. As soon as an organism dies, however, it ceases to exchange carbon compounds with its environment. Its decaying ^{14}C is no longer replenished, and the ratio of ^{14}C to ^{12}C in its remains decreases over time. Paleontologists can use the ratio of ^{14}C to ^{12}C in fossil material to date fossils that are less than 60,000 years

FIGURE 18.1 Radioactive Isotopes Allow Us to Date Ancient Rocks The decay of radioactive isotopes into stable isotopes happens at a steady rate. A half-life is the time it takes for half of the remaining atoms to decay in this way. (A) The graph demonstrates the principle of half-life using carbon-14 (^{14}C) as an example. The half-life of ^{14}C is 5,700 years. (B) Different radioisotopes have different characteristic half-lives that allow us to measure how much time has elapsed since the rocks containing them were laid down.

old (and thus the sedimentary rocks that contain those fossils). If fossils are older than that, so little ^{14}C remains that the limits of detection using this particular isotope are reached.

Radiometric dating methods have been expanded and refined

Sedimentary rocks are formed from materials that existed for varying lengths of time before being weathered, fragmented, and transported, sometimes over long distances, to the site of their deposition. Therefore, the radioisotopes in sedimentary rock do not contain reliable information about the date of its formation. Radiometric dating of rocks older than 60,000 years requires estimating radioisotope concentrations in *igneous* rocks, which are formed when molten material cools. To date sedimentary strata, geologists search for places where volcanic ash or lava flows have intruded into the sedimentary rock.

A preliminary estimate of the age of an igneous rock determines which radioisotopes can be used to date it (**FIGURE 18.1B**). The decay of potassium-40 (which has a half-life of 1.3 billion years) to argon-40, for example, has been used to date many of the ancient events in the evolution of life. Fossils in the adjacent sedimentary rock that are similar to those in other rocks of known ages provide additional clues to the rock's age.

MAJOR EVENTS IN THE HISTORY OF LIFE

Humans evolve; many large mammals become extinct
Diversification of birds, mammals, flowering plants, and insects

Dinosaurs continue to diversify; mass extinction at end of period
(≈76% of species disappear)

Diverse dinosaurs; radiation of ray-finned fishes; first fossils of flowering plants

Early dinosaurs; first mammals; marine invertebrates diversify;
mass extinction at end of period (≈65% of species disappear)

Reptiles diversify; giant amphibians and flying insects present;
mass extinction at end of period (≈96% of species disappear)

Extensive "fern" forests; first reptiles; insects diversify

Fishes diversify; first insects and amphibians; mass extinction at end
of period (≈75% of marine species disappear)

Jawless fishes diversify; first ray-finned fishes; plants and animals
colonize land

Mass extinction at end of period (≈75% of species disappear)

Rapid diversification of multicellular animals; diverse photosynthetic
protists

Earliest fossils of multicellular animals

Eukaryotes evolve

Origin of life; prokaryotes flourish

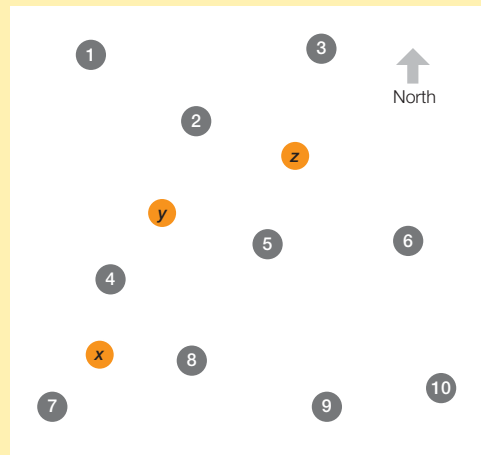

APPLY THE CONCEPT

Events in Earth's history can be dated

Imagine you have been assigned the job of producing a geological map of volcanic rocks that were formed between 400 and 600 million years ago. You collect samples from ten sites (1–10 on the map at lower right). Then you can determine the ratio of ^{206}Pb to ^{238}U for each sample and use these ratios to estimate the ages of the rock samples, as given in the table below. Use the data to answer the following questions.

SITE	$^{206}\text{Pb}/^{238}\text{U}$ RATIO ESTIMATED	AGE (MYA)
1	0.076	474
2	0.077	479
3	0.069	431
4	0.081	505
5	0.076	474
6	0.070	435
7	0.089	550
8	0.080	500
9	0.079	495
10	0.077	479

1. Use the table shown here and Table 18.1 to assign each sample to a geological period.
2. Use these estimated ages and geological periods of the samples to mark rough boundaries between the geological periods among the sample locations on the map below.
3. If you wanted to refine the boundary between the Ordovician and Silurian on your map, which of three new sampling sites—*x*, *y*, or *z*—would you add to your analysis next?

Scientists have used several methods to construct a geological time scale

Radiometric dating of rocks, combined with fossil analysis, is the most powerful method of determining geological age. But in places where sedimentary rocks do not contain suitable igneous intrusions and few fossils are present, paleontologists turn to other dating methods.

One method, known as **paleomagnetic dating**, relates the ages of rocks to patterns in Earth's magnetism, which change over time. Earth's magnetic poles move and occasionally reverse themselves. Both sedimentary and igneous rocks preserve a record of Earth's magnetic field at the time they were formed, and that paleomagnetism can be used to determine the ages of those rocks. Other dating methods use information about continental drift, information about sea level changes, and molecular clocks (the last of which was described in Concept 16.3).

Using all of these methods, geologists developed a geological time scale. They divided the history of life into *eras*, which in turn are subdivided into *periods* (TABLE 18.1). They based the boundaries between these divisions of time on the striking differences they observed in the assemblages of fossil organisms contained in successive strata. Geologists defined and named these divisions before they were able to establish the ages of rocks or fossils, and refined the geological time scale as new methods for geological dating were developed.

Do You Understand Concept 18.1?

- What observations about fossils suggested to geologists that they could be used to determine the relative ages of rocks?
- Why are radioisotopes not measured directly from sedimentary rocks to determine their ages?
- Given the problems of dating sedimentary rocks using radioisotopes, what other methods can geologists use to date sedimentary rocks?

The relative time spans at the left of Table 18.1 give us a sense of the scope of geological time—especially the vast expanse of Precambrian time during which, as we describe next, early life evolved amid stupendous physical changes in Earth and its atmosphere.

concept 18.2 Changes in Earth's Physical Environment Have Affected the Evolution of Life

Physical changes to Earth did not end in the Precambrian. Earth has continued to undergo massive physical changes throughout its history that have influenced the evolution of life. And, in its turn, life has influenced Earth's physical environment.

The continents have not always been where they are today

The globes and maps that adorn our walls, shelves, and books give an impression of a static Earth. It would be easy for us to assume that the continents have always been where they are. But we would be wrong. The idea that Earth's land masses have changed position over the millennia, and that they continue to do so, was first put forth in 1912 by the German meteorologist and geophysicist Alfred Wegener. His idea was initially met with skepticism and resistance. By the 1960s, however, physical evidence and increased understanding of **plate tectonics**—the geophysics of the movement of major land masses—had convinced virtually all geologists of the reality of Wegener's vision.

Earth's crust consists of several solid plates approximately 40 kilometers thick, which collectively make up the *lithosphere*. The lithospheric plates float on a fluid layer of molten rock, or *magma* (FIGURE 18.2). Heat produced by radioactive decay deep in Earth's core sets up convection currents in the fluid magma, which rises and exerts tremendous pressure on the solid plates. Where the pressure of the rising magma pushes plates apart, ocean basins may form. Where it pushes plates together, the plates may move sideways past each other. Alternatively, one plate may slide under the other, which can lead to the formation of mountain ranges and volcanoes. The movement of the lithospheric plates and the continents they carry is known as **continental drift**.

Many physical conditions on Earth have oscillated in response to plate tectonic processes such as continental drift and volcanic activity. We now know that the movement of the plates has brought continents together at times and at other times has pushed them apart (see the maps across the top of

Figure 18.12). The positions and sizes of the continents influence oceanic circulation patterns, global climates, and sea levels. Sea level is influenced directly by plate tectonic processes (which can influence the depth of ocean basins) and indirectly by oceanic circulation patterns, which affect patterns of glaciation. As climates cool, glaciers tie up water over land masses; as climates warm, they melt and release water.

Some of these dramatic changes in Earth's physical parameters resulted in **mass extinctions**, during which a large proportion of the species living at the time disappeared. These mass extinctions are the cause of the striking differences in fossil assemblages that geologists used to divide the units of the geological time scale. After each mass extinction, the diversity of life rebounded, but recovery took millions of years.

Earth's climate has shifted between hot and cold conditions

Through much of its history, Earth's climate was considerably warmer than it is today, and temperatures decreased more gradually toward the poles. At other times, Earth was colder than it is today. Rapid drops in sea level near the ends of the Ordovician, Devonian, Permian, Triassic, and Cretaceous periods, and most recently in the Quaternary period, resulted mainly from increased global glaciation (FIGURE 18.3). Many of these drops in sea level were accompanied by mass extinctions—particularly of marine organisms, which could not survive the disappearance of the shallow seas that covered vast areas of the continental shelves.

Earth's cold periods were separated by long periods of milder climates. Because we are living in one of the colder periods, it is difficult for us to imagine the mild climates that were found at high latitudes during much of the history of life. The Quaternary period has been marked by a series of glacial advances, interspersed with warmer *interglacial* intervals during which the glaciers retreated.

Evolution of the Continents

FIGURE 18.2 Plate Tectonics and Continental Drift The heat of Earth's core generates convection currents in the fluid magma underlying the lithospheric plates. Those currents push the lithospheric plates, along with the land masses they carry, together or apart. Where lithospheric plates collide, one may slide under the other, creating mountain ranges and often volcanoes.

FIGURE 18.3 Sea Levels Have Changed Repeatedly Most mass extinctions of marine organisms (indicated by asterisks) have coincided with low sea levels. Rapid drops in sea level are associated with periods of increased glaciation.

Weather refers to the daily events at a given location, such as individual storms and the high and low temperatures on a given day. *Climate* refers to long-term average expectations over the various seasons at a given location. Weather often changes rapidly; climates typically change slowly. However, major climatic shifts have taken place over periods as short as 5,000 to 10,000 years, primarily as a result of changes in Earth's orbit around the sun. A few climatic shifts have been even more rapid; during one Quaternary interglacial period, the ice-locked Antarctic Ocean became nearly ice-free in less than 100 years. Some climate changes have been so rapid that the extinctions caused by them appear to be nearly instantaneous in the fossil record. Such rapid changes are usually caused by sudden shifts in ocean currents.

We are currently living in a time of rapid climate change thought to be caused by a buildup of atmospheric CO_2 , primarily from the burning of fossil fuels by human populations. We are reversing the energy transformations accrued in the burial and decomposition of organic material that occurred (especially) in the Carboniferous and the Permian, but we are doing so over a few hundred years, rather than the many millions of years over which those deposits accumulated. The current rate of increase of atmospheric CO_2 is unprecedented in Earth's history. A doubling of the atmospheric CO_2 concentration—which may happen during the current century—is expected to increase the average temperature of Earth, change rainfall patterns, melt glaciers and ice caps, and raise sea level.

LINK The consequences of today's rapid climate changes will be discussed in Concept 46.5

Volcanoes have occasionally changed the history of life

Most volcanic eruptions produce only local or short-lived effects, but a few large volcanic eruptions have had major consequences for life. When Krakatau (a volcanic island in the Sunda Strait off Indonesia) erupted in 1883, it ejected more than 25 cubic kilometers of ash and rock, as well as large quantities of sulfur dioxide gas (SO_2). The SO_2 was ejected into the stratosphere and carried by high-altitude winds around the planet. Its presence led to high concentrations of sulfurous acid (H_2SO_3) in high-altitude clouds, creating a "parasol effect" so that less sunlight reached Earth's surface. Global temperatures dropped by 1.2°C in the year following the eruption, and global weather patterns showed strong effects for another 5 years. More recently, the eruption of Mount Pinatubo in the Philippines in 1991 (**FIGURE 18.4**) temporarily reduced global temperatures by about 0.5°C . Although these individual volcanoes had only relatively short-term effects on global temperatures, they suggest that the simultaneous eruption of many volcanoes could have a much stronger effect on Earth's climate.

FRONTIERS The temporary cooling of our planet that has taken place after volcanic eruptions led some scientists to propose a controversial plan for slowing or even reversing the recent pattern of global warming. Clouds of small reflective particles injected high into the stratosphere (using high-altitude planes, or ground-to-sky pipelines supported by balloons) could reflect small amounts of sunlight and thereby keep Earth from warming too quickly. Although such a scheme might have unintended consequences, nations may begin to consider such radical solutions to counter the deadly consequences of global warming.

What would cause many volcanoes to erupt at the same time? The collision of continents during the Permian period (about 275 mya) formed a single, gigantic land mass and caused a multitude of massive volcanic eruptions as the continental

FIGURE 18.4 Volcanic Eruptions Can Cool Global Temperatures When Mount Pinatubo erupted in 1991, it increased the concentrations of sulfuric acid in high-altitude clouds, which temporarily lowered global temperatures by about 0.5°C.

plates overrode one another (see Figure 18.2). Emissions from these eruptions blocked considerable sunlight, contributing to the advance of glaciers and a consequent drop in sea level (see Figure 18.3). Thus volcanoes were probably responsible, at least in part, for the greatest mass extinction in Earth's history.

Extraterrestrial events have triggered changes on Earth

At least 30 meteorites of sizes between tennis and soccer balls strike Earth each year. Collisions with larger meteorites or comets are rare, but such collisions have probably been responsible for several mass extinctions. Several types of evidence tell us about these collisions. Their craters, and the dramatically disfigured rocks that result from their impact, are found in many places. Geologists have discovered compounds in these rocks that contain helium and argon with isotope ratios characteristic of meteorites, which are very different from the ratios found elsewhere on Earth.

A meteorite caused or contributed to a mass extinction at the end of the Cretaceous period (about 65 mya). The first clue that a meteorite was responsible came from the abnormally

high concentrations of the element iridium found in a thin layer separating rocks deposited during the Cretaceous from rocks deposited during the Tertiary (**FIGURE 18.5**). Iridium is abundant in some meteorites, but it is exceedingly rare on Earth's surface. When scientists then discovered a circular crater 180 km in diameter buried beneath the northern coast of the Yucatán Peninsula of Mexico, they constructed the following scenario. When it collided with Earth, the meteorite released energy equivalent to that of 100 million megatons of high explosives, creating great tsunamis. A massive plume of debris rose into the atmosphere, spread around Earth, and descended. The descending debris heated the atmosphere to several hundred degrees and ignited massive fires. It also blocked the sun, preventing plants from photosynthesizing. The settling debris formed the iridium-rich layer. About a billion tons of soot with a composition matching that of smoke from forest fires was also deposited. These events had devastating effects on biodiversity. Many fossil species (including non-avian dinosaurs) that are found in Cretaceous rocks are not found in the Tertiary rocks of the next stratum.

Oxygen concentrations in Earth's atmosphere have changed over time

As the continents have moved over Earth's surface, the world has experienced other physical changes, including large increases and decreases in atmospheric oxygen concentrations. The atmosphere of early Earth probably contained little or no free oxygen gas (O_2). The increase in atmospheric O_2 came in two big steps more than a billion years apart.

FIGURE 18.5 Evidence of a Meteorite Impact The white layers of rock are Cretaceous in age; the layers at the upper left were deposited in the Tertiary. Between the two is a thin, dark layer of clay that contains large amounts of iridium, a metal common in some meteorites but rare on Earth. Its high concentration in these sediments, deposited about 65 million years ago, suggests the impact of a large meteorite at that time.

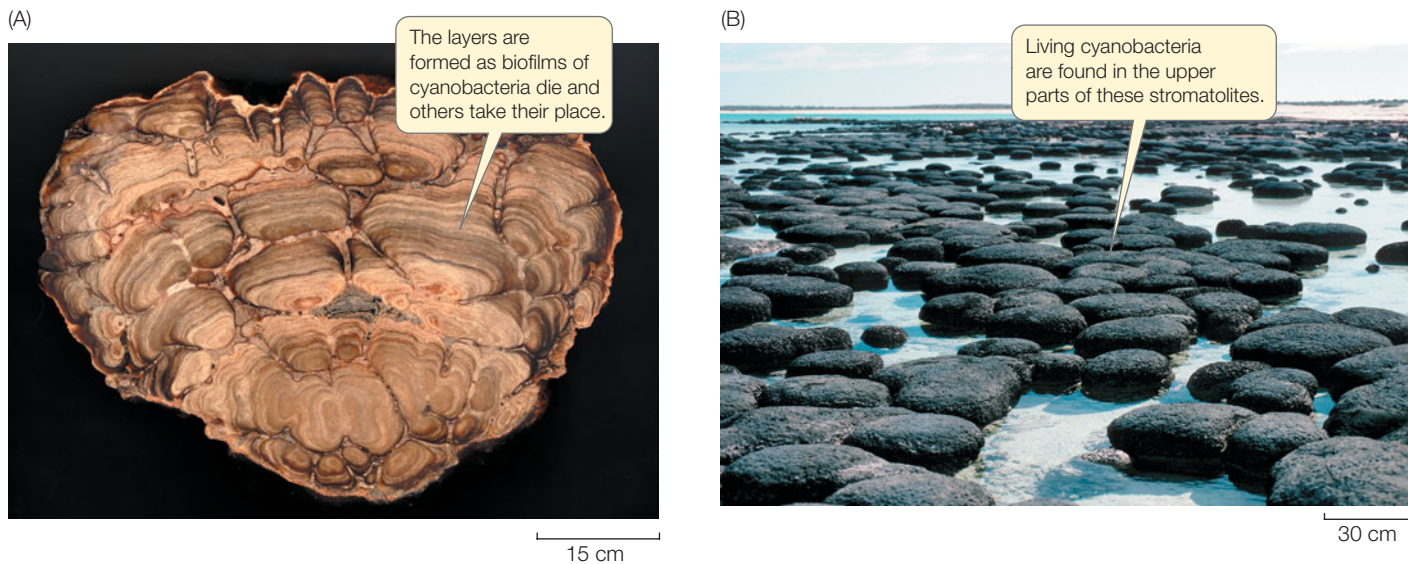

FIGURE 18.6 Stromatolites (A) A vertical section through a fossil stromatolite. (B) These rocklike structures are living stromatolites that thrive in the very salty waters of Shark Bay in Western Australia.

The first step occurred at least 2.4 billion years ago (bya), when certain bacteria evolved the ability to use water as the source of hydrogen ions for photosynthesis. By chemically splitting H_2O , these bacteria generated O_2 as a waste product. They also made electrons available for reducing CO_2 to form the carbohydrate end-products of photosynthesis (see Concepts 6.5 and 6.6). The second step occurred about a billion years later, when some of these bacteria became symbiotic within eukaryote cells, leading to the evolution of chloroplasts in photosynthetic plants and other eukaryotes.

One group of O_2 -generating bacteria, the *cyanobacteria*, formed rocklike structures called *stromatolites*, which are abundantly preserved in the fossil record. To this day, cyanobacteria

still form stromatolites in a few very salty places (**FIGURE 18.6**). Cyanobacteria liberated enough O_2 to open the way for the evolution of oxidation reactions as the energy source for the synthesis of ATP.

The evolution of life irrevocably changed the physical nature of Earth. Those physical changes, in turn, influenced the evolution of life. When it first appeared in the atmosphere, O_2 was poisonous to most of the anaerobic prokaryotes that inhabited Earth at the time. Over millennia, however, prokaryotes that evolved the ability to tolerate and use O_2 not only survived but gained the advantage. Aerobic metabolism proceeds more rapidly, and harvests energy more efficiently, than anaerobic metabolism. Organisms with aerobic metabolism replaced anaerobes in most of Earth's environments.

An atmosphere rich in O_2 also made possible larger and more complex organisms. Small single-celled aquatic organisms can obtain enough oxygen by simple diffusion even when dissolved oxygen concentrations in the water are very low. Larger single-celled organisms, however, have lower surface area-to-volume ratios; to obtain enough oxygen by simple diffusion, they must live in an environment with a relatively high oxygen concentration. Bacteria can thrive at 1 percent of the current oxygen concentration; eukaryotic cells require levels that are at least 2–3 percent of the current concentration. (For concentrations of dissolved oxygen in the oceans to have reached these levels, much higher atmospheric concentrations were needed.)

FIGURE 18.7 Larger Cells and Organisms Need More Oxygen Changes in atmospheric oxygen concentrations have strongly influenced, and been influenced by, the evolution of life. (Note that the horizontal axis of the graph is on a logarithmic scale.)

Probably because it took many millions of years for Earth to develop an oxygenated atmosphere, only single-celled prokaryotes lived on Earth for more than 2 billion years. About 1.5 bya, atmospheric O_2 concentrations became high enough for larger eukaryotic cells to flourish (**FIGURE 18.7**). Further increases in atmospheric O_2 concentrations in the late Precambrian enabled several groups of multicellular organisms to evolve.

INVESTIGATION

FIGURE 18.8 Atmospheric Oxygen Concentrations and Body Size in Insects C. Jaco Klok and his colleagues asked whether insects raised in hyperoxic conditions would evolve to be larger than their counterparts raised under today's atmospheric conditions. They raised strains of fruit flies (*Drosophila melanogaster*) under both conditions to test the effects of increased O_2 concentrations on the evolution of body size.

HYPOTHESIS

In hyperoxic conditions, increased partial pressure of oxygen results in evolution of increased body size in flying insects.

METHOD

1. Separate a population of fruit flies into multiple lines.
2. Raise half the lines in current atmospheric (control) conditions; raise the other lines in hyperoxic (experimental) conditions. Continue all lines for seven generations.
3. Raise the F_8 individuals of all lines under identical (current) atmospheric conditions.
4. Weigh 50 flies from each of the replicate lines and test for statistical differences in body weight.

RESULTS

The average body mass of F_8 individuals of both sexes raised under hyperoxic conditions was significantly ($p < 0.001$) greater than that of individuals in the control lines:

CONCLUSION

Increased O_2 concentrations led to evolution of larger body size in fruit flies, consistent with the trends seen among other flying insects in the fossil record.

ANALYZE THE DATA

The table shows the average body masses of the flies raised in hyperoxic conditions in the F_0 (i.e., before the first generation in hyperoxia), F_1 , F_2 , and F_8 generations.

Generation	Average body mass (mg)	
	Males	Females
F_0	0.732	1.179
F_1	0.847	1.189
F_2	0.848	1.254
F_8	0.878	1.392

- A. Graph body mass versus generation for males and females.
- B. Do the rates of evolution of larger body size appear to be constant throughout the experiment?
- C. If you doubled the number of generations in the experiment, would you expect the increase in body mass seen under the hyperoxic conditions to double? Why or why not?

O_2 concentrations increased again during the Carboniferous and Permian periods because of the evolution of large vascular plants. These plants lived in the expansive lowland swamps that existed at the time (see Table 18.1). Massive amounts of organic material were buried in these swamps as the plants died, leading to the formation of Earth's vast coal deposits. Because the buried organic material was not subject to oxidation as it decomposed, and because the living plants were producing large quantities of O_2 , atmospheric O_2 increased to concentrations that have not been reached again in Earth's history (see Figure 18.7). As mentioned at the opening of this chapter, these high concentrations of atmospheric O_2 allowed the evolution of giant flying insects and amphibians that could not survive in today's atmosphere.

The drying of the lowland swamps at the end of the Permian reduced burial of organic matter as well as the production of O_2 , so atmospheric O_2 concentrations dropped rapidly. Over the past 200 million years, with the diversification of flowering plants, O_2 concentrations have again increased, but not to the levels that characterized the Carboniferous and Permian periods.

Biologists have conducted experiments that demonstrate the changing selection pressures that can accompany changes in atmospheric O_2 concentrations. When fruit flies (*Drosophila*) are raised in *hyperoxic* conditions (i.e., with artificially increased atmospheric concentrations of O_2), they evolve larger body sizes in just a few generations (FIGURE 18.8). The present atmospheric O_2 concentrations appear to constrain body size in these flying insects; increases in O_2 appear to relax those constraints. This experiment demonstrates that the *stabilizing selection* on body size at present O_2 concentrations can quickly switch to *directional selection* for a change in body size in response to a change in O_2 concentrations (see Concept 15.4).

Do You Understand Concept 18.2?

- How have volcanic eruptions and meteorite strikes influenced the course of life's evolution?
- Explain why an occasional major winter blizzard is irrelevant to discussions of global climatic warming.
- Research and explain the different climatic responses to the "parasol effect" of major volcanic eruptions and the "greenhouse effect" of long-term CO_2 emissions. What is the fundamental difference in the two effects?
- How have increases in atmospheric concentrations of O_2 affected the evolution of multicellular organisms?

The many dramatic physical events of Earth's history have influenced the nature and timing of evolutionary changes among Earth's living organisms. We will now look more closely at some of the major events that characterize the history of life on Earth.

APPLY THE CONCEPT

Changes in Earth's atmosphere have affected the evolution of life

In the experiment shown in Figure 18.8, body mass of individuals in the experimental population of *Drosophila* increased (on average) about 2% per generation in the high-oxygen environment (although the rate of increase was not constant over the experiment). What rate of increase in body mass per generation would be sufficient to account for the giant dragonflies of the Permian?

1. Assume that the average rate of increase in dragonfly size during the Permian was much slower than the rate observed in the experiment in Figure 18.8. We'll assume that the actual rate of increase for dragonflies was just 0.01% per generation, rather than the 2% observed over a few generations for *Drosophila*. We'll assume further that dragonflies complete just one generation per year (as opposed to 40 or more

generations for *Drosophila*). Starting with an average body mass of 1 gram, calculate the projected increase in body mass over 50,000 years.*

2. What percentage of the Permian period does 50,000 years represent? Use Table 18.1 for your calculation.
3. Given your calculations, do you think that increased oxygen concentrations during the Permian were sufficient to account for the evolution of giant dragonflies? Why or why not?

*This calculation is similar to computing compound interest for a savings account. Use the formula $W = S(1 + R)^N$, where W = the final mass, S = the starting mass (1 gram), R = the rate of increase per generation (0.0001 in this case), and N = the number of generations.

concept 18.3 Major Events in the Evolution of Life Can Be Read in the Fossil Record

How do we know about the physical changes in Earth's environment and their effects on the evolution of life? To reconstruct life's history, scientists rely heavily on the fossil record. Geologists divided Earth's history into eras and periods based on their distinct fossil assemblages (see Table 18.1). Biologists refer to the assemblage of all organisms of all kinds living at a particular time or place as a **biota**. All of the plants living at a particular time or place are its **flora**; all of the animals are its **fauna**.

About 300,000 species of fossil organisms have been described, and the number steadily grows. The number of named species, however, is only a tiny fraction of the species that have ever lived. We do not know how many species lived in the past, but we have ways of making reasonable estimates. Of the present-day biota, nearly 1.8 million species have been named. The actual number of living species is probably well over 10 million, and possibly much higher, because many species have not yet been discovered and described by biologists. So the number of described fossil species is only about 3 percent of the estimated minimum number of living species. Life has existed on Earth for about 3.8 billion years. Many species last only a few million years before undergoing speciation or going extinct; therefore, Earth's biota must have turned over many times during geological history. So the total number of species that have lived over evolutionary time must vastly exceed the number living today. Why have only about 300,000 of these tens of millions of species been described from fossils to date?

Several processes contribute to the paucity of fossils

Only a tiny fraction of organisms ever become fossils, and only a tiny fraction of fossils are ever discovered by paleontologists.

Most organisms live and die in oxygen-rich environments in which they quickly decompose. They are not likely to become fossils unless they are transported by wind or water to sites that lack oxygen, where decomposition proceeds slowly or not at all. Furthermore, geological processes transform many rocks, destroying the fossils they contain, and many fossil-bearing rocks are deeply buried and inaccessible. Paleontologists have studied only a tiny fraction of the sites that contain fossils, although they find and describe many new ones every year.

The fossil record is most complete for marine animals that had hard skeletons (which resist decomposition). Among the nine major animal groups with hard-shelled members, approximately

Solenopsis sp.

FIGURE 18.9 Insect Fossils Chunks of amber—fossilized tree resin—often contain insects that were preserved when they were trapped in the sticky resin. This fire ant fossil is some 30 million years old.

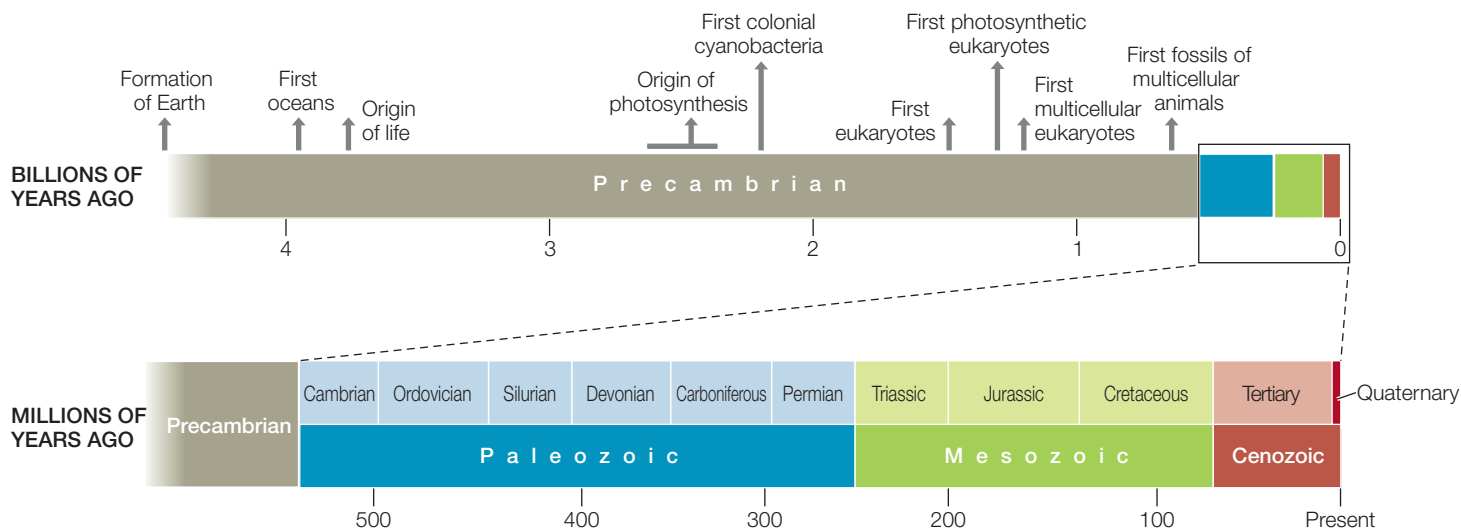

FIGURE 18.10 A Sense of Life's Time The top timeline shows the 4.5-billion-year history of Earth. Most of this history is accounted for by the Precambrian, a 3.4-billion-year time span that saw the origin of life and the evolution of cells, photosynthesis, and multicellularity. The final 600 million years are expanded in the bottom timeline and detailed in Figure 18.12.

200,000 species have been described from fossils—roughly twice the number of living marine species in these same groups. Paleontologists lean heavily on these groups in their interpretations of the evolution of life. Insects and spiders are also relatively well represented in the fossil record because they are numerically abundant and have hard exoskeletons (FIGURE 18.9). The fossil record, though incomplete, is good enough to document clearly the factual history of the evolution of life.

By combining information about physical changes during Earth's history with evidence from the fossil record, scientists have composed portraits of what Earth and its inhabitants may have looked like at different times. We know in general where the continents were and how life changed over time, but many of the details are poorly known, especially for events in the more remote past.

Precambrian life was small and aquatic

Life first appeared on Earth about 3.8 bya. By about 1.5 bya, eukaryotic organisms had evolved. The fossil record of organisms that lived prior to 550 mya is fragmentary, but it is good enough to establish that the total number of species and individuals increased dramatically in the late Precambrian.

For most of its history, life was confined to the oceans, and all organisms were small. Over the long Precambrian—more than

3 billion years—the shallow seas slowly began to teem with life. For most of the Precambrian, life consisted of microscopic prokaryotes; eukaryotes evolved about three-quarters of the way through the era (FIGURE 18.10). Unicellular eukaryotes and small multicellular animals fed on floating photosynthetic microorganisms. Small floating organisms, known collectively as *plankton*, were strained from the water and eaten by slightly larger *filter-feeding* animals. Other animals ingested sediments on the seafloor and digested the remains of organisms within them. By the late Precambrian (630–542 mya), many kinds of multicellular soft-bodied animals had evolved. Some of them were very different from any animals living today and may be members of groups that have no living descendants (FIGURE 18.11).

FIGURE 18.11 Precambrian Life These fossils of soft-bodied marine invertebrates, excavated at Ediacara in southern Australia, were formed about 600 million years ago. These organisms, which are very different from later life forms, illustrate the diversity of life at the end of the Precambrian.

Charniodiscus arboreus

Tribrachidium heraldicum

Dickinsonia costata

FRONTIERS Some Precambrian-age tracks preserved in ancient seabeds were once attributed to large multicellular animals that left no direct fossil remains. But recent deep-sea studies of the relatively large (but single-celled) spherical protist *Gromia sphaerica* have shown that these organisms can pull themselves along the seafloor using pseudopods, thereby creating tracks similar to those preserved in the Precambrian rocks. The grape-sized *Gromia* “roll” along the sea bottom, even pulling themselves up moderate inclines. This finding has stimulated paleontologists to reconsider the source of some Precambrian tracks.

Life expanded rapidly during the Cambrian period

The Cambrian period (542–488 mya) marks the beginning of the Paleozoic era. The O₂ concentration in the Cambrian atmosphere was approaching its current level, and the land masses had come together to form several large continents. A geologically rapid diversification of life took place that is sometimes referred to as the **Cambrian explosion** (although in fact it began before the Cambrian, and the “explosion” took millions of years). Many of the major animal groups represented by species alive today first appeared during the Cambrian. Such periods of rapid diversification are known as **evolutionary radiations**. **FIGURE 18.12** provides an overview of the continental and biotic shifts that characterized the Cambrian and subsequent periods.

For the most part, fossils tell us only about the hard parts of organisms, but in three known Cambrian fossil beds—the Burgess Shale in British Columbia, Sirius Passet in northern Greenland, and the Chengjiang site in southern China—the soft parts of many animals were preserved. Crustacean arthropods (crabs, shrimps, and their relatives) are the most diverse group in the Chinese fauna; some of them were large carnivores. Multicellular life was largely or completely aquatic during the Cambrian. If there was life on land at this time, it was probably restricted to microorganisms.

Many groups of organisms that arose during the Cambrian later diversified

Geologists divide the remainder of the Paleozoic era into the Ordovician, Silurian, Devonian, Carboniferous, and Permian periods. Each period is characterized by the diversification of specific groups of organisms. Mass extinctions marked the ends of the Ordovician, Devonian, and Permian.

THE ORDOVICIAN (488–444 MYA) During the Ordovician period, the continents, which were located primarily in the Southern Hemisphere, still lacked multicellular plants. Evolutionary radiation of marine organisms was spectacular during the early Ordovician, especially among animals, such as brachiopods and mollusks, that lived on the seafloor and filtered small prey from the water. At the end of the Ordovician, as massive glaciers formed over the southern continents, sea levels dropped about 50 meters, and ocean temperatures dropped. About 75 percent of all animal species became extinct, probably because of these major environmental changes.

THE SILURIAN (444–416 MYA) During the Silurian period, the continents began to merge together. Marine life rebounded from the mass extinction at the end of the Ordovician. Animals able to swim in open water and feed above the ocean floor appeared for the first time. Jawless fishes diversified, and the first fishes with supporting rays in their fins evolved (see Figure 23.38). The tropical sea was uninterrupted by land barriers, and most marine organisms were widely distributed. On land, the first vascular plants evolved late in the Silurian (about 420 mya). The first terrestrial arthropods—scorpions and millipedes—evolved at about the same time.

THE DEVONIAN (416–359 MYA) Rates of evolutionary change accelerated in many groups of organisms during the Devonian period. The major land masses continued to move slowly toward each other. In the oceans there were great evolutionary radiations of corals and of shelled, squidlike cephalopod mollusks. Fishes diversified as jawed forms replaced jawless ones (see Figure 23.39) and as bony armor gave way to the less rigid scales of modern fishes.

Terrestrial communities changed dramatically during the Devonian. Club mosses, horsetails, and tree ferns became common; some attained the size of large trees. Their roots accelerated the weathering of rocks, resulting in the development of the first forest soils. The first plants to produce seeds appeared in the Devonian. The earliest fossil centipedes, spiders, mites, and insects date to this period, as do the earliest fossil terrestrial amphibians.

A massive extinction of about 75 percent of all marine species marked the end of the Devonian. Paleontologists are uncertain about its cause, but two large meteorites collided with Earth at about that time (one in present-day Nevada, the other in western Australia) and may have been responsible, or at least a contributing factor. The continued coalescence of the continents, with the corresponding reduction in the area of continental shelves, may have also contributed to this mass extinction.

THE CARBONIFEROUS (359–297 MYA) Large glaciers formed over high-latitude portions of the southern land masses during the Carboniferous period, but extensive swamp forests grew on the tropical continents. These forests were dominated by giant tree ferns and horsetails with small leaves. Their fossilized remains formed the coal we now mine for energy. In the seas, crinoids (sea lilies and feather stars) reached their greatest diversity, forming “meadows” on the seafloor.

FIGURE 18.12 A Brief History of Multicellular Life on Earth ►

The geologically rapid “explosion” of life during the Cambrian saw the rise of several animal groups that have representatives surviving today. The following three pages depict life’s history from the Cambrian forward. The movements of the major continents during the past half-billion years are shown in the maps of Earth, and associated biotas for each time period are depicted. The artists’ reconstructions are based on fossils such as those shown in the photographs.

Cambrian

Marrella splendens

Ottoia sp.

Anomalocaris canadensis (claw only)

Devonian

Archaeopteris

Eusthenopteron fordi

Extensive swamp forests produce coal; origin of amniotes; great increase in terrestrial animal diversity

Giant amphibians and flying insects; ray-finned fishes abundant in fresh water

On land, conifers become dominant plants; frogs and reptiles begin to diversify

Dinosaurs, pterosaurs, ray-finned fishes diversify; first mammals appear

First known flowering plant fossils

300

200

Extinction of 96% of Earth's species; oxygen levels drop rapidly

Permian

Triassic

Megatypus schucherti (wing)

Walchia piniformis

Phleboteris smithii

Coelophysis bauri

Cretaceous

Chasmosaurus belli

Sapindopsis belviderensis (leaves)

Tertiary

Hyracotherium leporinum

Plesiadapis fodinatus (jaw)

FIGURE 18.13 Evidence of Insect Diversification The margins of this fossil fern leaf from the Carboniferous have been chewed by insects.

The diversity of terrestrial animals increased greatly during the Carboniferous. Snails, scorpions, centipedes, and insects were abundant and diverse. Insects evolved wings, becoming the first animals to fly. Flight gave herbivorous insects easy access to tall plants; plant fossils from this period show evidence of chewing by insects (**FIGURE 18.13**). The terrestrial vertebrates split into two lineages. The *amphibians* became larger and better adapted to terrestrial existence, while the sister lineage led to the *amniotes*—vertebrates with well-protected eggs that can be laid in dry places (see Concept 23.6).

THE PERMIAN (297–251 MYA) During the Permian period, the continents coalesced into a single supercontinent, known as **Pangaea**. Permian rocks contain representatives of many of the major groups of insects we know today. By the end of the period the amniotes had split into two lineages: the reptiles, and a second lineage that would lead to the mammals. Ray-finned fishes became common in the fresh waters of Pangaea.

Toward the end of the Permian, conditions for life deteriorated. Massive volcanic eruptions resulted in outpourings of lava that covered large areas of Earth. The ash and gases produced by the volcanoes blocked sunlight and cooled the climate, resulting in the largest glaciers in Earth's history. Atmospheric oxygen concentrations gradually dropped from about 30 percent to 15 percent. At such low concentrations, most animals would have been unable to survive at elevations above 500 meters; thus about half of the land area would have been uninhabitable at the end of the Permian. The combination of these changes resulted in the most drastic mass extinction in Earth's history. Scientists estimate that about 96 percent of all multicellular species became extinct at the end of the Permian.

Geographic differentiation increased during the Mesozoic era

The few organisms that survived the Permian mass extinction found themselves in a relatively empty world at the start of the Mesozoic era (251 mya). As Pangaea slowly began to break apart, the biotas of the newly separated continents began to

diverge. The oceans rose and once again flooded the continental shelves, forming huge, shallow inland seas. Atmospheric oxygen concentrations gradually rose. Life once again proliferated and diversified, but different groups of organisms came to the fore. The three groups of phytoplankton (floating photosynthetic organisms) that dominate today's oceans—dinoflagellates, coccolithophores, and diatoms—became ecologically important at this time; their remains are the primary origin of the world's oil deposits. Seed-bearing plants replaced the trees that had ruled the Permian forests.

The Mesozoic era is divided into three periods: the Triassic, Jurassic, and Cretaceous. The Triassic and Cretaceous were terminated by mass extinctions, probably caused by meteorite impacts.

THE TRIASSIC (251–200 MYA) Pangaea began to break apart during the Triassic period. Many invertebrate groups diversified, and many burrowing animals evolved from groups living on the surfaces of seafloor sediments. On land, conifers and seed ferns were the dominant trees. The first frogs and turtles appeared. A great radiation of reptiles began, which eventually gave rise to crocodylians, dinosaurs, and birds. The end of the Triassic was marked by a mass extinction that eliminated about 65 percent of the species on Earth.

THE JURASSIC (200–145 MYA) During the Jurassic period, Pangaea became fully divided into two large continents: **Laurasia**, which drifted northward, and **Gondwana**, which drifted southward. Ray-finned fishes rapidly diversified in the oceans. The first lizards appeared, and flying reptiles (pterosaurs) evolved. Most of the large terrestrial predators and herbivores of the period were dinosaurs. Several groups of mammals made their first appearance, and the earliest known fossils of flowering plants are from late in this period.

THE CRETACEOUS (145–65 MYA) By the early Cretaceous period, Laurasia and Gondwana had begun to break apart into the continents we know today. A continuous sea encircled the tropics. Sea levels were high, and Earth was warm and humid. Life proliferated both on land and in the oceans. Marine invertebrates increased in diversity. On land, the reptile radiation continued as dinosaurs diversified further and the first snakes appeared. Early in the Cretaceous, flowering plants began the radiation that led to their current dominance of the land. By the end of the period, many groups of mammals had appeared.

As described in Concept 18.2, another meteorite-caused mass extinction took place at the end of the Cretaceous. In the seas, many planktonic organisms and bottom-dwelling invertebrates became extinct. On land, almost all animals larger than about 25 kg in body weight became extinct. Many species of insects died out, perhaps because the growth of their food plants was greatly reduced following the impact. Some species in northern North America and Eurasia survived in areas that were not subjected to the devastating fires that engulfed most low-latitude regions.

Modern biotas evolved during the Cenozoic era

By the early Cenozoic era (65 mya), the positions of the continents resembled those of today, but Australia was still attached to Antarctica, and the Atlantic Ocean was much narrower. The Cenozoic was characterized by an extensive radiation of mammals, but other groups were also undergoing important changes.

Flowering plants diversified extensively and came to dominate world forests, except in the coolest regions, where the forests were composed primarily of gymnosperms. Mutations of two genes in one group of plants (the legumes) allowed them to use atmospheric nitrogen directly by forming symbioses with a few species of nitrogen-fixing bacteria. The evolution of this symbiosis was the first “green revolution” and dramatically increased the amount of nitrogen available for terrestrial plant growth; this symbiosis remains fundamental to the ecological base of life as we know it today (see Chapter 25).

The Cenozoic era is divided into the Tertiary and the Quaternary periods. Because both the fossil record and our subsequent knowledge of evolutionary history become more extensive as we approach our own time, paleontologists have subdivided these two periods into *epochs* (TABLE 18.2).

THE TERTIARY (65–2.6 MYA) During the Tertiary period, Australia began its northward drift. By 20 mya it had nearly reached its current position. The early Tertiary was a hot and humid time, and the ranges of many plants shifted latitudinally. The tropics were probably too hot to support rainforest vegetation and instead were clothed in low-lying vegetation. In the middle of the Tertiary, however, Earth’s climate became considerably cooler and drier. Many lineages of flowering plants evolved herbaceous (nonwoody) forms, and grasslands spread over much of Earth.

By the start of the Cenozoic era, invertebrate faunas had already come to resemble those of today. It is among the terrestrial vertebrates that evolutionary changes during the Tertiary were most rapid. Frogs, snakes, lizards, birds, and mammals all underwent extensive radiations during this period. Three waves of mammals dispersed from Asia to North America across one of the several land bridges that have intermittently connected the two continents during the past 55 million years. Rodents, marsupials, primates, and hoofed mammals appeared in North America for the first time.

TABLE 18.2 Subdivisions of the Cenozoic Era

PERIOD	EPOCH	ONSET (MYA)
Quaternary	Holocene (Recent)	0.01 (~10,000 years ago)
	Pleistocene	2.6
Tertiary	Pliocene	5.3
	Miocene	23
	Oligocene	34
	Eocene	55.8
	Paleocene	65

THE QUATERNARY (2.6 MYA TO PRESENT) We are living in the Quaternary period. It is subdivided into two epochs, the Pleistocene and the Holocene (the Holocene is also known as the Recent).

The Pleistocene was a time of drastic cooling and climate fluctuations. During 4 major and about 20 minor “ice ages,” massive glaciers spread across the continents, and the ranges of animal and plant populations shifted toward the equator. The last of these glaciers retreated from temperate latitudes less than 15,000 years ago. Organisms are still adjusting to this change. Many high-latitude ecological communities have occupied their current locations for no more than a few thousand years.

It was during the Pleistocene that divergence within one group of mammals, the primates, resulted in the evolution of the hominoid lineage. Subsequent hominoid radiation eventually led to the species *Homo sapiens*—modern humans. Many large bird and mammal species became extinct in Australia and in the Americas when *H. sapiens* arrived on those continents about 45,000 and 15,000 years ago, respectively. Many paleontologists believe these extinctions were the result of hunting and other influences of *Homo sapiens*.

LINK The evolution of modern humans and their close relatives during the Pleistocene is discussed in Concept 23.7

The tree of life is used to reconstruct evolutionary events

The fossil record reveals broad patterns in life’s evolution. To reconstruct major events in the history of life, biologists also rely on the phylogenetic information in the tree of life. We can use phylogeny, in combination with the fossil record, to reconstruct the timing of such major events as the acquisition of mitochondria in the ancestral eukaryotic cell, the several independent origins of multicellularity, and the movement of life onto dry land. We can also follow major changes in the genomes of organisms, and we can even reconstruct many gene sequences of species that are long extinct.

Changes in Earth’s physical environment have clearly influenced the diversity of organisms we see on the planet today. To study the evolution of that diversity, biologists examine the evolutionary relationships among species. Deciphering phylogenetic relationships is an important step in understanding how life has diversified on Earth. The next part of this book explores the major groups of life and the different solutions these groups have evolved to major challenges such as reproduction, energy acquisition, dispersal, and escape from predation.

Do You Understand Concept 18.3?

- Why have so few of the organisms that have existed over Earth’s history become fossilized?
- What do we mean by the “Cambrian explosion”? How long did it last, and in what sense was it an “explosion”?
- What are some of the ways in which continental drift has affected the evolution of life?

Can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

ANSWER Several experiments have been conducted to test the link between O_2 concentrations and evolution of body size in flying insects. One of these is discussed in Figure 18.8. The results of these experiments are consistent with the evolution of larger body size in flying insects in hyperoxic (high-oxygen) environments.

Experiments have also been conducted under *hypoxic* (low-oxygen) conditions, as existed at the end of the Permian. These experiments suggest that the evolution of body size is constrained under hypoxic conditions, even under strong artificial selection for larger body size. These latter results are consistent with the extinction of many large flying insects at the end of the Permian as a result of rapidly decreasing O_2 concentrations. Giant flying insects simply could not have survived the lower O_2 concentrations that existed at that time. The mass extinction at the end of the Permian is the only known mass extinction that involved considerable loss of insect diversity.

18 SUMMARY

concept 18.1 Events in Earth's History Can Be Dated

- The relative ages of organisms can be determined by the dating of fossils and the **strata** of **sedimentary rocks** in which they are found.
- **Radiometric dating** techniques use a variety of radioisotopes with different **half-lives** to date events in the remote past. **Review Figure 18.1**
- Geologists divide the history of life into eras and periods, based on major differences in the fossil assemblages found in successive strata. **Review Table 18.1**

concept 18.2 Changes in Earth's Physical Environment Have Affected the Evolution of Life

- Earth's crust consists of solid lithospheric plates that float on fluid magma. **Continental drift** is caused by convection currents in the magma, which move the plates and the continents that lie on top of them. **Review Figure 18.2 and ANIMATED TUTORIAL 18.1**
- Major physical events on Earth, such as continental collisions and volcanic eruptions, have affected Earth's climate, atmosphere, and sea levels. In addition, extraterrestrial events such as meteorite strikes have created sudden and dramatic environmental shifts. All of these changes affected the history of life. **Review Figure 18.3 and Table 18.1**
- Oxygen-generating cyanobacteria liberated enough O_2 to open the door to oxidation reactions in metabolic pathways. Aerobic

prokaryotes were able to harvest more energy than anaerobic organisms and began to proliferate. Increases in atmospheric O_2 concentrations supported the evolution of large eukaryotic cells and, eventually, multicellular organisms. **Review Figures 18.7 and 18.8**

concept 18.3 Major Events in the Evolution of Life Can Be Read in the Fossil Record

- Paleontologists use fossils and evidence of geological changes to determine what Earth and its biota may have looked like at different times. **Review Figure 18.12**
- During the Precambrian, which accounts for most of life's history, life was confined to the oceans. Multicellular life diversified extensively during the **Cambrian explosion**, a prime example of an **evolutionary radiation**.
- The periods of the Paleozoic era were each characterized by the diversification of specific groups of organisms.
- During the Mesozoic era, distinct terrestrial **biotas** evolved on each continent.
- Five episodes of **mass extinction** punctuated the history of life in the Paleozoic and Mesozoic eras.
- Earth's **flora** has been dominated by flowering plants since the Cenozoic era began.
- The tree of life can be used to reconstruct the timing of evolutionary events.

See **WEB ACTIVITY 18.1** for a concept review of this chapter.

Diversity

Bacteria, Archaea, and Viruses

19

On the night of January 25, 1995, the British merchant vessel *Lima* was off the coast of Somalia, near the Horn of Africa. This area is infamous for bands of pirates, so the crew was keeping a watchful eye on the seas. On the horizon, they spotted an eerie whitish glow. It was directly in their path, and there was no way to avoid it. Was the glow the result of some strange trick of piracy?

Within 15 minutes of first spotting the glow, the *Lima* was surrounded by glowing waters for as far as her crew could see. As the ship's log recorded, "it appeared as though the ship was sailing over a field of snow or gliding over the clouds." Fortunately for the crew, the glow had nothing to do with pirates.

For centuries, mariners in this part of the world had reported occasional "milky seas" in which the sea surface produced a strange glow at night, extending from horizon to horizon. Scientists to that point had never been able to confirm the reality or the cause of such phenomena. It was well established, however, that many organisms can emit light by *bioluminescence*—a complex, enzyme-catalyzed biochemical reaction that results in the emission of light but not heat.

But what kind of organisms could cause the vast expanse of bioluminescence observed by the *Lima*? Some protists are known to emit flashes of light when disturbed, but they could not produce the sustained and uniform glow seen in milky seas. The only organisms known to produce the quality of bioluminescence consistent with milky seas are prokaryotes, such as bacteria of the genus *Vibrio*.

Using information supplied by the *Lima*, biologists scanned satellite images of the Indian Ocean for the specific light wavelengths emitted by *Vibrio*. The

satellite images clearly showed thousands of square kilometers of *Vibrio*-produced milky seas.

Why does *Vibrio* produce bioluminescence? These bacteria can live freely, but they thrive inside the guts of fish. Inside a fish, they may attach themselves to food particles, including phytoplankton, and may then be expelled as waste. At low densities, *Vibrio* populations do not glow. But as the bacteria reproduce on the phytoplankton, their population increases. When it reaches a certain density, the bacteria begin to glow. The glow attracts other fish, which ingest the bacteria along with the phytoplankton—giving the bacteria a new home and food source for a while.

How do *Vibrio* populations detect when they are dense enough to produce bioluminescence?*

*You will find the answer to this question on page 386.

A satellite image reveals thousands of square kilometers of "milky seas" in the Indian Ocean. This expanse of bioluminescence is produced by *Vibrio* bacteria.

KEY CONCEPTS

- 19.1 Life Consists of Three Domains That Share a Common Ancestor
- 19.2 Prokaryote Diversity Reflects the Ancient Origins of Life
- 19.3 Ecological Communities Depend on Prokaryotes
- 19.4 Viruses Have Evolved Many Times

concept 19.1 Life Consists of Three Domains That Share a Common Ancestor

You may think that you have little in common with a bacterium. But all multicellular eukaryotes—including you—share many attributes with bacteria and archaea, together called *prokaryotes*. For example, all organisms, whether eukaryotes or prokaryotes,

- have plasma membranes and ribosomes (see Chapter 4).
- have a common set of metabolic pathways, such as glycolysis (see Chapter 6).
- replicate DNA semiconservatively (see Chapter 9).
- use DNA as the genetic material to encode proteins, and use a similar genetic code to produce those proteins by transcription and translation (see Chapter 10).

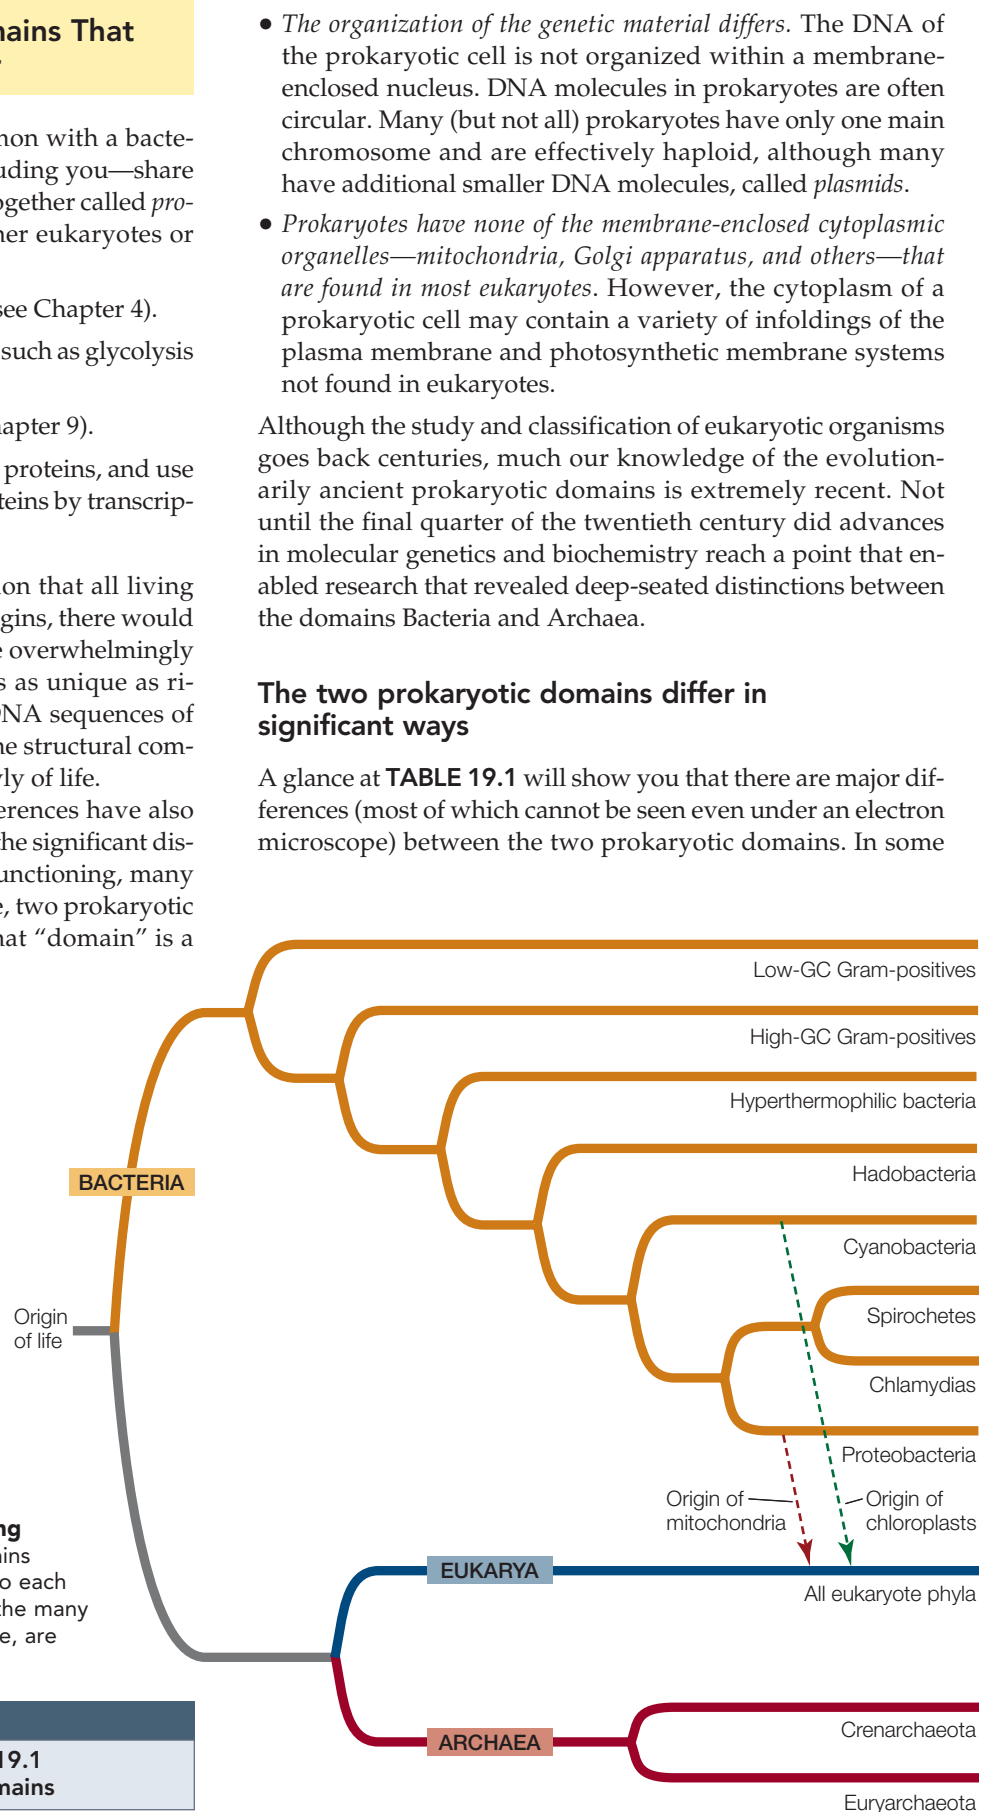

These shared features support the conclusion that all living organisms are related. If life had multiple origins, there would be little reason to expect all organisms to use overwhelmingly similar genetic codes or to share structures as unique as ribosomes. Furthermore, similarities in the DNA sequences of universal genes (such as those that encode the structural components of ribosomes) confirm the monophyly of life.

Despite these commonalities, major differences have also evolved across the diversity of life. Based on the significant distinctions in cell structure and biochemical functioning, many biologists now recognize three *domains* of life, two prokaryotic and one eukaryotic (FIGURE 19.1). Note that “domain” is a subjective term used for the largest divisions of life.

All prokaryotic organisms are unicellular, although they may form large coordinated colonies or biofilms consisting of many individuals. The domain Eukarya, by contrast, encompasses both unicellular and multicellular life forms. As was described in Chapter 4, prokaryotic cells differ from eukaryotic cells in some important ways:

- *Prokaryotic cells do not divide by mitosis.* Instead, after replicating their DNA, prokaryotic cells divide by their own method, *binary fission*.

FIGURE 19.1 The Three Domains of the Living World This summary classification of the domains Bacteria and Archaea shows their relationships to each other and to Eukarya. The relationships among the many clades of bacteria, not all of which are listed here, are incompletely resolved at this time.

- *The organization of the genetic material differs.* The DNA of the prokaryotic cell is not organized within a membrane-enclosed nucleus. DNA molecules in prokaryotes are often circular. Many (but not all) prokaryotes have only one main chromosome and are effectively haploid, although many have additional smaller DNA molecules, called *plasmids*.
- *Prokaryotes have none of the membrane-enclosed cytoplasmic organelles—mitochondria, Golgi apparatus, and others—that are found in most eukaryotes.* However, the cytoplasm of a prokaryotic cell may contain a variety of infoldings of the plasma membrane and photosynthetic membrane systems not found in eukaryotes.

Although the study and classification of eukaryotic organisms goes back centuries, much of our knowledge of the evolutionarily ancient prokaryotic domains is extremely recent. Not until the final quarter of the twentieth century did advances in molecular genetics and biochemistry reach a point that enabled research that revealed deep-seated distinctions between the domains Bacteria and Archaea.

The two prokaryotic domains differ in significant ways

A glance at TABLE 19.1 will show you that there are major differences (most of which cannot be seen even under an electron microscope) between the two prokaryotic domains. In some

Operons	Yes	Yes	Rare
Plasmids	Yes	Yes	Rare
RNA polymerases	One	One ^b	Three
Ribosomes sensitive to chloramphenicol and streptomycin	Yes	No	No
Ribosomes sensitive to diphtheria toxin	No	Yes	Yes

^a70S ribosomes are smaller than 80S ribosomes.

^bArchaeal RNA polymerase is similar to eukaryotic polymerases.

ways archaea are more like eukaryotes; in other ways they are more like bacteria. (Note that we use lowercase when referring to the members of these domains and uppercase when referring to the domains themselves.) The basic unit of an *archaeon* (the term for a single archaeal organism) or *bacterium* (a single bacterial organism) is the prokaryotic cell. Each single-celled organism contains a full complement of genetic and protein-synthesizing systems, including DNA, RNA, and all the enzymes needed to transcribe and translate the genetic information into proteins. The prokaryotic cell also contains at least one system for generating the ATP it needs.

Genetic studies clearly indicate that all three domains had a single common ancestor. Across a major portion of their genome, eukaryotes share a more recent common ancestor with Archaea than they do with Bacteria (see Figure 19.1). However, the mitochondria of eukaryotes (as well as the chloroplasts of photosynthetic eukaryotes, such as plants) originated through endosymbiosis with a bacterium. Some biologists prefer to view the origin of eukaryotes as a fusion of two equal partners (one ancestor that was related to modern archaea, and another that was more closely related to modern bacteria). Others view the divergence of the early eukaryotes from the archaea as a separate and earlier event than the later endosymbioses. In either case, some eukaryote genes are most closely related to those of archaea, while others are most closely related to those of bacteria. The tree of life therefore contains some merging of lineages as well as the predominant diverging of lineages.

LINK The origin of mitochondria and chloroplasts by endosymbiosis is described in Concept 20.1

The last common ancestor of the three domains probably lived about 3 billion years ago. It probably had DNA as its genetic material, and its machinery for transcription and translation probably produced RNAs and proteins, respectively. This

ancestor probably had a circular chromosome. Archaea, Bacteria, and Eukarya are all the products of billions of years of mutation, natural selection, and genetic drift, and they are all well adapted to present-day environments. The earliest prokaryote fossils, which date back at least 3.5 billion years, indicate that there was considerable diversity among the prokaryotes even during those earliest days of life.

The small size of prokaryotes has hindered our study of their evolutionary relationships

Until about 300 years ago, nobody had even *seen* an individual prokaryote; these organisms remained invisible to humans until the invention of the first simple microscope. Prokaryotes are so small, however, that even the best light microscopes don't reveal much about them. It took advanced microscopic equipment and modern molecular techniques to open up the microbial world. (Microscopic organisms—both prokaryotes and eukaryotes—are often collectively referred to as *microbes*.)

Before DNA sequencing became practical, taxonomists based prokaryote classification on observable phenotypic characters such as shape, color, motility, nutritional requirements, and sensitivity to antibiotics. One of the characters most widely used to classify prokaryotes is the structure of their cell walls.

The cell walls of almost all bacteria contain **peptidoglycan**, a cross-linked polymer of amino sugars that produces a meshlike structure around the cell. Peptidoglycan is a substance unique to bacteria; its absence from the cell walls of archaea is a key difference between the two prokaryotic domains. Peptidoglycan is also an excellent target for combating pathogenic (disease-causing) bacteria because it has no counterpart in eukaryotic cells. Antibiotics such as penicillin and ampicillin, as well as other agents that specifically interfere with the synthesis of peptidoglycan-containing cell walls, tend to have little, if any, effect on the cells of humans and other eukaryotes.

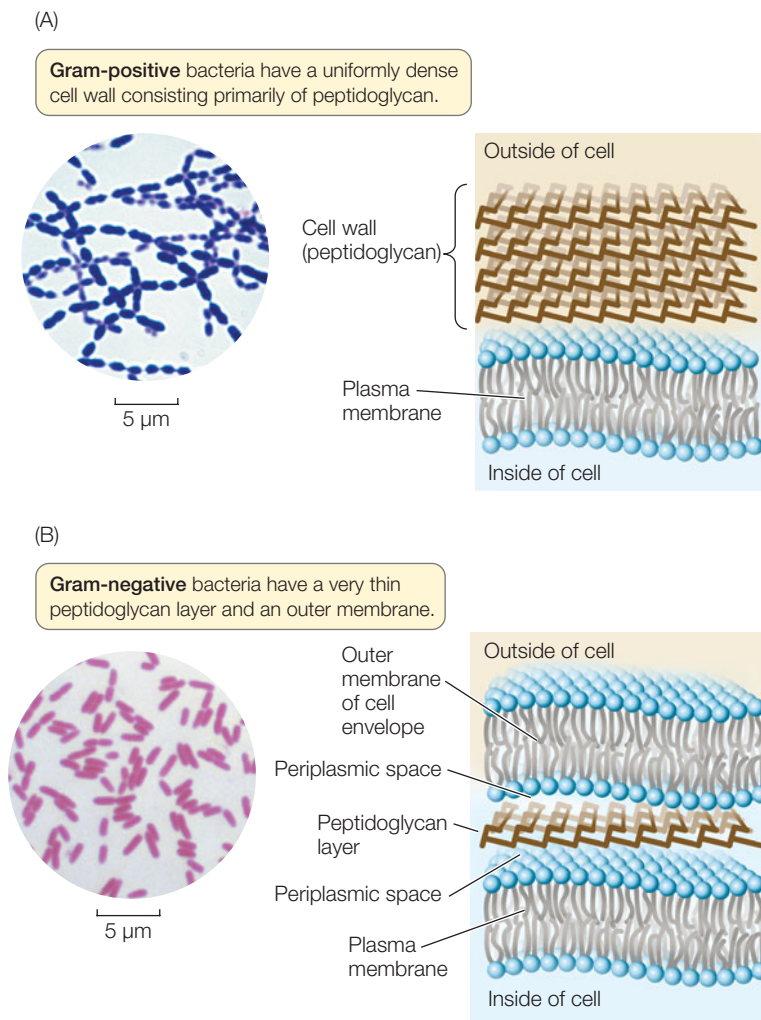

FIGURE 19.2 The Gram Stain and the Bacterial Cell Wall When treated with Gram stain, the cell walls of bacteria react in one of two ways. (A) Gram-positive bacteria have a thick peptidoglycan cell wall that retains the violet dye and appears deep blue or purple. (B) Gram-negative bacteria have a thin peptidoglycan layer that does not retain the violet dye, but picks up the counterstain and appears pink to red.

The **Gram stain** is a technique that separates most types of bacteria into two distinct groups, Gram-positive and Gram-negative. A smear of bacterial cells on a microscope slide is soaked in a violet dye and treated with iodine; it is then washed with alcohol and counterstained with a red dye (safranin). **Gram-positive bacteria** retain the violet dye and appear blue to purple (FIGURE 19.2A). The alcohol washes the violet stain out of **Gram-negative bacteria**, which then pick up the safranin counterstain and appear pink to red (FIGURE 19.2B). For most bacteria, the effect of the Gram stain is determined by the chemical structure of the cell wall.

- A *Gram-negative cell wall* usually has a thin peptidoglycan layer, which is surrounded by a second, outer membrane quite distinct in chemical makeup from the

yourBioPortal.com

Go to WEB ACTIVITY 19.1
Gram Stain and Bacteria

plasma membrane (see Figure 19.2B). Between the plasma membrane and the outer membrane is a *periplasmic space*. This space contains proteins that are important in digesting some materials, transporting others, and detecting chemical gradients in the environment.

- A *Gram-positive cell wall* usually has about five times as much peptidoglycan as a Gram-negative cell wall. Its thick peptidoglycan layer is a meshwork that may serve some of the same purposes as the periplasmic space of the Gram-negative cell envelope (cell wall plus outer membrane).

Shape is another phenotypic characteristic that is useful for the basic identification of bacteria. Three major shapes are common—spheres, rods, and spiral forms (FIGURE 19.3). Many bacterial names are based on these shapes. A spherical bacterium is called a **coccus** (plural *cocci*). Cocci may live singly or may associate in two- or three-dimensional arrays as chains, plates, blocks, or clusters of cells. A rod-shaped bacterium is called a **bacillus** (plural *bacilli*). The spiral form (like a corkscrew), or **helix** (plural *helices*), is the third main bacterial shape. Bacilli and helices may be single, form chains, or gather in regular clusters. Among the other bacterial shapes are long filaments and branched filaments.

Less is known about the shapes of archaea because many of these organisms have never been seen. Many archaea are known only from samples of DNA from the environment. However, the species whose morphologies are known include cocci, bacilli, and even triangular and square-shaped species; the last grow on surfaces, arranged like sheets of postage stamps.

FIGURE 19.3 Bacterial Cell Shapes This composite, colored micrograph shows three common bacterial shapes. Spherical cells are called cocci; these are a species of *Enterococcus* from the mammalian gut. Rod-shaped cells are called bacilli; *Escherichia coli* also reside in the gut. The spiral-shaped helices are *Leptospira interrogans*, a human pathogen.

The nucleotide sequences of prokaryotes reveal their evolutionary relationships

Analyses of the nucleotide sequences of ribosomal RNA (rRNA) genes provided the first comprehensive evidence of evolutionary relationships among prokaryotes. For several reasons, rRNA is particularly useful for phylogenetic studies of living organisms:

- rRNA was present in the common ancestor of all life and is therefore evolutionarily ancient.
- No free-living organism lacks rRNA, so rRNA genes can be compared throughout the tree of life.
- rRNA plays a critical role in translation in all organisms, so lateral transfer of rRNA genes among distantly related species is unlikely.
- rRNA has evolved slowly enough that gene sequences from even distantly related species can be aligned and analyzed.

Comparisons of rRNA genes from a great many organisms have revealed the probable phylogenetic relationships throughout the tree of life. Databases such as GenBank contain rRNA gene sequences from hundreds of thousands of species—more than any other type of gene sequence.

Although studies of rRNA genes reveal much about the evolutionary relationships of prokaryotes, they don't always reveal the entire evolutionary history of these organisms. In some groups of prokaryotes, analyses of multiple gene sequences have suggested several different phylogenetic patterns. How could such differences among different gene sequences arise? Studies of whole prokaryotic genomes have revealed that even distantly related prokaryotes sometimes exchange genetic material.

Lateral gene transfer can lead to discordant gene trees

As noted earlier, prokaryotes reproduce by binary fission. If we could follow these divisions back through evolutionary time, we would be tracing the path of the complete tree of life

for bacteria and archaea. This underlying tree of relationships (represented in highly abbreviated form in Appendix A) is called the *organismal* (or *species*) *tree*. Because whole genomes are replicated during binary fission, we would expect phylogenetic trees constructed from most gene sequences (see Chapter 16) to reflect these same relationships.

Even though binary fission is an asexual process, there are other processes—including transformation, conjugation, and transduction—that allow the exchange of genetic information between some prokaryotes without reproduction. Thus prokaryotes can exchange and recombine their DNA with that of other individuals (this is sex in the genetic sense of the word), but this genetic exchange is not directly linked to reproduction, as it is in most eukaryotes.

LINK Prokaryote exchange of genetic material by transformation, conjugation, and transduction is described in Concept 8.4

From early in evolution to the present day, some genes have been moving “sideways” from one prokaryote species to another, a phenomenon known as **lateral gene transfer**. Lateral gene transfers are well documented, especially among closely related species; some have been documented even across the domains of life.

Consider, for example, the genome of *Thermotoga maritima*, a bacterium that can survive extremely high temperatures. In comparing the 1,869 gene sequences of *T. maritima* against sequences encoding the same proteins in other species, investigators found that some of this bacterium's genes have their closest relationships not with the genes of other bacterial

FIGURE 19.4 Lateral Gene Transfer Complicates Phylogenetic Relationships (A) The phylogeny of four hypothetical prokaryote species, two of which have been involved in a lateral transfer of gene x. (B) A tree based only on gene x shows the phylogeny of the laterally transferred gene, rather than the organismal phylogeny. (C) In many cases, a consensus tree based on a “stable core” of genes accurately reflects the organismal phylogeny.

species, but with the genes of archaea that live in similar extreme environments.

When genes involved in lateral transfer events are sequenced and analyzed, the resulting individual *gene trees* will not match the organismal tree in every respect (FIGURE 19.4). The individual gene trees will vary because the history of lateral transfer events is different for each gene. Biologists can reconstruct the underlying organismal phylogeny by comparing multiple genes (to produce a *consensus tree*) or by concentrating on genes that are unlikely to be involved in lateral gene transfer events. For example, genes that are involved in fundamental cellular processes (such as the rRNA genes discussed above) are unlikely to be replaced by the same genes from other species because functional, locally adapted copies of these genes are already present.

What kinds of genes are most likely to be involved in lateral gene transfer? Genes that result in a new adaptation that confers higher fitness on a recipient species are most likely to be transferred repeatedly among species. For example, genes that produce antibiotic resistance are often transferred among bacterial species on plasmids, especially under the strong selection pressure such as that imposed by modern antibiotic medications. Improper or overly frequent use of antibiotics can select for resistant strains of bacteria that are much harder to treat. This selection for antibiotic resistance explains why informed physicians have become more careful in prescribing antibiotics.

It is debatable whether lateral gene transfer has seriously complicated our attempts to resolve the tree of prokaryotic life. Recent work suggests that it has not; although it complicates studies in some individual species, it need not present problems at higher taxonomic levels. It is now possible to make nucleotide sequence comparisons involving entire genomes, and these studies are revealing a *stable core* of crucial genes that are uncomplicated by lateral gene transfer. Gene trees based on this stable core more accurately reveal the organismal phylogeny (see Figure 19.4). The problem remains, however, that only a very small proportion of the prokaryotic world has been described and studied.

The great majority of prokaryote species have never been studied

Most prokaryotes have defied all attempts to grow them in pure culture, causing biologists to wonder how many species, and possibly even clades, we might be missing. A window onto this problem was opened with the introduction of a new way of examining nucleic acid sequences. When biologists are unable to work with the whole genome of a single prokaryote species, they can instead examine individual genes collected from a random sample of the environment (see Figure 12.7).

Norman Pace of the University of Colorado isolated individual rRNA gene sequences from extracts of environmental samples such as soil and seawater. Comparing such sequences with previously known ones revealed that an extraordinary number of the sequences were new, implying that they came from previously unrecognized species. Biologists have described

only about 10,000 species of bacteria and only a few hundred species of archaea (see Figure 1.4). The results of Pace's and similar studies suggest that there may be millions—perhaps hundreds of millions—of prokaryote species on Earth. Other biologists put the estimate much lower, arguing that the high dispersal ability of many bacterial species greatly reduces local endemism (i.e., the number of species restricted to a small geographic area). Only the magnitude of these estimates differs, however; all sides agree that we have just begun to uncover Earth's bacterial and archaeal diversity.

Do You Understand Concept 19.1?

- Why were all prokaryotes once considered “equal,” and what findings led to the establishment of Bacteria and Archaea as separate domains?
- How did biologists classify bacteria before it became possible to determine nucleotide sequences?
- Why are nucleotide sequences of rRNA genes particularly useful for evolutionary studies?
- How does lateral gene transfer complicate evolutionary studies?

Despite the challenges of reconstructing the phylogeny of prokaryotes, taxonomists are beginning to establish evolutionary classification systems for these organisms. With a full understanding that new information requires periodic revisions in these classifications, we next apply a current system of classification to organize our survey of prokaryote diversity.

concept 19.2 Prokaryote Diversity Reflects the Ancient Origins of Life

The prokaryotes were alone on Earth for a very long time, adapting to new environments and to changes in existing environments. They have survived to this day, in massive numbers and incredible diversity, and they are found everywhere. If success is measured by numbers of individuals, the prokaryotes are the most successful organisms on Earth. Individual bacteria and archaea in the oceans number more than 3×10^{28} —perhaps 100 million times greater than the number of stars in the visible universe. Closer to home, the individual bacteria living in your intestinal tract outnumber all the humans who have ever lived.

Given our still fragmentary knowledge of prokaryote diversity, it is not surprising that there are several different hypotheses about the relationships of the major groups of prokaryotes. In this book we use a widely accepted classification system that has considerable support from nucleotide sequence data. We will discuss the eight bacterial groups that have the broadest phylogenetic support and have received the most study: the low-GC Gram-positives, high-GC Gram-positives, hyperthermophilic bacteria, hadobacteria, cyanobacteria, spirochetes, chlamydias, and proteobacteria (see Figure 19.1). We will then

describe the archaea, whose diversity is even less well studied than that of the bacteria.

The low-GC Gram-positives include the smallest cellular organisms

The **low-GC Gram-positives**, also known as *Firmicutes*, derive the first part of their name from the relatively low ratio of G-C to A-T nucleotide base pairs in their DNA. The second part of their name is less accurate: some of the low-GC Gram-positives are in fact Gram-negative, and some have no cell wall at all. Despite these differences, phylogenetic analyses of DNA sequences support the monophyly of this bacterial clade.

Some low-GC Gram-positives can produce heat-resistant resting structures called **endospores** (FIGURE 19.5). When a key nutrient such as nitrogen or carbon becomes scarce, the bacterium replicates its DNA and encapsulates one copy, along with some of its cytoplasm, in a tough cell wall heavily thickened with peptidoglycan and surrounded by a spore coat. The parent cell then breaks down, releasing the endospore. Endospore production is not a reproductive process; the endospore merely replaces the parent cell. The endospore, however, can survive harsh environmental conditions that would kill the parent cell, such as high or low temperatures or drought, because it is *dormant*—its normal metabolic activity is suspended. Later, if it encounters favorable conditions, the endospore becomes metabolically active and divides, forming new cells that are like the parent cells. Members of this endospore-forming group of low-GC Gram-positives include the many species of *Clostridium* and

FIGURE 19.5 A Structure for Waiting Out Bad Times Some low-GC Gram-positive bacteria can replicate their DNA and encase it in a resistant endospore. In harsh conditions, the parent cell breaks down and the endospore survives in a dormant state until conditions improve.

FIGURE 19.6 Staphylococci “Grape clusters” are the usual arrangement of these low-GC Gram-positive coccal bacteria, often the cause of skin or wound infections.

Bacillus. Some of their endospores can be reactivated after more than 1,000 years of dormancy. There are even credible claims of reactivation of *Bacillus* endospores after millions of years.

Dormant endospores of *Bacillus anthracis* are the source of an *exotoxin* (a toxin produced by the bacteria’s metabolism and released into the environment) that causes anthrax. Anthrax is primarily a disease of cattle and sheep, but it can also be fatal in humans. The endospores reactivate when they sense macrophages in the cytoplasm of mammalian blood cells. *Bacillus anthracis* has been used as a bioterrorism agent because large quantities of its endospores are relatively easy to transport and spread among human populations, where they may be inhaled or ingested.

Low-GC Gram-positives of the genus *Staphylococcus*—the **staphylococci** (FIGURE 19.6)—are abundant on the human body surface; they are responsible for boils and many other skin problems. *Staphylococcus aureus* is the best-known human pathogen in this genus; it is present in 20 to 40 percent of normal adults (and in 50 to 70 percent of hospitalized adults). In addition to skin diseases, *S. aureus* can cause respiratory, intestinal, and wound infections.

Another interesting group of low-GC Gram-positives, the **mycoplasmas**, lack cell walls, although some have a stiffening material outside the plasma membrane. The mycoplasmas are among the smallest cellular organisms known (FIGURE 19.7). The smallest mycoplasmas capable of multiplying by fission have a diameter of about 0.2 μm. They are small in another crucial sense as well: they have less than half as much DNA as most other prokaryotes. It has been speculated that the DNA in a mycoplasma, which codes for fewer than 500 proteins, may be close to the minimum amount required to encode the essential properties of a living cell (see Figure 12.8).

Mycoplasma sp.

0.7 μm

FIGURE 19.7 Tiny Cells With about one-fifth as much DNA as *E. coli*, mycoplasmas are among the smallest known bacteria.

Some high-GC Gram-positives are valuable sources of antibiotics

High-GC Gram-positives, also known as *Actinobacteria*, have a higher ratio of G-C to A-T nucleotide base pairs than do the low-GC Gram-positives. These bacteria develop an elaborately branched system of filaments (**FIGURE 19.8**) that resembles the filamentous growth habit of fungi, albeit at a reduced scale. Some high-GC Gram-positives reproduce by forming chains of spores at the tips of the filaments. In species that do not form spores, the branched, filamentous growth ceases and the structure breaks up into typical cocci or bacilli, which then reproduce by binary fission.

Actinomyces sp.

2 μm

FIGURE 19.8 Actinomycetes are High-GC Gram-Positives The tangled, branching filaments seen in this scanning electron micrograph are typical of this medically important bacterial group.

The high-GC Gram-positives include several medically important bacteria. *Mycobacterium tuberculosis* causes tuberculosis, which kills 3 million people each year. Genetic data suggest that this bacterium arose 3 million years ago in East Africa, making it the oldest known human bacterial pathogen. The genus *Streptomyces* produces streptomycin as well as hundreds of other antibiotics. We derive most of our antibiotics from members of the high-GC Gram-positives.

Hyperthermophilic bacteria live at very high temperatures

Several lineages of bacteria and archaea are **extremophiles**: they thrive under extreme conditions that would kill most other organisms. The **hyperthermophilic bacteria**, for example, are *thermophiles* (Greek, “heat-lovers”). Genera such as *Aquifex* live near volcanic vents and in hot springs, sometimes at temperatures near the boiling point of water. Some species of *Aquifex* need only hydrogen, oxygen, carbon dioxide, and mineral salts to live and grow. Species of the genus *Thermotoga* live deep underground in oil reservoirs, as well as in other high-temperature environments.

Biologists have hypothesized that high temperatures characterized the ancestral conditions for life on Earth, given that most environments on early Earth were much hotter than those of today. Reconstructions of ancestral bacterial genes have supported this hypothesis by showing that the ancestral sequences functioned best at elevated temperatures. The monophyly of the hyperthermophilic bacteria, however, is not well established.

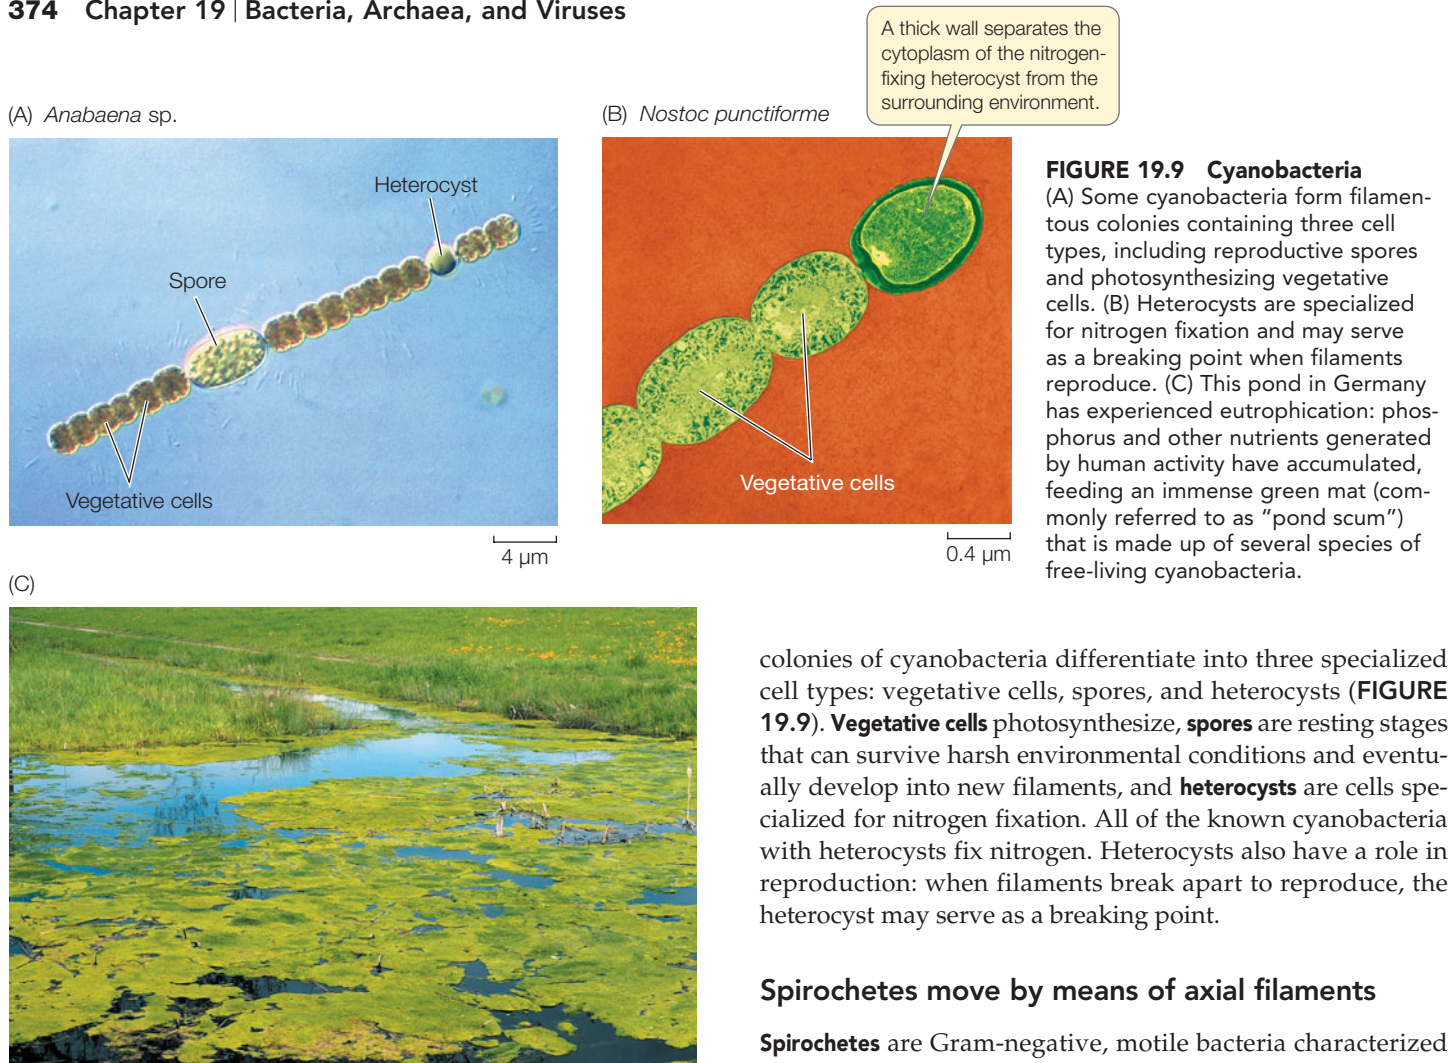

Hadobacteria live in extreme environments

The **hadobacteria**, including such genera as *Deinococcus* and *Thermus*, are another group of thermophilic extremophiles. The group’s name is derived from Hades, the ancient Greek name for the underworld. *Deinococcus* are resistant to radiation and can consume nuclear waste and other toxic materials. They can also survive extremes of cold as well as hot temperatures. Another member of this group, *Thermus aquaticus*, was the source of the thermally stable DNA polymerase that was critical for the development of the polymerase chain reaction. *Thermus aquaticus* was originally isolated from a hot spring, but it can be found wherever hot water occurs (including many residential hot water heaters).

Cyanobacteria were the first photosynthesizers

Cyanobacteria, sometimes called *blue-green bacteria* because of their pigmentation, are photosynthetic bacteria that require only water, nitrogen gas, oxygen, a few mineral elements, light, and carbon dioxide to survive. They use chlorophyll *a* for photosynthesis and release oxygen gas (O_2); many species also fix nitrogen. Photosynthesis by these bacteria was the basis of the “green revolution” that transformed Earth’s atmosphere (see Concept 18.2).

Cyanobacteria carry out the same type of photosynthesis that is characteristic of eukaryotic photosynthesizers. They

colonies of cyanobacteria differentiate into three specialized cell types: vegetative cells, spores, and heterocysts (FIGURE 19.9). **Vegetative cells** photosynthesize, **spores** are resting stages that can survive harsh environmental conditions and eventually develop into new filaments, and **heterocysts** are cells specialized for nitrogen fixation. All of the known cyanobacteria with heterocysts fix nitrogen. Heterocysts also have a role in reproduction: when filaments break apart to reproduce, the heterocyst may serve as a breaking point.

Spirochetes move by means of axial filaments

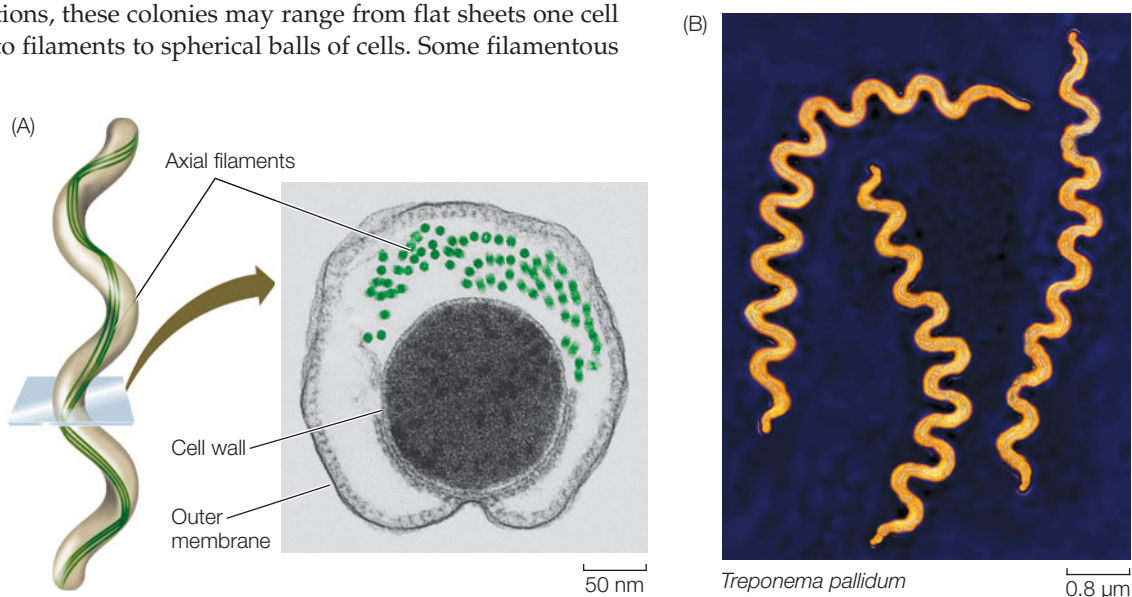

Spirochetes are Gram-negative, motile bacteria characterized by unique structures called *axial filaments* (FIGURE 19.10A),

contain elaborate and highly organized internal membrane systems called *photosynthetic lamellae*. As mentioned in Concept 19.1, the chloroplasts of photosynthetic eukaryotes are derived from an endosymbiotic cyanobacterium.

Cyanobacteria may live free as single cells or associate in multicellular colonies. Depending on the species and on growth conditions, these colonies may range from flat sheets one cell thick to filaments to spherical balls of cells. Some filamentous

FIGURE 19.10 Spirochetes Get Their Shape from Axial Filaments

(A) A spirochete from the gut of a termite, seen in cross section, shows the axial filaments used to produce a corkscrew-like movement of these helical prokaryotes. (B) This spirochete species causes syphilis in humans.

which are modified flagella running through the periplasmic space. The cell body is a long cylinder coiled into a helix (FIGURE 19.10B). The axial filaments begin at either end of the cell and overlap in the middle. Motor proteins connect the axial filaments to the cell wall, enabling the corkscrew-like movement of the bacterium. Many spirochetes are parasites of humans; a few are pathogens, including those that cause syphilis and Lyme disease. Others live free in mud or water.

Chlamydias are extremely small parasites

Chlamydias are among the smallest bacteria (0.2–1.5 μm in diameter). They can live only as parasites in the cells of other organisms. It was once believed that their obligate parasitism resulted from an inability to produce ATP—that chlamydias were “energy parasites.” However, genome sequencing indicates that chlamydias have the genetic capacity to produce at least some ATP. They can augment this capacity by using an enzyme called a translocase, which allows them to take up ATP from the cytoplasm of their host in exchange for ADP from their own cells.

These tiny, Gram-negative cocci are unique among prokaryotes because of a complex life cycle that involves two different forms of cells, *elementary bodies* and *reticulate bodies* (FIGURE 19.11). Various strains of chlamydias cause eye infections (especially trachoma), sexually transmitted diseases, and some forms of pneumonia in humans.

The proteobacteria are a large and diverse group

By far the largest group of bacteria, in terms of number of described species, is the **proteobacteria**. The proteobacteria include

FIGURE 19.11 Chlamydias Change Form during Their Life Cycle Elementary bodies and reticulate bodies are the two major phases of the chlamydia life cycle.

Salmonella typhimurium

FIGURE 19.12 Proteobacteria Include Human Pathogens

These conjugating cells of *Salmonella typhimurium* are exchanging genetic material (see Concept 8.4). Representing only one group of the highly diverse proteobacteria, this pathogen causes a wide range of gastrointestinal illnesses in humans.

many species of Gram-negative photoautotrophs that use light-driven reactions to metabolize sulfur, as well as dramatically diverse bacteria that bear no phenotypic resemblance to the photoautotrophic species. Genetic and morphological evidence indicates that the mitochondria of eukaryotes were derived from a proteobacterium by endosymbiosis.

Among the proteobacteria are some nitrogen-fixing genera, such as *Rhizobium*, and other bacteria that contribute to the global nitrogen and sulfur cycles. *Escherichia coli*, one of the most studied organisms on Earth, is a proteobacterium. So, too, are many of the most famous human pathogens, such as *Yersinia pestis* (which causes bubonic plague), *Vibrio cholerae* (cholera), and *Salmonella typhimurium* (gastrointestinal disease; FIGURE 19.12). The bioluminescent *Vibrio* we discussed at the start of the chapter are also members of this group.

FRONTIERS There are many potential applications of the genes that encode bioluminescent proteins in bacteria. Already, these genes are inserted into the genomes of other species where the resulting bioluminescence is used as a marker of gene expression. Proposals for making use of bioluminescence in bioengineered organisms include crop plants that glow when they become water-stressed and need to be irrigated, and glowing trees that could light highways at night in place of electric lights.

Although fungi cause most plant diseases, and viruses cause others, about 200 known plant diseases are of bacterial origin. *Crown gall*, with its characteristic tumors (FIGURE 19.13), is one of the most striking. The causal agent of crown gall is

FIGURE 19.13 Crown Gall Crown gall, a type of tumor shown here growing on the trunk of a white oak, is caused by the proteobacterium *Agrobacterium tumefaciens*.

Agrobacterium tumefaciens, a proteobacterium that harbors a plasmid used in recombinant DNA studies as a vehicle for inserting genes into new plant hosts.

Gene sequencing enabled biologists to differentiate the domain Archaea

The separation of Archaea from Bacteria and Eukarya was originally based on phylogenetic relationships determined from sequences of rRNA genes. It was supported when biologists sequenced the first archaeal genome. That genome consisted of 1,738 genes, more than half of which were unlike any genes ever found in the other two domains.

Archaea are well known for living in extreme habitats such as those with high salinity (salt content), low oxygen concentrations, high temperatures, or high or low pH (FIGURE 19.14). Many archaea are not extremophiles, however, but live in moderate habitats—they are common in soil, for example. Perhaps the largest numbers of archaea live in the ocean depths.

One current classification scheme divides Archaea into two principal groups, **Crenarchaeota** and **Euryarchaeota**. Less is known about two more recently discovered groups, **Korarchaeota** and **Nanoarchaeota**. In fact, we know relatively little about the phylogeny of archaea, in part because the study of these prokaryotes is still in its early stages.

Two characteristics shared by all archaea are the absence of peptidoglycan in their cell walls and the presence of lipids of distinctive composition in their cell membranes (see Table 19.1). The unusual lipids in the membranes of

INVESTIGATION

FIGURE 19.14 What Is the Highest Temperature Compatible with Life? Can any organism thrive at temperatures above 120°C? This is the temperature used for sterilization, known to destroy all previously described organisms. Kazem Kashefi and Derek Lovley isolated an unidentified prokaryote from water samples taken near a hydrothermal vent and found it survived and even multiplied at 121°C. The organism was dubbed “Strain 121,” and its gene sequencing results indicate that it is an archaeal species.

HYPOTHESIS

Some prokaryotes can survive at temperatures above the 120°C threshold of sterilization.

METHOD

1. Seal samples of unidentified, iron-reducing, thermal vent prokaryotes in tubes with a medium containing Fe^{3+} as an electron acceptor. Control tubes contain Fe^{3+} but no organisms.
2. Hold both tubes in a sterilizer at 121°C for 10 hours. If the iron-reducing organisms are metabolically active, they will reduce the Fe^{3+} to Fe^{2+} (as magnetite, which can be detected with a magnet).

RESULTS

The solids are attracted to the magnet, indicating that the organisms in this solution are alive and engaged in iron-reducing biochemical reactions.

CONCLUSION

This thermal vent organism (Strain 121) can survive at temperatures above the previously defined sterilization limit.

ANALYZE THE DATA

After Strain 121 was isolated, its growth was examined at various temperatures. The table shows generation time (the time between cell divisions) at nine temperatures.

Temperature (°C)	Generation time (hr)
85	10
90	4
95	3
100	2.5
105	2
110	4
115	6
120	20
130	No growth, but cells not killed

- Make a graph showing generation time as a function of temperature.
- Which temperature appears to be closest to the optimum for growth of Strain 121?
- Note that no growth occurred at 130°C, but that the cells were not killed. How would you demonstrate that these cells were still alive?

archaea are found in all archaea and in no bacteria or eukaryotes. Most lipids in bacterial and eukaryotic membranes contain unbranched long-chain fatty acids connected to glycerol molecules by *ester linkages*:

In contrast, some lipids in archaeal membranes contain long-chain hydrocarbons connected to glycerol molecules by *ether linkages*:

These ether linkages are a synapomorphy of archaea.

In addition, the long-chain hydrocarbons of archaea are branched. One class of archaeal lipids, with hydrocarbon chains 40 carbon atoms in length, contains glycerol at *both* ends of the hydrocarbons (FIGURE 19.15). These lipids form a *lipid monolayer* structure that is unique to archaea. They still fit into a biological membrane because they are twice as long as the typical lipids in the bilayers of other membranes. Lipid monolayers and bilayers are both found among the archaea. The effects, if any, of these structural features on membrane performance are unknown. In spite of this striking difference in their lipids, the membranes of all three domains have similar overall structures, dimensions, and functions.

Most crenarchaeotes live in hot or acidic places

Most known crenarchaeotes are either thermophilic, acidophilic (acid loving), or both. Members of the genus *Sulfolobus* live in hot sulfur springs at temperatures of 70°C to 75°C. They become metabolically inactive at 55°C (131°F). Hot sulfur springs are also extremely acidic. *Sulfolobus* grows best in the

FIGURE 19.15 Membrane Architecture in Archaea The long-chain hydrocarbons of many archaeal lipids have glycerol molecules at both ends, so that the membranes they form consist of a lipid monolayer. In contrast, the membranes of other archaea, bacteria, and eukaryotes consist of a lipid bilayer.

FIGURE 19.16 Crenarchaeotes Like It Hot Thermophilic archaea can thrive in the intense heat of volcanic hot sulfur springs such as those in Wyoming's Yellowstone National Park.

range from pH 2 to pH 3, but some members of this genus readily tolerate pH values as low as 0.9. Most acidophilic thermophiles maintain an internal pH of 5.5 to 7 (close to neutral) in spite of their acidic environment. These and other thermophiles thrive where very few other organisms can even survive (FIGURE 19.16).

Euryarchaeotes are found in surprising places

Some species of Euryarchaeota are **methanogens**: they produce methane (CH₄) by reducing carbon dioxide, and this is the key step in their energy metabolism. All of the methanogens are *obligate anaerobes* (see Concept 19.3). Comparison of their rRNA gene sequences has revealed a close evolutionary relationship among these methanogenic species, which were previously assigned to several different groups of bacteria.

Methanogenic euryarchaeotes release approximately 2 billion tons of methane gas into Earth's atmosphere each year, accounting for 80 to 90 percent of the methane that enters the atmosphere, including that produced in some mammalian digestive systems. Approximately a third of this methane comes from methanogens living in the guts of ruminants such as cattle, sheep, and deer, and another large fraction comes from methanogens living in the guts of termites and cockroaches. Methane is increasing in Earth's atmosphere by about 1 percent per year and contributes to the greenhouse effect (see Concept 46.4). Part of that increase is due to increases in cattle and rice farming and the methanogens associated with both.

Another group of euryarchaeotes, the **extreme halophiles** (salt lovers), lives exclusively in very salty environments. Because they contain pink carotenoid pigments, these archaea are sometimes easy to see (FIGURE 19.17). Extreme halophiles grow in

FIGURE 19.17 Extreme Halophiles Highly saline environments such as these commercial seawater evaporating ponds in San Francisco Bay are home to extreme halophiles. The archaea are easily visible here because of the rich red coloration from their carotenoid pigments.

the Dead Sea and in brines of all types; the reddish pink spots that can occur on pickled fish are colonies of halophilic archaea. Few other organisms can live in the saltiest of the homes that the extreme halophiles occupy; most would “dry” to death, losing too much water to the hypertonic environment. Extreme halophiles have been found in lakes with pH values as high as 11.5—the most alkaline environment inhabited by living organisms, and almost as alkaline as household ammonia.

Some of the extreme halophiles have a unique system for trapping light energy and using it to form ATP—without using any form of chlorophyll—when oxygen is in short supply. They use the pigment *retinal* (also found in the vertebrate eye) combined with a protein to form a light-absorbing molecule called *microbial rhodopsin*.

Another member of the Euryarchaeota, *Thermoplasma*, has no cell wall. It is thermophilic and acidophilic, its metabolism is aerobic, and it lives in coal deposits. Its genome of 1,100,000 base pairs is among the smallest (along with the mycoplasmas) of any free-living organism, although some parasitic organisms have even smaller genomes.

FRONTIERS The halophilic euryarchaeote *Haloferax mediterranei* (see Figure 1.2) accumulates large quantities of a white polyester for carbon and energy storage. The structure and synthesis of this molecule is being studied for possible use of the polyester as a substitute for petroleum-based products.

Korarchaeotes and nanoarchaeotes are less well known

The korarchaeotes are known only from DNA isolated directly from hot springs. No korarchaeote has been successfully grown in pure culture.

FIGURE 19.18 A Nanoarchaeote Growing in Mixed Culture with a Crenarchaeote *Nanoarchaeum equitans* (red), discovered living near deep-sea hydrothermal vents, is the only representative of the nanoarchaeote group so far identified. This tiny organism lives attached to cells of the crenarchaeote *Ignicoccus* (green). For this confocal laser micrograph, the two species were visually differentiated by fluorescent dye “tags” that are specific to their distinct gene sequences.

Another distinctive archaeal lineage has been discovered at a deep-sea hydrothermal vent off the coast of Iceland. It is the first representative of the group christened Nanoarchaeota because of their minute size (Greek *nanos*, “dwarf”). This organism is a parasite that lives on cells of *Ignicoccus*, a crenarchaeote. Because of their association, the two species can be grown together in culture (FIGURE 19.18).

Do You Understand Concept 19.2?

- How does the diversity of environments occupied by prokaryotes compare with the diversity of environments occupied by multicellular organisms you may be familiar with?
- Explain why Gram staining is of limited use in understanding the evolutionary relationships of bacteria.
- What makes the membranes of archaea unique?
- Given that all species of life have evolved for the same amount of time since their common origin, how would you respond to someone who characterizes prokaryotes as “primitive”?

Prokaryotes are found almost everywhere on Earth and live in a wide variety of ecosystems. Next we examine the contributions of prokaryotes to the functioning of those ecosystems.

concept 19.3 Ecological Communities Depend on Prokaryotes

Prokaryotic cells and their associations do not usually live in isolation. Rather, they live in communities of many different species, often including microscopic eukaryotes. While some

microbial communities are harmful to humans, others provide important services. They help us digest our food, break down municipal waste, and recycle organic matter and chemical elements in the environment.

Many prokaryotes form complex communities

Some microbial communities form layers in sediments; others form clumps a meter or more in diameter. Many microbial communities tend to form dense **biofilms**. Upon contacting a solid surface, the cells bind to that surface and secrete a sticky, gel-like polysaccharide matrix that traps other cells (FIGURE 19.19). Once this biofilm forms, it is difficult to kill the cells.

Pathogenic bacteria are difficult for the immune system—and modern medicine—to combat once they form a biofilm. For example, the film may be impermeable to antibiotics. Worse, some drugs stimulate the bacteria in a biofilm to lay down more matrix, making the film even more impermeable. Biofilms may form on just about any available surface, including contact lenses and artificial joint replacements. They foul metal pipes and cause corrosion, a major problem in steam-driven electricity generation plants. The material on our teeth that we call dental plaque is a biofilm. Fossil stromatolites—large, rocky structures made up of alternating layers of fossilized microbial biofilm and calcium carbonate—are among the oldest remnants of life on Earth (see Figure 18.6A).

Biofilms are the subject of much current research. For example, some biologists are studying the chemical signals that prokaryotes in biofilms use to communicate with one another. By blocking the signals that lead to the production of the matrix polysaccharides, researchers may be able to prevent biofilms from forming.

FIGURE 19.19 Forming a Biofilm (A) Free-living prokaryotes readily attach themselves to surfaces and form films that are stabilized and protected by a surrounding matrix. Once the population is large enough, the developing biofilm can send chemical signals that attract other microorganisms. (B) Scanning electron microscopy reveals a biofilm of dental plaque. The bacteria (red) are embedded in a matrix consisting of proteins from both bacterial secretions and saliva.

Prokaryotes have amazingly diverse metabolic pathways

Bacteria and archaea outdo the eukaryotes in terms of metabolic diversity. Although they are much more diverse in size and shape, eukaryotes draw on fewer metabolic mechanisms for their energy needs. In fact, much of the eukaryotes' energy metabolism is carried out in organelles—mitochondria and chloroplasts—that are endosymbiotic descendants of bacteria. The long evolutionary history of bacteria and archaea, during which they have had time to explore a wide variety of habitats, has led to the extraordinary diversity of their metabolic “lifestyles”—their use or nonuse of oxygen, their energy sources, their sources of carbon atoms, and the materials they release as waste products.

ANAEROBIC VERSUS AEROBIC METABOLISM Some prokaryotes can live only by anaerobic metabolism because oxygen is poisonous to them. These oxygen-sensitive organisms are called **obligate anaerobes**. Other prokaryotes can shift their metabolism between anaerobic and aerobic modes and are thus called **facultative anaerobes**. Many facultative anaerobes alternate between anaerobic metabolism (such as fermentation) and cellular

TABLE 19.2 How Organisms Obtain Their Energy and Carbon

NUTRITIONAL CATEGORY SOURCE	ENERGY SOURCE	CARBON
Photoautotrophs (found in all three domains)	Light	Carbon dioxide
Photoheterotrophs (some bacteria)	Light	Organic compounds
Chemolithotrophs (some bacteria, many archaea)	Inorganic substances	Carbon dioxide
Chemoheterotrophs (found in all three domains)	Organic compounds	Organic compounds

respiration as conditions dictate. **Aerotolerant anaerobes** cannot conduct cellular respiration, but they are not damaged by oxygen when it is present. By definition, an *anaerobe* does not use oxygen as an electron acceptor for its respiration.

At the other extreme from the obligate anaerobes, some prokaryotes are **obligate aerobes**, unable to survive for extended periods in the *absence* of oxygen. They require oxygen for cellular respiration.

NUTRITIONAL CATEGORIES All living organisms face the same nutritional challenges: they must synthesize energy-rich compounds such as ATP to power their life-sustaining metabolic reactions, and they must obtain carbon atoms to build their own organic molecules. Biologists recognize four broad nutritional categories of organisms: photoautotrophs, photoheterotrophs, chemolithotrophs, and chemoheterotrophs. Prokaryotes are represented in all four groups (TABLE 19.2).

Photoautotrophs perform photosynthesis. They use light as their energy source and carbon dioxide (CO₂) as their carbon source. The cyanobacteria, like green plants and other

photosynthetic eukaryotes, use chlorophyll *a* as their key photosynthetic pigment and produce oxygen gas (O₂) as a by-product of noncyclic electron transport.

There are other photoautotrophs among the bacteria, but these organisms use *bacteriochlorophyll* as their key photosynthetic pigment, and they do not produce O₂. Instead, some of these photosynthesizers produce particles of pure sulfur, because hydrogen sulfide (H₂S), rather than H₂O, is their electron donor for photophosphorylation. Many proteobacteria fit into this category. Bacteriochlorophyll molecules absorb light of longer wavelengths than the chlorophyll molecules used by other photosynthesizing organisms. As a result, bacteria using this pigment can grow in water under fairly dense layers of algae, using light of wavelengths that are not absorbed by the algae (FIGURE 19.20).

Photoheterotrophs use light as their energy source but must obtain their carbon atoms from organic compounds made by other organisms. Their “food” consists of organic compounds such as carbohydrates, fatty acids, and alcohols. For example, compounds released from plant roots (as in rice paddies) or from decomposing photosynthetic bacteria in hot springs are taken up by photoheterotrophs and metabolized to form building blocks for other compounds. Sunlight provides the ATP necessary for metabolism through photophosphorylation.

Chemolithotrophs (also called *chemoautotrophs*) obtain their energy by oxidizing inorganic substances, and they use some of that energy to fix carbon. Some chemolithotrophs use reactions identical to those of the typical photosynthetic cycle, but others use alternative pathways for carbon fixation. Some bacteria oxidize ammonia or nitrite ions to form nitrate ions. Others oxidize hydrogen gas, hydrogen sulfide, sulfur, and other materials. Many archaea are chemolithotrophs.

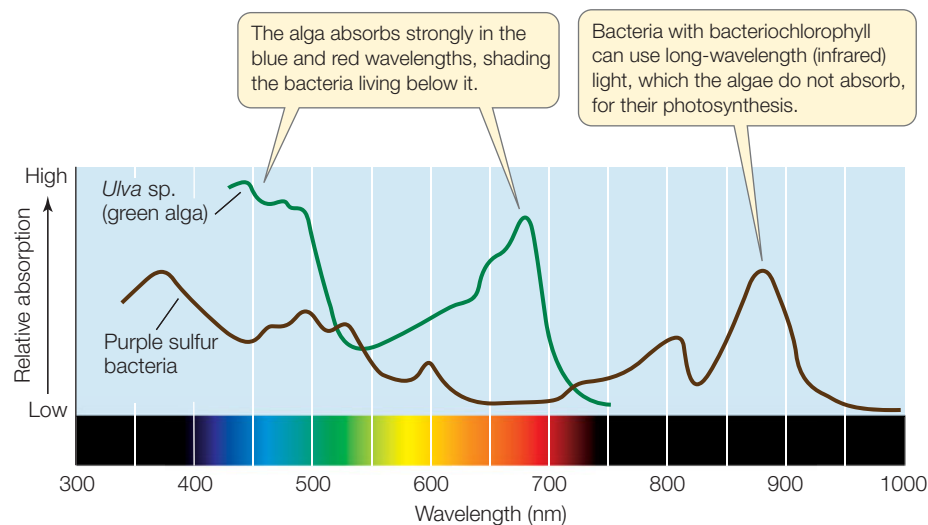

Finally, **chemoheterotrophs** obtain both energy and carbon atoms from one or more complex organic compounds that have been synthesized by other organisms. Most known bacteria and archaea are chemoheterotrophs—as are all animals and fungi and many protists.

Prokaryotes play important roles in element cycling

The metabolic diversity of the prokaryotes makes them key players in the cycles that keep elements moving through ecosystems. Many prokaryotes are *decomposers*: organisms that metabolize organic compounds in dead organic material and return the

FIGURE 19.20 Bacteriochlorophyll Absorbs Long-Wavelength Light

The green alga *Ulva* contains chlorophyll, which absorbs no light of wavelengths longer than 750 nm. Purple sulfur bacteria, which contain bacteriochlorophyll, can conduct photosynthesis using longer wavelengths. As a result, these bacteria can grow under layers of algae.

products to the environment as inorganic substances. Prokaryotes, along with fungi, return tremendous quantities of carbon to the atmosphere as carbon dioxide, thus carrying out a key step in the carbon cycle.

The key metabolic reactions of many prokaryotes involve nitrogen or sulfur. For example, some bacteria carry out respiratory electron transport without using oxygen as an electron acceptor. These organisms use oxidized inorganic ions such as nitrate, nitrite, or sulfate as electron acceptors. Examples include the **denitrifiers**, which release nitrogen to the atmosphere as nitrogen gas (N_2). These normally aerobic bacteria, mostly species of the genera *Bacillus* and *Pseudomonas*, use nitrate (NO_3^-) as an electron acceptor in place of oxygen if they are kept under anaerobic conditions:

Denitrifiers play a key role in the cycling of nitrogen through ecosystems. Without denitrifiers, which convert nitrate ions back into nitrogen gas, all forms of nitrogen would leach from the soil and end up in lakes and oceans, making life on land much more difficult.

Nitrogen fixers convert atmospheric nitrogen gas into a chemical form (ammonia) that is usable by the nitrogen fixers themselves as well as by other organisms:

All organisms require nitrogen in order to build proteins, nucleic acids, and other important compounds. Nitrogen fixation is thus vital to life as we know it. This all-important biochemical process is carried out by a wide variety of archaea and bacteria (including cyanobacteria) but by no other organisms, so we depend on these prokaryotes for our very existence.

LINK For descriptions of the role of nitrogen in plant nutrition and of the global nitrogen cycle, see Concepts 25.2 and 46.3

Ammonia is oxidized to nitrate in soil and in seawater by chemolithotrophic bacteria called **nitrifiers**. Bacteria of two genera, *Nitrosomonas* and *Nitrosococcus*, convert ammonia (NH_3) to nitrite ions (NO_2^-), and *Nitrobacter* oxidize nitrite to nitrate (NO_3^-), the form of nitrogen most easily used by many plants. What do the nitrifiers get out of these reactions? Their metabolism is powered by the energy released by the oxidation of ammonia or nitrite. For example, by passing the electrons from nitrite through an electron transport system, *Nitrobacter* can make ATP, and using some of this ATP, can also make NADH. With this ATP and NADH, the bacterium can convert CO_2 and H_2O into glucose.

We have already seen the importance of the cyanobacteria in the cycling of oxygen: in ancient times, the oxygen generated by their photosynthesis converted Earth's atmosphere from an anaerobic to an aerobic environment. Other prokaryotes—both bacteria and archaea—contribute to the cycling of sulfur. Deep-sea hydrothermal vent ecosystems depend on chemolithotrophic prokaryotes that are incorporated into large communities of crabs, mollusks, and giant worms, all living at a depth of

2,500 meters—below any hint of sunlight. These bacteria obtain energy by oxidizing hydrogen sulfide and other substances released in the near-boiling water flowing from volcanic vents in the ocean floor.

Prokaryotes live on and in other organisms

Prokaryotes work together with eukaryotes in many ways. As we have seen, the mitochondria and chloroplasts of eukaryotes are descended from what were once free-living bacteria. Much later in evolutionary history, some plants became associated with bacteria to form cooperative nitrogen-fixing nodules on their roots.

Many animals harbor a variety of bacteria and archaea in their digestive tracts. Cattle depend on prokaryotes to perform important steps in digestion. Like most animals, cattle cannot produce cellulase, the enzyme needed to start the digestion of the cellulose that makes up the bulk of their plant food. However, bacteria living in a special section of the gut, called the rumen, produce enough cellulase to process the daily diet for the cattle.

FRONTIERS Humans use some of the metabolic products—especially vitamins B_{12} and K—produced by bacteria living in our large intestine. These prokaryotes line our intestines with a dense biofilm that is in intimate contact with the mucosal lining of the gut. This biofilm facilitates nutrient transfer from the intestine into the body, functioning like a specialized “tissue” that is essential to our health. This biofilm has a complex ecology that scientists have just begun to explore in detail—including the possibility that the species composition of an individual's prokaryote gut fauna may contribute to obesity (or the resistance to it).

Humans are heavily populated both inside and out by bacteria. A 2009 study identified more than 1,000 species of bacteria that live on human skin. Many of these bacteria are thought to be critical to maintaining the skin's health.

Of the tiny percentage of all prokaryotes that are pathogens, all those that are known are in the domain Bacteria. Although only a few bacterial species are pathogens, popular notions of bacteria as “germs” and fear of the consequences of infection arouse our curiosity about those few.

A small minority of bacteria are pathogens

The late nineteenth century was a productive era in the history of medicine—a time when bacteriologists, chemists, and physicians proved that many diseases are caused by microbial agents. During this time, the German physician Robert Koch laid down a set of four rules for establishing that a particular microorganism causes a particular disease:

1. The microorganism is always found in individuals with the disease.
2. The microorganism can be taken from the host and grown in pure culture.

Marshall and Warren set out to satisfy Koch's postulates:

Test 1

The microorganism must be present in every case of the disease.

Results: Biopsies from the stomachs of many patients revealed that the bacterium was always present if the stomach was inflamed or ulcerated.

Test 2

The microorganism must be cultured from a sick host.

Results: The bacterium was isolated from biopsy material and eventually grown in culture media in the laboratory.

Test 3

The isolated and cultured bacteria must be able to induce the disease.

Results: Marshall was examined and found to be free of bacteria and inflammation in his stomach. After drinking a pure culture of the bacterium, he developed stomach inflammation (gastritis).

Test 4

The bacteria must be recoverable from newly infected individuals.

Results: Biopsy of Marshall's stomach 2 weeks after he ingested the bacteria revealed the presence of the bacterium, now christened *Helicobacter pylori*, in the inflamed tissue.

Conclusion

Antibiotic treatment eliminated the bacteria and the inflammation in Marshall. The experiment was repeated on healthy volunteers, and many patients with gastric ulcers were cured with antibiotics. Thus Marshall and Warren demonstrated that the stomach inflammation leading to ulcers is caused by *H. pylori* infections in the stomach.

3. A sample of the culture produces the same disease when injected into a new, healthy host.
4. The newly infected host yields a new, pure culture of microorganisms identical to those obtained in the second step.

These rules, called **Koch's postulates**, were important tools in a time when it was not widely understood that microorganisms cause disease. Although modern medical science has more powerful diagnostic tools, Koch's postulates remain useful. For

Helicobacter pylori

1.5 μm

FIGURE 19.21 Satisfying Koch's Postulates Robin Warren and Barry Marshall of the University of Western Australia won the 2005 Nobel Prize in Medicine for showing that ulcers are caused not by the action of stomach acid but by infection with the bacterium *Helicobacter pylori*.

example, physicians were taken aback in the 1990s when stomach ulcers—long accepted and treated as the result of excess stomach acid—were shown by Koch's postulates to be caused by the bacterium *Helicobacter pylori* (FIGURE 19.21).

For an organism to be a successful pathogen, it must:

- arrive at the body surface of a potential host;
- enter the host's body;
- evade the host's defenses;
- reproduce inside the host; and
- infect a new host.

Failure to complete any of these steps ends the reproductive career of a pathogenic organism. Yet in spite of the many defenses available to potential hosts (see Chapter 31), some bacteria are very successful pathogens. Pathogenic bacteria are often surprisingly difficult to combat, even with today's arsenal of antibiotics. One source of this difficulty is their ability to form biofilms.

For the host, the consequences of a bacterial infection depend on several factors. One is the **invasiveness** of the pathogen: its ability to multiply in the host's body. Another is its **toxigenicity**: its ability to produce *toxins*, chemical substances that are harmful to the host's tissues. *Corynebacterium diphtheriae*, the agent that causes diphtheria, has low invasiveness and multiplies only in the throat, but its toxigenicity is so great that the entire body is affected. In contrast, *Bacillus anthracis*, which

APPLY THE CONCEPT

A small minority of bacteria are pathogens

Imagine you are in charge of maintaining a trout hatchery. Some trout are exhibiting loss of tissue at the tips of their fins, and you suspect a bacterial infection. You isolate and culture two species of bacteria from a trout with affected fins.

1. How would you satisfy the first of Koch's postulates?
2. Imagine that bacterium 1 satisfies the first of Koch's postulates, but bacterium 2 does not. What presence or

absence of data from the cultures from many samples of infected fish would lead you to this conclusion?

3. You already know that bacterium 1 satisfies the second of Koch's postulates. You decide to conduct a test of the third postulate. To your surprise, the test animals are all healthy and show no sign of disease. What are some possible explanations? How would you test your hypotheses?

causes anthrax, has low toxigenicity but is so invasive that the entire bloodstream ultimately teems with the bacteria.

There are two general types of bacterial toxins: exotoxins and endotoxins. **Endotoxins** are released when certain Gram-negative bacteria grow or lyse (burst). Endotoxins are lipopolysaccharides (complexes consisting of a polysaccharide and a lipid component) that form part of the outer bacterial membrane. Endotoxins are rarely fatal to the host; they normally cause fever, vomiting, and diarrhea. Among the endotoxin producers are some strains of the proteobacteria *Salmonella* and *Escherichia*.

Exotoxins are soluble proteins released by living, multiplying bacteria. They are highly toxic—often fatal—to the host. Human diseases induced by bacterial exotoxins include tetanus (*Clostridium tetani*), cholera (*Vibrio cholerae*), and bubonic plague (*Yersinia pestis*). Anthrax is caused by three exotoxins produced by *Bacillus anthracis*. Botulism is caused by exotoxins produced by *Clostridium botulinum*, which are among the most poisonous ever discovered. The lethal dose for humans of one exotoxin of *C. botulinum* is about one-millionth of a gram. Nonetheless, much smaller doses of this exotoxin, marketed under various trade names (e.g., Botox), are used to treat muscle spasms and for cosmetic purposes (temporary wrinkle reduction in the skin).

Do You Understand Concept 19.3?

- How do biofilms form, and why are they of special interest to researchers?
- How are the four nutritional categories of prokaryotes distinguished?
- How is nitrogen metabolism in the prokaryotes vital to other organisms? Given the roles of bacteria in the nitrogen cycle, how would you answer people who consider all bacteria to be “germs” and dangerous?

Before moving on to discuss the diversity of eukaryotic life, it is appropriate to consider another category of life that includes some pathogens: the viruses. Although they are not cellular, viruses are numerically among the most abundant forms of life on Earth. Their effects on other organisms are enormous. Where did viruses come from, and how do they fit into the tree of life? Biologists are still working to answer these questions.

concept 19.4 Viruses Have Evolved Many Times

Some biologists do not think of viruses as living organisms, primarily because they are not cellular and must depend on cellular organisms for basic life functions such as replication and metabolism. But viruses are derived from the cells of living organisms. They use the same essential forms of genetic information storage and transmission as do cellular organisms. Viruses infect all cellular forms of life—bacteria, archaea, and eukaryotes. They replicate, mutate, evolve, and interact with

other organisms, often causing serious diseases in their hosts. Finally, viruses clearly evolve independently of other organisms, so it is almost impossible not to treat them as a part of life.

Several factors make virus phylogeny difficult to resolve. The tiny size of many virus genomes restricts the phylogenetic analyses that can be conducted to relate viruses to cellular organisms. Their rapid mutation rate, which results in rapid evolution of virus genomes, tends to cloud evolutionary relationships over long periods. There are no known fossil viruses (viruses are too small and delicate to fossilize), so the paleontological record offers no clues to virus origins. Finally, viruses are highly diverse (**FIGURE 19.22**). Several lines of evidence support the hypothesis that viruses have evolved repeatedly within each of the major groups of life. The difficulty in resolving deep evolutionary relationships of viruses makes a phylogeny-based classification difficult. Instead, viruses are placed in one of several functionally similar groups on the basis of the structure of their genomes (for example, whether the genomes are composed of RNA or DNA, and are double- or single-stranded). Most of these defined groups are not thought to represent monophyletic taxa, however.

Many RNA viruses probably represent escaped genomic components

Although viruses are now obligate parasites of cellular species, many viruses may once have been cellular components involved in basic cellular functions—that is, they may be “escaped” components of cellular life that now evolve independently of their hosts.

NEGATIVE-SENSE SINGLE-STRANDED RNA VIRUSES A case in point is a class of viruses whose genome is composed of single-stranded *negative-sense* RNA: RNA that is the complement of the mRNA needed for protein translation. Many of these *negative-sense single-stranded RNA viruses* have only a few genes, including one for an RNA-dependent RNA polymerase that allows them to make mRNA from their negative-sense RNA genome. Modern cellular organisms cannot generate mRNA in this manner (at least in the absence of viral infections), but scientists speculate that single-stranded RNA genomes may have been common in the distant past, before DNA became the primary molecule for genetic information storage.

A self-replicating RNA polymerase gene that began to replicate independently of a cellular genome could conceivably acquire a few additional protein-coding genes through recombination with its host’s DNA. If one or more of these genes were to foster the development of a protein coat, the virus might then survive outside the host and infect new hosts. It is believed that this scenario has been repeated many times independently across the tree of life, given that many of the negative-sense single-stranded RNA viruses that infect organisms from bacteria to humans are not closely related to one another. In other words, negative-sense single-stranded RNA viruses do not represent a distinct taxonomic group, but rather exemplify a particular process of cellular escape that probably happened many different times.

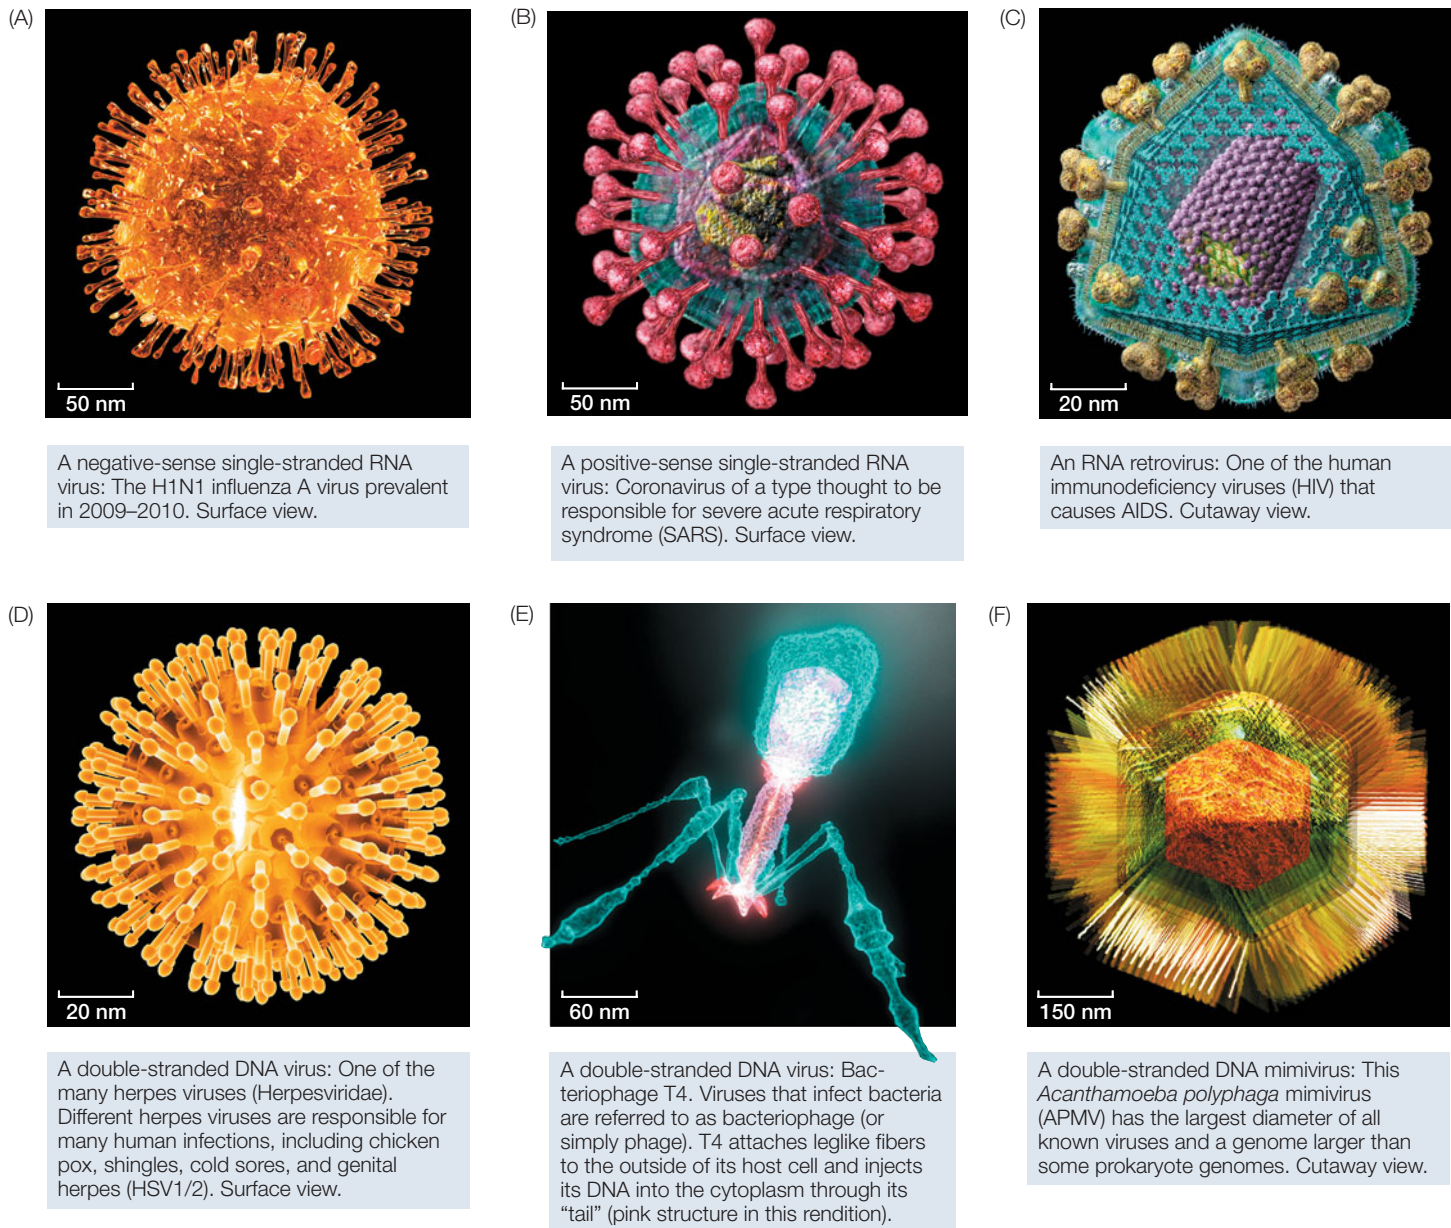

FIGURE 19.22 Viruses Are Diverse Relatively small genomes and rapid evolutionary rates make it difficult to reconstruct phylogenetic relationships among some classes of viruses. Instead, viruses are classified largely by general characteristics of their genomes. The images here are computer artists’ reconstructions based on cryoelectron micrographs.

Familiar examples of negative-sense single-stranded RNA viruses include the viruses that cause measles, mumps, rabies, and influenza (see Figure 19.22A).

POSITIVE-SENSE SINGLE-STRANDED RNA VIRUSES The genome of another type of single-stranded RNA virus is composed of positive-sense RNA. Positive-sense genomes are already set for translation; no replication of the genome to form a complement strand is needed before protein translation can take place.

Positive-sense single-stranded RNA viruses (see Figure 19.22B) are the most abundant and diverse class of viruses. Most of the viruses that cause diseases in crop plants are members of this group. These viruses kill patches of cells in the leaves or stems of plants, leaving live cells amid a patchwork of discolored dead tissue (giving them the name of *mosaic* or *mottle viruses*; **FIGURE 19.23**). Other viruses in this group infect bacteria, fungi, and animals. Human diseases caused by positive-sense single-stranded RNA viruses include polio, hepatitis C, and the common cold. As is true of the other functionally defined groups of viruses, these viruses appear to have evolved multiple times across the tree of life from different groups of cellular ancestors.

APPLY THE CONCEPT

Viruses have evolved many times

When Gram-staining revealed the first mimivirus (discovered living inside an amoeba), it was mistakenly identified as a parasitic Gram-positive bacterium. It was soon discovered that this species was not cellular, however, and it was reclassified as a virus. The graph below shows the genome size and number of protein-coding genes for various species of bacteria. Use the graph to answer the following questions.

1. What is a likely explanation for the generally smaller genome size and smaller number of protein-coding genes in parasitic bacteria than in most free-living species? Can you form a hypothesis about which species of parasitic bacteria are likely to have existed for the longest time as parasites?
2. The genome of *Acanthamoeba polyphaga mimivirus* (the first discovered mimivirus) is 1,181,404 base pairs, encompassing 911 protein-coding genes. Plot the relevant data for this mimivirus on the graph. How does your result fit with the hypothesis that the mimivirus evolved from a parasitic bacterium?
3. Earlier in this chapter, we described a minute, parasitic group of archaea, the Nanoarchaeota (see Figure 19.18). The genome of one species, *Nanoarchaeum equitans*, is 490,885 base pairs and contains 536 protein-coding genes. Plot the relevant data for this species on the graph. How does the genome of this parasitic archaea species differ from the genomes of the parasitic bacteria? From the genome of the mimivirus?

FIGURE 19.23 Mosaic Viruses Are a Problem for Agriculture Mosaic, or “mottle,” viruses are the most diverse class of viruses. This leaf is from an apple tree infected with mosaic virus.

RNA RETROVIRUSES The *RNA retroviruses* are best known as the group that includes the human immunodeficiency viruses (HIV; see Figure 19.22C). Like the previous two categories of viruses, RNA retroviruses have genomes composed of single-stranded RNA and probably evolved as escaped cellular components.

Retroviruses are so named because they regenerate themselves by reverse transcription. When the retrovirus enters the nucleus of its vertebrate host, viral reverse transcriptase produces complementary DNA (cDNA) from the viral RNA genome and then replicates the single-stranded cDNA to produce double-stranded DNA. Another virally encoded enzyme called integrase catalyzes the integration of the new piece of double-stranded viral DNA into the host’s genome. The viral genome is then replicated along with the host cell’s DNA; the integrated retroviral DNA is known as a *provirus*. Many components of the genomes of cellular species (such as retrotransposons; see Concept 12.3) resemble components of retroviruses.

Retroviruses are only known to infect vertebrates, although genomic elements that resemble portions of these viruses are a component of the genomes of a wide variety of organisms, including bacteria, plants, and many animals. Several retroviruses are associated with the development of various forms of cancer, as cells infected with these viruses are likely to undergo uncontrolled replication.

DOUBLE-STRANDED RNA VIRUSES *Double-stranded RNA viruses* may have evolved repeatedly from single-stranded RNA ancestors—or perhaps vice versa. These viruses, which are not closely related to one another, infect organisms from throughout the tree of life. Many plant diseases are caused by double-stranded RNA viruses. Other viruses of this type cause many cases of infant diarrhea in humans.

Some DNA viruses may have evolved from reduced cellular organisms

Another class of viruses is composed of viruses that have a double-stranded DNA genome (see Figure 19.22D–F). This group is also almost certainly polyphyletic (with many independent origins). Many of the common phage that infect bacteria (*bacteriophage*) are double-stranded DNA viruses, as are the viruses that cause smallpox and herpes in humans.

Some biologists think that at least some of the DNA viruses may represent highly reduced parasitic organisms that have lost their cellular structure as well as their ability to survive as free-living species. For example, the *mimiviruses*, which are some of the largest DNA viruses (see Figure 19.22F), have a genome in excess of a million base pairs of DNA that encode over 900 proteins. This genome is similar in size to the genomes of many parasitic bacteria and about twice as large as the genome of the smallest bacteria. Phylogenetic analyses of these DNA viruses suggest that they have evolved repeatedly from cellular organisms. Furthermore, recombination among different viruses may have allowed the exchange of various genetic modules, further complicating the history and origins of these viruses.

Do You Understand Concept 19.4?

- Why is it difficult to place viruses precisely within the tree of life?
- What are the two main hypotheses of virus origins?

It appears that the enormous diversity of viruses is, at least in part, a result of their multiple origins from many different cellular organisms. It may be best to view viruses as spinoffs from the various branches on the tree of life—sometimes evolving independently of cellular genomes, sometimes recombining with them. One way to think of viruses is as the “bark” on the tree of life: certainly an important component all across the tree, but not quite like the main branches.

How do *Vibrio* populations detect when they are dense enough to produce bioluminescence?

ANSWER Bacteria release chemical substances that are sensed by other bacteria of the same species. They can announce their availability for conjugation by means of such signals. They can also monitor the density of their population. As the density of bacteria in a particular region increases, the concentration of a chemical signal builds up. When the bacteria sense that their population has become sufficiently dense, they can commence activities that smaller densities could not manage, such as forming a biofilm (see Figure 19.19). This phenomenon is called *quorum sensing*.

In the case of *Vibrio*, bioluminescence requires a critical concentration of a chemical signal produced by the bacteria. At low densities, there is not enough of this substance to produce bioluminescence, so free-living bacteria do not glow. When a colony of bacteria is growing on phytoplankton, however, concentrations of this substance are high enough to produce light at a rate of about 10^3 photons per second per cell. This light does more than amaze human observers: by attracting fish that consume the phytoplankton on which the bacteria are growing, it gets the bacteria into a new host.

19

SUMMARY

concept 19.1 Life Consists of Three Domains That Share a Common Ancestor

- Two of life’s three domains, Bacteria and Archaea, are prokaryotic. They are distinguished from Eukarya in several ways, including their lack of a nucleus and of membrane-enclosed organelles. **Review Table 19.1**
- Eukaryotes are related to both Archaea and Bacteria and appear to have formed through endosymbiosis between members of these two lineages. The last common ancestor of all three domains probably lived about 3 billion years ago. **Review Figure 19.1 and ANIMATED TUTORIAL 19.1**

- Early attempts to classify prokaryotes were hampered by the organisms’ small size and the difficulties of growing them in pure culture.
- The cell walls of almost all bacteria contain **peptidoglycan**, whereas the cell walls of archaea and eukaryotes lack peptidoglycan.
- Bacteria can be differentiated into two groups by the **Gram stain**. **Gram-negative bacteria** have a periplasmic space between the plasma membrane and a distinct outer membrane. **Gram-positive bacteria** have a thick cell wall containing about five times as much peptidoglycan as a Gram-negative wall. **Review Figure 19.2 and WEB ACTIVITY 19.1**

- The three most common bacterial morphologies are **cocci** (spheres), **bacilli** (rods), and **helices** (spirals). **Review Figure 19.3**
- The cells of some bacteria aggregate, forming multicellular colonies.
- Phylogenetic classification of prokaryotes is now based principally on the nucleotide sequences of rRNA and other genes involved in fundamental cellular processes.
- Prokaryotes reproduce asexually by binary fission, but may exchange genetic material. Reproduction and genetic exchange are not directly linked in prokaryotes.
- Although lateral gene transfer has occurred throughout prokaryotic evolutionary history, elucidation of prokaryote phylogeny is still possible. **Review Figure 19.4**

concept 19.2 Prokaryote Diversity Reflects the Ancient Origins of Life

- Prokaryotes are the most numerous organisms on Earth, only a small fraction of prokaryote diversity has been characterized to date.
- Some **high-GC Gram-positives** produce important antibiotics.
- The **low-GC Gram-positives** include the **mycoplasmas**, which are among the smallest cellular organisms ever discovered.
- The photosynthetic **cyanobacteria** release oxygen into the atmosphere. Cyanobacteria may live free as single cells or associate in multicellular colonies. **Review Figure 19.9**
- **Spirochetes** have unique structures called axial filaments that allow them to move in a corkscrew-like manner. **Review Figure 19.10**
- The **proteobacteria** embrace the largest number of known species of bacteria. Smaller groups include the **hyperthermophilic bacteria**, **hadobacteria**, and **chlamydias**.
- The best-studied groups of Archaea are **Crenarchaeota** and **Euryarchaeota**.
- Many archaea are **extremophiles**. Most known crenarchaeotes are thermophilic, acidophilic, or both. Some euryarchaeotes are **methanogens**; **extreme halophiles** are also found among the euryarchaeotes. **Review Figure 19.14**

- Ether linkages in the branched long-chain hydrocarbons of the lipids that make up their cell membranes are a synapomorphy of Archaea. **Review Figure 19.15**

concept 19.3 Ecological Communities Depend on Prokaryotes

- Prokaryotes form complex communities, of which **biofilms** are one example. **Review Figure 19.19**
- Prokaryote metabolism is very diverse. Some prokaryotes are anaerobic, others are aerobic, and still others can shift between these modes.
- Prokaryotes fall into four broad nutritional categories: **photoautotrophs**, **photoheterotrophs**, **chemolithotrophs**, and **chemoheterotrophs**. **Review Table 19.2**
- Prokaryotes play key roles in the cycling of elements such as nitrogen, oxygen, sulfur, and carbon. One such role is as decomposers of dead organisms.
- Some prokaryotes metabolize sulfur or nitrogen. **Nitrogen fixers** convert nitrogen gas into a form that organisms can metabolize. **Nitrifiers** convert that nitrogen into forms that can be used by plants, and **denitrifiers** return nitrogen to the atmosphere.
- Prokaryotes inhabit the guts of many animals (including humans) and help them digest food.
- **Koch's postulates** establish the criteria by which an organism may be classified as a pathogen. Relatively few bacteria—and no archaea—are known to be pathogens. **Review Figure 19.21**

concept 19.4 Viruses Have Evolved Many Times

- Viruses have evolved many times from many different groups of cellular organisms. They do not represent a single taxonomic group.
- Some viruses are probably derived from escaped genetic elements of cellular species; others are thought to have evolved as highly reduced parasites.
- Viruses are categorized by the nature of their genomes.

The Origin and Diversification of Eukaryotes

20

In summer 2005, a devastating red tide crippled the shellfish industry along the Atlantic coast of North America from Canada to Massachusetts. This red tide was produced by a bloom of dinoflagellates of the genus *Alexandrium*. These protists produce a powerful toxin that accumulates in clams, mussels, and oysters. A person who eats a mollusk contaminated with the toxin can experience a syndrome known as paralytic shellfish poisoning. The losses to the shellfish industry in 2005 were estimated at \$50 million, and many people were sickened by eating mollusks that were harvested before the problem was diagnosed.

Several species of dinoflagellates produce toxic red tides in many parts of the world. Along the Gulf of Mexico, red tides caused by dinoflagellates of the genus *Karenia* produce a neurotoxin that affects the central nervous systems of fish, which become paralyzed and cannot respire effectively. Huge numbers of dead fish wash up on Gulf Coast beaches during a *Karenia* red tide. In addition, wave action can produce aerosols of the *Karenia* toxin, and these aerosols often cause asthma-like symptoms in humans on shore.

After the losses that resulted from the 2005 red tide, biologists at the Woods Hole Oceanographic Institution (WHOI) on Cape Cod began to monitor and model dinoflagellate populations off the New England coast. If biologists could accurately forecast future blooms, people in the area could be made aware of the problem in advance and adjust the shellfish harvest (and their eating habits) accordingly.

Biologists from WHOI monitored counts of dinoflagellates in the water and in seafloor sediments. They also monitored river runoff, water currents, water

temperature and salinity, winds, and tides. An additional environmental factor was the “nor’easter” storms common along the New England coast. By correlating their measurements of these environmental factors with dinoflagellate counts, biologists produced a model that predicted growth of dinoflagellate populations.

In spring 2008, the WHOI team determined that all the factors were in place to produce another red tide like the one of 2005—if a nor’easter occurred to blow the dinoflagellates toward the coast. A nor’easter did occur at just the wrong time, and another red tide materialized in summer 2008, just as predicted. But this time, people were warned. Shellfish harvesters adjusted their harvest, and many fewer people were harmed by eating toxic mollusks.

Blooms of dinoflagellates can cause toxic red tides, such as this one in the Bountiful Islands off the coast of Queensland, Australia.

Red tides are harmful, but can dinoflagellates also be beneficial to marine ecosystems?

KEY CONCEPTS

- 20.1** Eukaryotes Acquired Features from Both Archaea and Bacteria
- 20.2** Major Lineages of Eukaryotes Diversified in the Precambrian
- 20.3** Protists Reproduce Sexually and Asexually
- 20.4** Protists Are Critical Components of Many Ecosystems

concept 20.1 Eukaryotes Acquired Features from Both Archaea and Bacteria

We easily recognize trees, mushrooms, and insects as plants, fungi, and animals, respectively. But there is a dazzling assortment of other eukaryotic organisms—mostly microscopic—that do not fit into these three groups. Eukaryotes that are not plants, animals, or fungi have traditionally been called **protists**. But phylogenetic analyses reveal that many of the groups we commonly refer to as protists are not, in fact, closely related. Thus the term “protist” does not describe a formal taxonomic group, but is a convenience term for “all the eukaryotes that are not plants, animals, or fungi.”

The unique characteristics of the eukaryotic cell lead scientists to conclude that the eukaryotes are monophyletic, and that a single eukaryotic ancestor diversified into the many different protist lineages as well as giving rise to the plants, fungi, and animals. As we saw in Concept 19.1, eukaryotes are generally thought to be more closely related to Archaea than to Bacteria. The mitochondria and chloroplasts of eukaryotes, however, are clearly derived from bacterial lineages (see Figure 19.1).

Traditionally, biologists have hypothesized that the *split* of Eukarya from Archaea was followed by the endosymbioses with bacterial lineages that led to the origin of mitochondria and chloroplasts. Some biologists prefer to view the origin of eukaryotes as the *fusion* of lineages from the two prokaryote groups. This difference is largely a semantic one that hinges on the subjective point at which we deem the eukaryote lineage to have become definitively “eukaryotic.” In either case, we can make some reasonable inferences about the events that led to the evolution of a new cell type, bearing in mind that the environment underwent an enormous change—from low to high availability of free atmospheric oxygen—during the course of these events.

The modern eukaryotic cell arose in several steps

Several events were important in the origin of the modern eukaryotic cell (FIGURE 20.1):

- The origin of a flexible cell surface
- The origin of a cytoskeleton

FIGURE 20.1 Evolution of the Eukaryotic Cell The loss of a rigid cell wall allowed the plasma membrane to fold inward and create more surface area, which facilitated the evolution of larger cells. As cells grew larger, cytoskeletal complexity increased, and the cell became increasingly compartmentalized. Endosymbioses involving bacteria gave rise to mitochondria and (in photosynthetic eukaryotes) to chloroplasts.

- The origin of a nuclear envelope, which enclosed a genome organized into chromosomes
- The appearance of *digestive vacuoles*
- The acquisition of certain organelles via endosymbiosis

FLEXIBLE CELL SURFACE Many fossil prokaryotes look like modern bacilli, and we presume that these ancient organisms, like most present-day prokaryotic cells, had firm cell walls. The first step toward the eukaryotic condition was the loss of the cell wall by an ancestral prokaryotic cell. This wall-less condition is present in some present-day prokaryotes. Let's consider the possibilities open to a flexible cell without a firm wall.

First, think of cell size. As a cell grows larger, its surface area-to-volume ratio decreases (see Figure 4.2). Unless the surface area can be increased, the cell volume will reach an upper limit. If the cell's surface is flexible, however, it can fold inward and become more elaborate, creating more surface area for gas and nutrient exchange. With a surface flexible enough to allow infolding, the cell can exchange materials with its environment rapidly enough to sustain a larger volume and more rapid metabolism (Figure 20.1, steps 1–2). Furthermore, a flexible surface can pinch off bits of the environment, bringing them into the cell by endocytosis. These infoldings of the cell surface, which also exist in some modern prokaryotes, were important for the evolution of large eukaryotic cells.

CHANGES IN CELL STRUCTURE AND FUNCTION Other early steps that were important for the evolution of the eukaryotic cell are likely to have included three advances: the formation of ribosome-studded internal membranes, some of which surrounded the DNA; development of a more complex cytoskeleton; and the evolution of digestive vacuoles (Figure 20.1, steps 3–7).

Until a few years ago, biologists thought that cytoskeletons were restricted to eukaryotes. Improved imaging technology and molecular analyses have now revealed homologs of many cytoskeletal proteins in prokaryotes, so simple cytoskeletons evolved before the origin of eukaryotes. The cytoskeleton of a eukaryote, however, is much more developed and complex than that of a prokaryote. This greater development of microfilaments and microtubules supports the eukaryotic cell and allows it to manage changes in shape, to distribute daughter chromosomes, and to move materials from one part of its larger cell to other parts. In addition, the presence of microtubules in the cytoskeleton could have given rise in some cells to the characteristic eukaryotic flagellum.

The DNA of a prokaryotic cell is attached to a site on its plasma membrane. If that region of the plasma membrane were to fold into the cell, the first step would be taken toward the evolution of a *nucleus*, a primary feature of the eukaryotic cell.

The nuclear envelope appeared early in the eukaryote lineage. The next step was probably *phagocytosis*—the ability to engulf and digest other cells. Early eukaryotes may also have

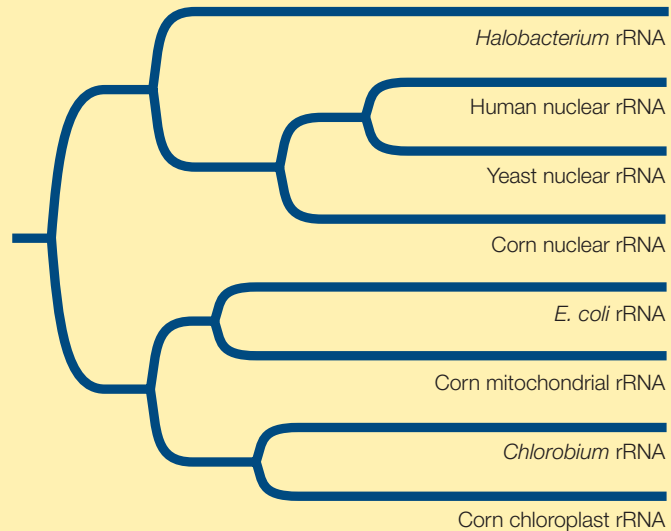

APPLY THE CONCEPT

Eukaryotes acquired features from both archaea and bacteria

Ribosomal RNA (rRNA) genes are present in the nuclear genome of eukaryotes. There are also rRNA genes in the genomes of mitochondria and chloroplasts. Therefore, photosynthetic eukaryotes have three different sets of rRNA genes, which encode the structural RNA of separate ribosomes in the nucleus, mitochondria, and chloroplasts, respectively. Translation of each genome takes place on its own set of ribosomes.

The gene tree shows the evolutionary relationships of rRNA gene sequences isolated from the nuclear genomes of humans, yeast, and corn; from an archaeon (*Halobacterium*), a proteobacterium (*E. coli*), and a cyanobacterium (*Chlorobium*); and from the mitochondrial and chloroplast genomes of corn. Use the gene tree to answer the following questions.

1. Why aren't the three rRNA genes of corn one another's closest relatives?
2. How would you explain the closer relationship of the mitochondrial rRNA gene of corn to the rRNA gene of *E. coli* than to the nuclear rRNA genes of other eukaryotes? Can you explain the relationship of the rRNA gene from the chloroplast of corn to the rRNA gene of the cyanobacterium?

3. If you were to sequence the rRNA genes from human and yeast mitochondrial genomes, where would you expect these two sequences to fit on the gene tree?

had an associated endoplasmic reticulum and Golgi apparatus, and perhaps one or more flagella of the eukaryotic type.

ENDOSYMBIOSIS At the same time the processes outlined above were taking place, cyanobacteria were generating O_2 as a product of photosynthesis. The increasing concentrations of O_2 in the atmosphere had disastrous consequences for most organisms of the time, which were unable to tolerate the newly oxidizing environment. But some prokaryotes managed to cope with these changes, and—fortunately for us—so did some of the new phagocytic eukaryotes.

At about this time, endosymbioses began to play a role in eukaryote evolution (Figure 20.1, steps 8–9). The theory of endosymbiosis proposes that certain organelles are the descendants of prokaryotes engulfed, but not digested, by ancient eukaryotic cells. One crucial event in the history of eukaryotes was the incorporation of a proteobacterium that evolved into the mitochondrion. Initially, the new organelle's primary function was probably to detoxify O_2 by reducing it to water. Later, this reduction became coupled with the formation of ATP in cellular respiration. Upon completion of this step, the essential modern eukaryotic cell was complete.

LINK You may wish to review the reactions of cellular respiration in Concept 6.2

Photosynthetic eukaryotes are the result of yet another endosymbiotic step: the incorporation of a prokaryote related to today's cyanobacteria, which became the chloroplast.

Chloroplasts have been transferred among eukaryotes several times

Eukaryotes in several different groups possess chloroplasts, and groups with chloroplasts appear in several distantly related eukaryote clades. Some of these groups differ in the photosynthetic pigments their chloroplasts contain. And not all chloroplasts are limited to a pair of surrounding membranes—in some microbial eukaryotes, they are surrounded by *three or more* membranes. We now view these observations as evidence of a remarkable series of endosymbioses. This conclusion is supported by extensive evidence from electron microscopy and nucleic acid sequence comparisons.

All chloroplasts trace their ancestry back to the engulfment of one cyanobacterium by a larger eukaryotic cell. This event, the step that first gave rise to the photosynthetic eukaryotes, is known as **primary endosymbiosis** (FIGURE 20.2A). The cyanobacterium, a Gram-negative bacterium, had both an inner and an outer membrane (see Figure 19.2B). Thus the original chloroplasts had two surrounding membranes: the inner and outer membranes of the cyanobacterium. Remnants of the peptidoglycan-containing cell wall of the bacterium are present

FIGURE 20.2 Endosymbiotic Events in the Evolution of Chloroplasts (A) A single instance of primary endosymbiosis ultimately gave rise to all of today's chloroplasts. (B) Secondary endosymbiosis—the uptake and retention of a chloroplast-containing cell by another eukaryotic cell—took place several times, independently.

Family Tree of Chloroplasts

in the form of a bit of peptidoglycan between the chloroplast membranes of *glaucoephytes*, the first eukaryote group to branch off following primary endosymbiosis (as we will see in Chapter 21). Primary endosymbiosis also gave rise to the chloroplasts of the red algae, green algae, and land plants. The red algal chloroplast retains certain pigments of the original cyanobacterial endosymbiont that are absent in green algal chloroplasts.

Almost all remaining photosynthetic eukaryotes are the result of additional rounds of endosymbiosis. For example, the photosynthetic *euglenids* derived their chloroplasts from **secondary endosymbiosis** (FIGURE 20.2B). Their ancestor took up a unicellular green alga, retaining its chloroplast and eventually losing the rest of the constituents of the alga. This history explains why the photosynthetic euglenids have the same photosynthetic pigments as the green algae and land plants. It also accounts for the third membrane of the euglenid chloroplast, which is derived from the euglenid's plasma membrane (as a result of endocytosis). An additional round—**tertiary endosymbiosis**—occurred when a dinoflagellate apparently lost its chloroplast and took up another protist that had acquired its chloroplast through secondary endosymbiosis.

Do You Understand Concept 20.1?

- Why was the development of a flexible cell surface a key event for eukaryote evolution?
- What do you consider the most critical events that led to the evolution of the eukaryotic cell? Why?
- Explain how increased availability of atmospheric oxygen (O₂) could have impacted the evolution of the eukaryotic cell.

The features that eukaryotes gained from archaea and bacteria have allowed them to exploit many different environments. This led to the evolution of great diversity among eukaryotes, beginning with a radiation that started in the Precambrian.

concept 20.2 Major Lineages of Eukaryotes Diversified in the Precambrian

Most eukaryotes can be classified in one of eight major clades that began to diversify about 1.5 billion years ago: alveolates, excavates, stramenopiles, plants, rhizaria, amoebozoans, fungi, and animals (FIGURE 20.3). Plants, fungi, and animals each have close protist relatives (such as the choanoflagellate relatives of animals), which we will discuss along with those major multicellular eukaryote groups in Chapters 21–23.

Each of the five major groups of protistan eukaryotes covered in this chapter consists of organisms with enormously diverse body forms and nutritional lifestyles. Some protists are motile, whereas others do not move; some are photosynthetic, others heterotrophic; most are unicellular, but some are multicellular. Most are microscopic, but a few are huge (giant kelps, for example, can grow to half the length of a football field). We refer

to the unicellular species of protists as *microbial eukaryotes*, but keep in mind that there are large, multicellular protists as well.

Biologists used to classify protists largely on the basis of their life histories and reproductive features (see Concept 20.3). In recent years, however, electron microscopy and gene sequencing have revealed many new patterns of evolutionary relatedness among these groups. Analyses of slowly evolving gene sequences are making it possible to explore evolutionary relationships among eukaryotes in ever greater detail and with greater confidence. Nonetheless, some substantial areas of uncertainty remain, and lateral gene transfer may complicate efforts to reconstruct the evolutionary history of protists (as was also true for prokaryotes; see Concept 19.1). Today we recognize great diversity among the many distantly related protist clades.

Alveolates have sacs under their plasma membranes

Alveolates are so named because they possess sacs called *alveoli* just beneath their plasma membranes, which may play a role in supporting the cell surface. All alveolates are unicellular, and most are photosynthetic, but they are diverse in body form. The groups considered in detail here are the *dinoflagellates*, *apicomplexans*, and *ciliates*.

DINOFLAGELLATES Most **dinoflagellates** are marine and photosynthetic; they are important primary producers of organic matter in the oceans. The dinoflagellates are of great ecological, evolutionary, and morphological interest. A distinctive mixture of photosynthetic and accessory pigments gives their chloroplasts a golden brown color. Some dinoflagellate species cause red tides, as discussed at the start of this chapter. Other species are photosynthetic endosymbionts that live within the cells of other organisms, including invertebrate animals (such as corals) and other marine protists (see Figures 20.13A and 20.19). Some are nonphotosynthetic and live as parasites within other marine organisms.

Dinoflagellates have a distinctive appearance. They generally have two flagella, one in an equatorial groove around the cell, the other starting near the same point as the first and passing down a longitudinal groove before extending into the surrounding medium (FIGURE 20.4). Some dinoflagellates can take on different forms, including amoeboid ones, depending on environmental conditions. It has been claimed that the dinoflagellate *Pfiesteria piscicida* can occur in at least two dozen distinct forms, although this claim is highly controversial. In any case, this remarkable dinoflagellate is harmful to fish and can, when present in great numbers, both stun and feed on them.

APICOMPLEXANS The exclusively parasitic **apicomplexans** derive their name from the *apical complex*, a mass of organelles contained in the *apical* end (the tip) of the cell. These organelles help the apicomplexan invade its host's tissues. For example, the apical complex enables *Plasmodium*, the causative agent of malaria, to enter its target cells in the human body after transmission by a mosquito (see p. 403).

FIGURE 20.3 Precambrian Divergence of Major Eukaryote Groups A phylogenetic tree shows one current hypothesis and estimated time line for the origin of the major groups of eukaryotes. The

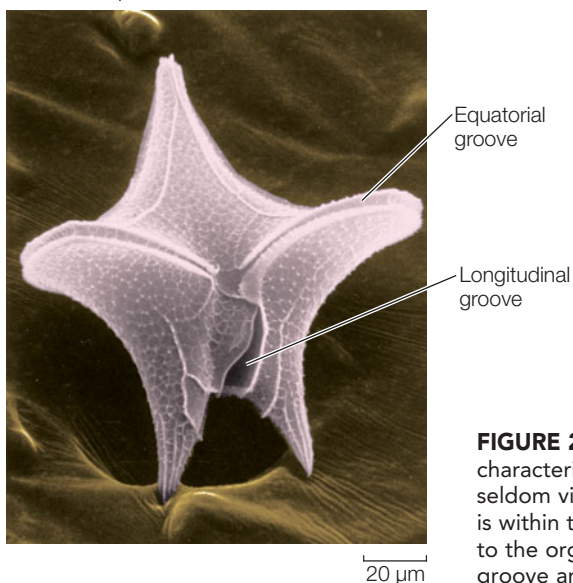

rapid divergence of major lineages between 1.5 and 1.4 bya makes reconstruction of their precise relationships difficult. The major multicellular groups (tinted boxes) will be covered in subsequent chapters.

Like many obligate parasites, apicomplexans have elaborate life cycles featuring asexual and sexual reproduction by a series of very dissimilar life stages. In many species, these life stages are associated with two different types of host organisms, as is the case with *Plasmodium*. Another apicomplexan, *Toxoplasma*, alternates between cats and rats to complete its life cycle. A rat infected with *Toxoplasma* loses its fear of cats,

which makes it more likely to be eaten by, and thus transfer the parasite to, a cat.

FRONTIERS Apicomplexans contain a much-reduced chloroplast, derived from secondary endosymbiosis of a red alga, that no longer has a photosynthetic function. Researchers are targeting this chloroplast in *Plasmodium* as the site of attack for a future antimalarial drug. Its discovery is viewed as an important advance in the effort to treat malaria victims, as existing medications only reduce the chance of initial infection and do not cure infected individuals.

Peridinium sp.

CILIATES The **ciliates** are named for their numerous hairlike cilia, which are shorter than, but otherwise identical to, eukaryotic flagella. The ciliates are much more complex in body form than are most other unicellular eukaryotes (FIGURE 20.5). Their definitive characteristic is the possession of two types of nuclei (whose roles we will describe in Concept 20.3 when we discuss protist reproduction). Almost all ciliates

FIGURE 20.4 A Dinoflagellate The presence of two flagella is characteristic of many dinoflagellates, although these appendages are seldom visible, being contained within deep grooves. One flagellum is within the equatorial groove and provides forward thrust and spin to the organism. The second flagellum originates in the longitudinal groove and acts like the rudder of a boat.

FIGURE 20.5 Diversity among the Ciliates (A) A free-swimming organism, this *Paramecium* belongs to a ciliate group whose members have many cilia of uniform length. (B) The barrel-shaped *Didinium nasutum* feeds on other ciliates, including *Paramecium*. Their cilia occur in two separate bands. (C) Some of the cilia in *Euplotes* fuse into flat sheets that direct food particles into an oral groove.

are heterotrophic, although a few contain photosynthetic endosymbionts.

Paramecium, a frequently studied ciliate genus, exemplifies the complex structure and behavior of ciliates (FIGURE 20.6). The slipper-shaped cell is covered by an elaborate *pellicle*, a structure composed principally of an outer membrane and an inner layer of closely packed, membrane-enclosed sacs (the *alveoli*) that surround the bases of the cilia. Defensive organelles called *trichocysts* are also present in the pellicle. In response to a threat, a microscopic explosion expels the trichocysts in a few milliseconds, and they emerge as sharp darts, driven forward at the tip of a long, expanding filament.

The cilia provide *Paramecium* with a form of locomotion that is generally more precise than locomotion by flagella or pseudopods. A *Paramecium* can coordinate the beating of its cilia to propel itself either forward or backward in a spiraling manner. It can also back off swiftly when it encounters a barrier or a negative stimulus. The coordination of ciliary beating is probably the result of a differential distribution of ion channels in the plasma membrane near the two ends of the cell.

Organisms living in fresh water are hypertonic to their environment. Many freshwater protists, including *Paramecium*, address this problem by means of specialized **contractile vacuoles** that excrete the excess water the organisms constantly take in by osmosis. The excess water collects in the contractile vacuoles, which then contract and expel the water from the cell.

Paramecium and many other protists engulf solid food by endocytosis, forming a **digestive vacuole** within which the food is digested. Smaller vesicles containing digested food pinch away from the digestive vacuole and enter the cytoplasm. These tiny vesicles provide a large surface area across which the products of digestion can be absorbed by the rest of the cell.

FIGURE 20.6 Anatomy of a *Paramecium* A *Paramecium*, with its many specialized organelles, exemplifies the complex body form of ciliates.

2 μm

2 μm

Excavates began to diversify about 1.5 billion years ago

The **excavates** include a number of diverse groups that began to split from one another soon after the origin of eukaryotes. Several groups of excavates lack mitochondria, an absence that once led to the view that these groups might represent early-diverging eukaryotes that diversified before the evolution of mitochondria. However, the discovery of nuclear genes normally associated with mitochondria in these organisms suggests that the absence of mitochondria is a derived condition. In other words, ancestors of these excavate groups probably possessed mitochondria that were lost or reduced over the course of evolution. The existence of these organisms today shows that eukaryotic life is possible without mitochondria.

DIPLOMONADS AND PARABASALIDS The **diplomonads** and **parabasalids** are unicellular and lack mitochondria. *Giardia lamblia*, a diplomonad, is a familiar parasite that contaminates water supplies and causes the intestinal disease giardiasis. This tiny organism contains two nuclei bounded by nuclear envelopes, and it has a cytoskeleton and multiple flagella (FIGURE 20.7A).

In addition to flagella and a cytoskeleton, the parabasalids have undulating membranes that also contribute to the cell's locomotion. *Trichomonas vaginalis* (FIGURE 20.7B) is a parabasalid responsible for a sexually transmitted disease in humans. Infection of the male urethra, where it may occur without symptoms, is less common than infection of the vagina.

HETEROLOBOSEANS The amoeboid body form appears in several protist groups that are only distantly related to one

FIGURE 20.7 Some Excavate Groups Lack Mitochondria (A) *Giardia*, a diplomonad, has flagella and two nuclei. (B) *Trichomonas*, a parabasalid, has flagella and undulating membranes. Neither of these organisms possesses mitochondria.

FRONTIERS *Giardia* infections usually result from drinking contaminated water. In the United States, these infections are most common in hikers and campers using spring or stream water in recreational areas. Recent research shows that *Giardia* can switch surface proteins to avoid detection by the host immune system, which explains why the human body has a difficult time clearing *Giardia* infections without drug treatment.

another. The body forms of **heteroloboseans**, for example, resemble those of loboseans, an amoebozoan group that is not at all closely related to heteroloboseans (see p. 399). Amoebas of the free-living heterolobosean genus *Naegleria*, some of which can enter the human body and cause a fatal disease of the nervous system, usually have a two-stage life cycle, in which one stage has amoeboid cells and the other flagellated cells.

EUGLENIDS AND KINETOPLASTIDS The **euglenids** and **kinetoplastids** together constitute a clade of unicellular excavates with flagella. Their mitochondria contain distinctive, disc-shaped cristae, and their flagella contain a crystalline rod not found in other organisms. They reproduce primarily asexually by binary fission.

The flagella of euglenids arise from a pocket at the anterior end of the cell. Spiraling strips of proteins under the plasma membrane control the cell's shape. Some euglenids are photosynthetic.

FIGURE 20.8 depicts a cell of the genus *Euglena*. Like most other euglenids, this common freshwater organism has a

FIGURE 20.8 A Photosynthetic Euglenid In the *Euglena* species illustrated in this drawing, the second flagellum is rudimentary. Note that the primary flagellum originates at the anterior of the organism and trails toward its posterior.

TABLE 20.1 A Comparison of Three Kinetoplastid Trypanosomes

	<i>TRYPANOSOMA BRUCEI</i>	<i>TRYPANOSOMA CRUZI</i>	<i>LEISHMANIA MAJOR</i>
Human disease	Sleeping sickness	Chagas' disease	Leishmaniasis
Insect vector	Tsetse fly	Assassin bug	Sand fly
Vaccine or effective cure	None	None	None
Strategy for survival	Changes surface recognition molecules frequently	Causes changes in surface recognition molecules on host cell	Reduces effectiveness of macrophage hosts
Site in human body	Bloodstream; attacks nerve tissue in final stages	Enters cells, especially muscle cells	Enters cells, primarily macrophages
Approximate number of deaths per year	50,000	43,000	60,000

complex cell structure. It propels itself through the water with the longer of its two flagella, which may also serve as an anchor to hold the organism in place. The second flagellum is often rudimentary.

The euglenids have diverse nutritional requirements. Many species are always heterotrophic. Other species are fully autotrophic in sunlight, using chloroplasts to synthesize organic compounds through photosynthesis. When kept in the dark, these euglenids lose their photosynthetic pigment and begin to feed exclusively on dissolved organic material in the water around them. Such a “bleached” *Euglena* resynthesizes its photosynthetic pigment when it is returned to the light and becomes autotrophic again. But *Euglena* cells treated with certain antibiotics or mutagens lose their photosynthetic pigment completely; neither they nor their descendants are ever autotrophs again. However, those descendants function well as heterotrophs.

The kinetoplastids are unicellular parasites with two flagella and a single, large mitochondrion. That mitochondrion contains a *kinetoplast*, a unique structure housing multiple circular DNA molecules and associated proteins. Some of these DNA molecules encode “guide proteins” that edit mRNA within the mitochondrion.

The kinetoplastids include several medically important species of pathogenic *trypanosomes* (TABLE 20.1). Some of these organisms are able to change their cell surface recognition molecules frequently, allowing them to evade our best attempts to kill them and thus eradicate the diseases they cause.

LINK The role of a pathogen’s cell surface recognition molecules in the mammalian immune response is covered in Chapter 31

Stramenopiles typically have two unequal flagella, one with hairs

A morphological synapomorphy of most **stramenopiles** is the possession of rows of tubular hairs on the longer of their two flagella. Some stramenopiles lack flagella, but they are descended from ancestors that possessed flagella. The stramenopiles include the diatoms and the brown algae, which are photosynthetic, and the oomycetes, which are not.

DIATOMS All of the **diatoms** are unicellular, although some species associate in filaments. Many have sufficient carotenoids in their chloroplasts to give them a yellow or brownish color. All of them synthesize carbohydrates and oils as photosynthetic storage products. Diatoms lack flagella except in male gametes.

Architectural magnificence on a microscopic scale is the hallmark of the diatoms. Almost all diatoms deposit silica (hydrated silicon dioxide) in their cell walls. The cell wall of a diatom is constructed in two pieces, with the top overlapping the bottom like the top of a petri dish. The silica-impregnated walls have intricate patterns unique to each species (FIGURE 20.9). Despite their remarkable morphological diversity, all diatoms are symmetrical—either bilaterally (with “right” and

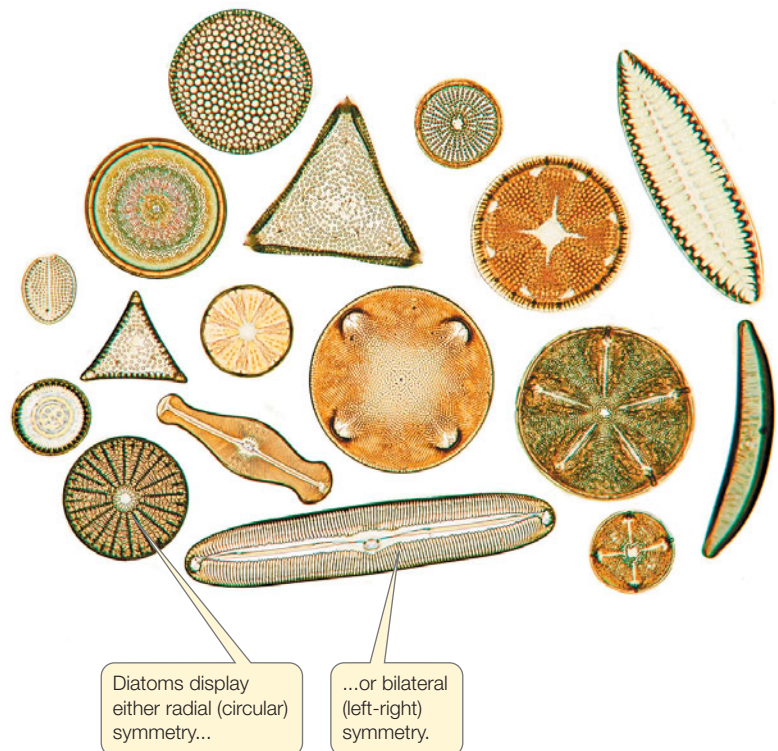

FIGURE 20.9 Diatom Diversity This bright-field micrograph illustrates the variety of species-specific forms found among the diatoms.

(A) *Himanthalia elongata*(B) *Postelsia palmaeformis*

FIGURE 20.10 Brown Algae (A) This seaweed illustrates the filamentous growth form of the brown algae. (B) Sea palms exemplify the leaflike growth form of brown algae. Sea palms and many other brown algal species are “glued” to the rocks by tough, branched structures called holdfasts that can withstand the pounding of the surf.

“left” halves) or radially (with the type of symmetry possessed by a circle).

Diatoms reproduce both sexually and asexually. Asexual reproduction by binary fission is somewhat constrained by the stiff cell wall. Both the top and bottom of the “petri dish” become tops of new “dishes” without changing appreciably in size; as a result, the new cell made from the former bottom is smaller than the parent cell. If this process continued indefinitely, one cell line would simply vanish, but sexual reproduction largely solves this potential problem. Gametes are formed, shed their cell walls, and fuse. The resulting zygote then grows substantially in size before a new cell wall is laid down.

Diatoms are found in all the oceans and are frequently present in great numbers. They are major photosynthetic producers in coastal waters and are among the dominant organisms in the dense “blooms” of phytoplankton that occasionally appear in the open ocean (see Concept 20.4). Diatoms are also common in fresh water and even occur on the wet surfaces of terrestrial mosses.

BROWN ALGAE The **brown algae** obtain their namesake color from the carotenoid *fucoxanthin*, which is abundant in their chloroplasts. The combination of this yellow-orange pigment with the green of chlorophylls *a* and *c* yields a brownish tinge. All brown algae are multicellular, and some are extremely large. Giant kelps, such as those of the genus *Macrocystis*, may be up to 60 meters long.

The brown algae are almost exclusively marine. They are composed either of branched filaments (FIGURE 20.10A) or of leaflike growths (FIGURE 20.10B). Some float in the open ocean; the most famous example is the genus *Sargassum*, which

forms dense mats in the Sargasso Sea in the mid-Atlantic. Most brown algae, however, attach themselves to rocks near the shore. A few thrive only where they are regularly exposed to heavy surf. All of the attached forms develop a specialized structure, called a *holdfast*, that literally glues them to the rocks. The “glue” of the holdfast is *alginic acid*, a gummy polymer of sugar acids found in the walls of many brown algal cells. In addition to its function in holdfasts, it cements algal cells and filaments together. It is harvested and used by humans as an emulsifier in ice cream, cosmetics, and other products.

OOMYCETES The **oomycetes** consist in large part of the water molds and their terrestrial relatives, such as the downy mildews. Water molds are filamentous and stationary. They are *absorptive heterotrophs*—that is, they secrete enzymes that digest large food molecules into smaller molecules that they can absorb. If you have seen a whitish, cottony mold growing on dead fish or dead insects in water, it was probably a water mold of the common genus *Saprolegnia* (FIGURE 20.11).

Oomycetes were once classified as fungi. However, we now know that their similarity to fungi is only superficial, and that the oomycetes are more distantly related to the fungi than are many other eukaryote groups, including humans (see Figure 20.3). For example, the cell walls of oomycetes are typically made of cellulose, whereas those of fungi are made of chitin.

The water molds, such as *Saprolegnia*, are all aquatic and **saprobic**—meaning they feed on dead organic matter. Some other oomycetes are terrestrial. Although most of the terrestrial oomycetes are harmless or helpful decomposers of dead

Saprolegnia sp.

FIGURE 20.11 An Oomycete The filaments of a water mold radiate from the carcass of an insect.

Elphidium crispum

FIGURE 20.12 Building Blocks of Limestone Some foraminiferans secrete calcium carbonate to form shells. The shells of different species have distinctive shapes. Over millions of years, the shells of foraminiferans have accumulated to form limestone deposits.

matter, a few are plant parasites that attack crops such as avocados, grapes, and potatoes.

Rhizaria typically have long, thin pseudopods

The three primary groups of **Rhizaria**—cercozoans, foraminiferans, and radiolarians—are unicellular and mostly aquatic. These organisms typically have long, thin pseudopods that contrast with the broader, lobelike pseudopods of the more familiar amoebozoans. The rhizaria have contributed to ocean sediments, some of which have become terrestrial features in the course of geological history.

CERCOZOANS The **cercozoans** are a diverse group with many forms and habitats. Some are aquatic; others live in soil. One group of cercozoans possesses chloroplasts derived from a green alga by secondary endosymbiosis—and that chloroplast contains a trace of the alga’s nucleus.

FORAMINIFERANS Some **foraminiferans** secrete external shells of calcium carbonate (**FIGURE 20.12**). These shells have accumulated over time to produce much of the world’s limestone. Some foraminiferans live as plankton; others live on the seafloor. Living foraminiferans have been found at the deepest point in the world’s oceans—10,896 meters down in the Challenger Deep in the western Pacific. At that depth, however, they cannot secrete normal shells because the surrounding water is too poor in calcium carbonate.

In living planktonic foraminiferans, long, threadlike, branched pseudopods extend through numerous microscopic apertures in the shell and interconnect to create a sticky, reticulated net, which the foraminiferans use to catch smaller plankton. In some foraminiferan species, the pseudopods provide locomotion.

RADIOLARIANS The **radiolarians** are recognizable by their thin, stiff pseudopods, which are reinforced by microtubules (**FIGURE 20.13A**). These pseudopods greatly increase the surface area of the cell, and they help the cell stay afloat in its marine environment.

Radiolarians are immediately recognizable by their distinctive radial symmetry. Almost all radiolarian species secrete glassy *endoskeletons* (internal skeletons). The skeletons of the different species are as varied as snowflakes, and many have elaborate geometric designs (**FIGURE 20.13B**). A few radiolarians are among the largest of the unicellular eukaryotes, measuring several millimeters across.

Amoebozoans use lobe-shaped pseudopods for locomotion

Amoebozoans appear to have diverged from other eukaryotes about 1.5 billion years ago (see Figure 20.3). It is not yet clear if they are more closely related to opisthokonts (including fungi and animals) or to other major groups of eukaryotes.

The lobe-shaped pseudopods of amoebozoans (**FIGURE 20.14**) are a hallmark of the amoeboid body form. Amoebozoan pseudopods differ in form and function from the slender

pseudopods of rhizaria. We consider three amoebozoan groups here: the loboseans and two groups known as slime molds.

LOBOSEANS **Loboseans** are small amoebozoans that feed on other small organisms and particles of organic matter by phagocytosis, engulfing them with pseudopods. Many loboseans are adapted for life on the bottoms of lakes, ponds, and other bodies of water. Their creeping locomotion and their manner of engulfing food particles fit them for life close to a

Nebela collaris

FIGURE 20.15 Life in a Glass House This testate amoeba has built a lightbulb-shaped shell, or test, by gluing sand grains together. Its pseudopods extend through the single aperture in the test.

relatively rich supply of sedentary organisms or organic particles. Most loboseans exist as predators, parasites, or scavengers. Members of one group of loboseans, the testate amoebas, live inside shells. Some of these amoebas produce casings by gluing sand grains together (**FIGURE 20.15**); other testate amoebas have shells secreted by the organism itself.

PLASMODIAL SLIME MOLDS If the nucleus of an amoeba began rapid mitotic division, accompanied by a tremendous increase in cytoplasm and organelles but no cytokinesis, the resulting organism would resemble the multinucleate mass of a **plasmoidal slime mold**. During its vegetative (feeding, nonreproductive) stage, a plasmoidal slime mold is a wall-less mass of cytoplasm with numerous diploid nuclei. This mass streams very slowly over its substrate in a remarkable network of strands called a *plasmodium* (**FIGURE 20.16A**). The plasmodium of such a slime mold is an example of a **coenocyte**: many nuclei enclosed in a

FIGURE 20.16 Plasmoidal Slime Molds (A) The plasmodial form of the slime mold *Hemitrichia serpula* covers rocks, decaying logs, and other objects as it engulfs bacteria and other food items; it is also responsible for its common name of “pretzel mold.” (B) Fruiting structures of *Hemitrichia*.

single plasma membrane. The outer cytoplasm of the plasmodium (closest to the environment) is normally less fluid than the interior cytoplasm and thus provides some structural rigidity.

Plasmodial slime molds provide a dramatic example of movement by cytoplasmic streaming. The outer cytoplasmic region of the plasmodium becomes more fluid in places, and cytoplasm rushes into those areas, stretching the plasmodium. This streaming somehow reverses its direction every few minutes as cytoplasm rushes into a new area and drains away from an older one, moving the plasmodium over its substrate. Sometimes an entire wave of plasmodium moves across a surface, leaving strands behind. Microfilaments and a contractile protein called *myxomyosin* interact to produce the streaming movement. As it moves, the plasmodium engulfs food particles by endocytosis—predominantly bacteria, yeasts, spores of fungi, and other small organisms as well as decaying animal and plant remains.

A plasmodial slime mold can grow almost indefinitely in its plasmodial stage as long as the food supply is adequate and other conditions, such as moisture and pH, are favorable. If conditions become unfavorable, however, one of two things can happen. First, the plasmodium can form an irregular mass of hardened cell-like components called a *sclerotium*. This resting structure rapidly becomes a plasmodium again when favorable conditions are restored.

Alternatively, the plasmodium can transform itself into spore-bearing *fruiting structures* (FIGURE 20.16B). These stalked or branched structures rise from heaped masses of plasmodium. They derive their rigidity from walls that form and thicken between their nuclei. The diploid nuclei of the plasmodium divide by meiosis as the fruiting structure develops. One or more knobs, called *sporangia*, develop on the end of the stalk. Within a sporangium, haploid nuclei become surrounded by walls to form *spores*. Eventually, as the fruiting structure dries, it sheds its spores.

The spores germinate into wall-less, haploid cells called *swarm cells*, which can either divide mitotically to produce more haploid swarm cells or function as gametes. Swarm cells can live as separate individual cells that move by means of flagella or pseudopods, or they can become walled and resistant *resting cysts* when conditions are unfavorable; when conditions improve again, the cysts release swarm cells. Two swarm cells can also fuse to form a diploid zygote, which divides by mitosis (but without a wall forming between the nuclei) and thus forms a new, coenocytic plasmodium.

CELLULAR SLIME MOLDS Whereas the plasmodium is the basic vegetative unit of the plasmodial slime molds, an amoeboid cell is the vegetative unit of the **cellular slime molds** (FIGURE 20.17). Large numbers of cells called *myxamoebas*, which have

Dictyostelium discoideum

FIGURE 20.17 A Cellular Slime Mold This composite micrograph shows the life cycle of the slime mold *Dictyostelium*.

0.25 mm

single haploid nuclei, engulf bacteria and other food particles by endocytosis and reproduce by mitosis and fission. This simple life cycle stage, consisting of swarms of independent, isolated cells, can persist indefinitely as long as food and moisture are available.

When conditions become unfavorable, the cellular slime molds aggregate and form fruiting structures, as do their plasmodial counterparts. The individual myxamoebas aggregate into a mass called a *slug* or *pseudoplasmodium*. Unlike the true plasmodium of the plasmodial slime molds, however, this structure is not simply a giant sheet of cytoplasm with many nuclei; the individual myxamoebas retain their plasma membranes and, therefore, their identity.

A slug may migrate over a substrate for several hours before becoming motionless and reorganizing to construct a delicate, stalked fruiting structure. Cells at the top of the fruiting structure develop into thick-walled spores, which are eventually released. Later, under favorable conditions, the spores germinate, releasing myxamoebas.

The cycle from myxamoebas through slug and spores to new myxamoebas is asexual. Cellular slime molds also have a sexual cycle, in which two myxamoebas fuse. The product of this fusion develops into a spherical structure that ultimately germinates, releasing new haploid myxamoebas.

Do You Understand Concept 20.2?

- Explain why the term “protists” does not refer to a formal taxonomic group.
- Contrast the major distinctive features of alveolates, excavates, stramenopiles, rhizaria, and amoebozoans. Which of these groups is most closely related to fungi and animals? What morphological evidence supports this relationship?
- The fossil record of eukaryotes in the Precambrian is poor compared with those of the Cambrian and later geological periods, even though eukaryotes were diversifying for the last billion years of the Precambrian. Can you think of some possible reasons for the better fossil record beginning in the Cambrian?

The ancient origins of major eukaryote lineages, and the adaptation of these lineages to a wide variety of lifestyles and environments, resulted in enormous protist diversity. It is not surprising, then, that reproductive modes among protists are also highly diverse.

concept 20.3 Protists Reproduce Sexually and Asexually

Although most protists engage in both asexual and sexual reproduction, sexual reproduction has yet to be observed in some groups. In some protists, as in all prokaryotes, the acts of sex and reproduction are not directly linked.

Several asexual reproductive processes have been observed among the protists:

- *Binary fission* is the equal splitting of one cell into two by mitosis followed by cytokinesis.
- *Multiple fission* is the splitting of one cell into multiple (i.e., more than two) cells.
- *Budding* refers to the outgrowth of a new cell from the surface of an old one.
- *Sporulation* is the formation of specialized cells (spores) that are capable of developing into new individuals.

Asexual reproduction results in offspring that are genetically nearly identical to their parents (they only differ by new mutations that may arise during DNA replication). Such asexually reproduced groups of nearly identical organisms are known as **clonal lineages**.

Sexual reproduction among the protists takes various forms. In some protists, as in animals, the gametes are the only haploid cells. In others, the zygote is the only diploid cell. In still others, both diploid and haploid cells undergo mitosis, giving rise to alternating multicellular diploid and haploid life stages.

Some protists have reproduction without sex and sex without reproduction

Members of the genus *Paramecium* are ciliates, which as we noted in Concept 20.2 are characterized by the possession of two types of nuclei in a single cell: commonly one *macronucleus* and from one to several *micronuclei*. The micronuclei, which are typical eukaryotic nuclei, are essential for genetic recombination. Each macronucleus contains many copies of the genetic information, packaged in units containing very few genes each. The macronuclear DNA is transcribed and translated to regulate the life of the cell.

When paramecia reproduce asexually, all of the nuclei are copied before the cell divides. Paramecia also have an elaborate sexual behavior called **conjugation**, in which two individuals line up tightly against each other and fuse in the oral groove region of the body. Nuclear material is extensively reorganized and exchanged over the next several hours (**FIGURE 20.18**). Each cell ends up with two haploid micronuclei, one of its own and one from the other cell, which fuse to form a new diploid micronucleus. A new macronucleus develops from the micronucleus through a series of dramatic chromosomal rearrangements. The exchange of nuclei is fully reciprocal: each of the two paramecia gives and receives an equal amount of DNA. The two organisms then separate and go their own ways, each equipped with new combinations of alleles.

Conjugation in *Paramecium* is a *sexual* process of genetic recombination, but it is not a *reproductive* process. Two cells begin the process, and two cells are there at the end, so no new cells are created. As a rule, each asexual clone of paramecia must periodically conjugate. Experiments have shown that if some species are not permitted to conjugate, the clones can live through no more than approximately 350 cell divisions before they die out.

FIGURE 20.18 Paramecia Achieve Genetic Recombination by Conjugating The exchange of micronuclei by two conjugating *Paramecium* individuals results in genetic recombination. After conjugation, the cells separate and continue their lives as two individuals.

Some protist life cycles feature alternation of generations

Alternation of generations is a type of life cycle found in many multicellular protists, all land plants, and some fungi. A multicellular, diploid, spore-producing organism gives rise to a multicellular, haploid, gamete-producing organism. When two haploid gametes fuse, a diploid organism is produced. The haploid organism, the diploid organism, or both may also reproduce asexually.

The two alternating (spore-producing and gamete-producing) generations differ genetically (one has diploid cells, the other haploid cells), but they may or may not differ morphologically. In **heteromorphic** alternation of generations, the two generations differ morphologically; in **isomorphic** alternation of generations, they do not. Examples of both heteromorphic and isomorphic alternation of generations are found among the brown algae.

The gamete-producing generation does not produce gametes by meiosis because the gamete-producing organism is already haploid. Instead, specialized cells of the diploid spore-producing organism, called **sporocytes**, divide meiotically to produce four haploid *spores*. The spores may eventually germinate and divide mitotically to produce the multicellular haploid generation, which then produces gametes by mitosis and cytokinesis.

Gametes, unlike spores, can produce new organisms only by fusing with other gametes. The fusion of two gametes produces a diploid zygote, which then undergoes mitotic divisions to produce a diploid organism. The diploid organism's sporocytes then undergo meiosis and produce haploid spores, starting the cycle anew.

Do You Understand Concept 20.3?

- Why is conjugation between paramecia considered a sexual process but not a reproductive process?
- Why do you think paramecia that are not allowed to conjugate begin to die out after about 350 rounds of asexual reproduction?
- Although most diploid animals have haploid stages (for example, eggs and sperm), their life cycles are not considered alternation of generations. Why not?

concept 20.4 Protists Are Critical Components of Many Ecosystems

Some protists are food for marine animals, while others poison those animals. Some are packaged as nutritional supplements for humans, and some are human pathogens. The remains of some form the sands of many modern beaches, and others are a major source of the oil that sometimes fouls those beaches.

Phytoplankton are primary producers

A single protist clade, the diatoms, performs about one-fifth of all photosynthetic carbon fixation on Earth—about the same amount as all of Earth's rainforests. These spectacular unicellular organisms (see Figure 20.9) are the predominant component of the phytoplankton, but the phytoplankton includes many other protists that contribute heavily to global photosynthesis. Like green plants on land, these "floating photosynthesizers" are the gateway for energy from the sun into the rest of the living world; in other words, they are *primary producers* that are eaten by heterotrophs, including animals and many other protists. Those consumers are, in turn, eaten by other consumers. Most aquatic heterotrophs (with the exception of some species in the deep sea) depend on photosynthesis performed by phytoplankton.

Some microbial eukaryotes are deadly

Some microbial eukaryotes are pathogens that cause serious diseases in humans and other vertebrates. The best-known pathogenic protists are members of the genus *Plasmodium*, a highly specialized group of apicomplexans that spend part of their life cycle as parasites in human red blood cells, where they are the cause of malaria. In terms of the number of people affected, malaria is one of the world's three most serious infectious diseases: it infects over 350 million people, and kills over 1 million people, each year. On average, about two people die from malaria every minute of every day—most of them in sub-Saharan Africa, although malaria occurs in more than 100 countries.

Mosquitoes of the genus *Anopheles* transmit *Plasmodium* to humans. The parasites enter the human circulatory system when an infected female *Anopheles* mosquito penetrates the skin in search of blood. The parasites find their way to cells in the liver and the lymphatic system, change their form, multiply, and re-enter the bloodstream, where they invade red blood cells.

The parasites multiply inside the red blood cells, which then burst, releasing new swarms of parasites. These episodes of bursting red blood cells coincide with the primary symptoms of malaria, which include fever, shivering, vomiting, joint pains, and convulsions. If another *Anopheles* bites the victim, the mosquito takes in *Plasmodium* cells along with blood. Some of the ingested cells develop into gametes that unite in the mosquito, forming zygotes. The zygotes lodge in the mosquito's gut, divide several times, and move into its salivary glands, from which they can be passed on to another human host. Thus

Plasmodium is an extracellular parasite in the mosquito vector and an intracellular parasite in the human host.

yourBioPortal.com

Go to ANIMATED TUTORIAL 20.3
Life Cycle of the Malarial Parasite

Plasmodium has proved to be a singularly difficult pathogen to attack. The complex *Plasmodium* life cycle is best broken by the removal of stagnant water, in which mosquitoes breed. Using insecticides to reduce the *Anopheles* population can also be effective, but the benefits must be weighed against the ecological, economic, and health risks posed by the insecticides themselves.

Even some of the phytoplankton that are such important primary producers can be deadly, as described in this chapter's opening story. Some diatoms and dinoflagellates reproduce in enormous numbers when environmental conditions are favorable for their growth. In the resulting "red tides," the concentration of dinoflagellates may reach 60 million per liter of ocean water and produce potent nerve toxins that harm or kill many vertebrates, especially fish.

Some microbial eukaryotes are endosymbionts

Endosymbiosis is common among the microbial eukaryotes, many of which live within the cells of animals. Many radiolarians harbor photosynthetic endosymbionts (see Figure 20.13A). As a result, these radiolarians, which are not photosynthetic themselves, appear greenish or golden, depending on the type of endosymbiont they contain. This arrangement is often

APPLY THE CONCEPT

Protists are critical components of many ecosystems

In most temperate regions of the oceans, there is a spring bloom of phytoplankton. Although the red tide blooms described in this chapter's opening story are harmful, phytoplankton blooms can also be beneficial for marine communities. In fact, many species of marine life depend on these blooms for their survival.

The dates of spring phytoplankton blooms near the coast of Nova Scotia, Canada, were determined by examining remote satellite images. The table at right presents these dates as deviations from the mean date of the spring bloom in this region. The table also gives the survival index for larval haddock (an important commercial fish) for the year after each bloom. The survival index is the ratio of the mass of juvenile fish to the mass of mature fish; higher values indicate better survival of larval fish.

1. Plot the survival index of larval haddock against the deviation in the date of the spring phytoplankton bloom. Calculate a correlation coefficient for their relationship (see Appendix B).

YEAR	DEVIATION IN BLOOM DATE* (DAYS)	SURVIVAL INDEX
1	+5	1.9
2	+11	2.2
3	-15	6.8
4	+5	1.9
5	-4	4.9
6	-20	10.3
7	+6	2.1
8	+14	1.9

*Negative values indicate blooms occurring earlier than the mean date; positive values indicate later blooms.

2. Formulate one or more hypotheses to explain your results. Keep in mind that larval haddock include phytoplankton in their diet, and that phytoplankton blooms also provide some cover in which larval fish can hide from potential predators.

mutually beneficial: the radiolarian can make use of the carbon compounds produced by its photosynthetic guest, and the guest may in turn make use of metabolites made by the host or receive physical protection. In some cases, the guest is exploited for its photosynthetic products while receiving little or no benefit itself.

Dinoflagellates are also common endosymbionts and can be found in both animals and other protists. Most, but not all, dinoflagellate endosymbionts are photosynthetic. Some

dinoflagellates live endosymbiotically in the cells of corals, contributing the products of their photosynthesis to the partnership. Their importance to the corals is demonstrated when the dinoflagellates die or are expelled by the corals as a result of changing environmental conditions such as rising water temperatures or increased water turbidity. This phenomenon is known as *coral bleaching*. Unless the corals can acquire new endosymbionts, they are ultimately damaged or destroyed as a result of their reduced food supply (FIGURE 20.19).

INVESTIGATION

FIGURE 20.19 Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching? Some corals lose their chief nutritional source when their photosynthetic endosymbionts die, often as a

result of changing environmental conditions. This experiment by Cynthia Lewis and Mary Alice Coffroth investigated the ability of corals to acquire new endosymbionts after bleaching.

HYPOTHESIS

Bleached corals can acquire new photosynthetic endosymbionts from their environment.

METHOD

1. Count numbers of *Symbiodinium*, a photosynthetic dinoflagellate, living symbiotically in samples of a coral (*Briareum* sp.).
2. Stimulate bleaching by maintaining all *Briareum* colonies in darkness for 12 weeks.
3. After 12 weeks of darkness, count numbers of *Symbiodinium* in the coral samples; then return all colonies to light.
4. In some of the bleached colonies (the experimental group), introduce *Symbiodinium* strain B211—dinoflagellates that contain a unique molecular marker. A control group of bleached colonies is not exposed to strain B211. Maintain both groups in the light for 6 weeks.

RESULTS

CONCLUSION

Corals can acquire new strains of endosymbionts from their environment following bleaching.

ANALYZE THE DATA

These data—the results of DNA analysis of the *Symbiodinium* endosymbionts—reveal that many of the experimental colonies took up strain B211 from their environment. The control colonies recovered their native *Symbiodinium*, except in colonies in which endosymbionts were completely lost. Use these data to answer the questions below.

	<i>Symbiodinium</i> strain present (% of colonies)			
	Non-B211	B211	None*	Colony died
Experimental colonies (strain B211 added)				
Pre-bleach	100	0	0	0
Post-bleach	58	0	42	0
Week 3	0	92	0	8
Week 6	8	58	8	25
Control colonies (no strain B211)				
Pre-bleach	100	0	0	0
Post-bleach	67	0	33	0
Week 3	67	0	33	0
Week 6	67	0	17	17

*Colonies remained alive but no *Symbiodinium* were detected.

- Are new strains of *Symbiodinium* taken up only by coral colonies that have lost all their original endosymbionts?
- Does the acquisition of a new *Symbiodinium* strain always result in survival of a recovering *Briareum* colony?
- In week 3, only strain B211 was detected in the experimental colonies, but in week 6, non-B211 *Symbiodinium* were detected in 8% of the experimental colonies. Can you suggest an explanation for this observation?

Pre-bleach

Post-bleach

We rely on the remains of ancient marine protists

Diatoms are lovely to look at, but their importance to us goes far beyond aesthetics, and even beyond their role as primary producers. Diatoms store oil as an energy reserve and to keep themselves afloat at the correct depth in the ocean. Over millions of years, diatoms have died and sunk to the ocean floor, where they have undergone chemical changes. In this way, they have become a major source of petroleum and natural gas, two of our most important energy supplies and political concerns.

Because the silica-containing cell walls of dead diatoms resist decomposition, some sedimentary rocks are composed almost entirely of diatom skeletons that sank to the seafloor over time. Diatomaceous earth, which is obtained from such rocks, has many industrial uses, such as insulation, filtration, and metal polishing. It has also been used as an “Earth-friendly” insecticide that clogs the tracheae (breathing structures) of insects.

Other ancient marine protists have also contributed to today’s world. Some foraminiferans, as we have seen, secrete shells of calcium carbonate. After they reproduce (by mitosis and cytokinesis), the daughter cells abandon the parent shell and make new shells of their own. The discarded shells of ancient foraminiferans make up extensive limestone deposits in various parts of the world, forming a layer hundreds to thousands of meters deep over millions of square kilometers of ocean bottom. Foraminiferan shells also make up much of the sand of some beaches. A single gram of such sand may contain as many as 50,000 foraminiferan shells and shell fragments.

The shells of individual foraminiferans are easily preserved as fossils in marine sediments. Each geological period has a distinctive assemblage of foraminiferan species. Because the shells of foraminiferan species have distinctive shapes (see Figure 20.12), and because they are so abundant, the remains of foraminiferans are especially valuable in classifying and

dating sedimentary rocks. In addition, analyses of the chemical makeup of foraminiferan shells can be used to estimate the global temperatures prevalent at the time when the shells were formed.

Do You Understand Concept 20.4?

- What is the role of female *Anopheles* mosquitoes in the transmission of malaria?
- Explain the role of dinoflagellates in the two very different phenomena of coral bleaching and red tides.
- What are some of the ways in which diatoms are important to human society?

The next three chapters will explore the three major groups of multicellular eukaryotes, along with the protist ancestors from which they arose. Chapter 21 will describe the origin and diversification of the plants, Chapter 22 will present the fungi, and Chapter 23 will describe the animals.

Red tides are harmful, but can dinoflagellates also be beneficial to marine ecosystems?

ANSWER Not all dinoflagellate blooms produce problems for other species. Dinoflagellates are important components of many ecosystems, as we have seen throughout this chapter. Corals and many other species depend on symbiotic dinoflagellates for photosynthesis (see Figure 20.19). In addition, as photosynthetic organisms, free-living planktonic dinoflagellates are among the most important primary producers in aquatic food webs. They are a major component of the phytoplankton and provide an important food source for many species (see Concept 20.4). Photosynthetic dinoflagellates also produce much of the atmospheric oxygen that most animals need to survive.

Some dinoflagellates produce a beautiful bioluminescence (**FIGURE 20.20**). Unlike the bioluminescent bacteria discussed at the start of Chapter 19, however, dinoflagellate bioluminescence is not steady. These protists produce flashes of light when disturbed, as people who swim in the ocean at night in certain regions often observe.

FIGURE 20.20 Light Up the Sea
Bioluminescent dinoflagellates flash as an outrigger disturbs the ocean surface off the island of Bali.

SUMMARY

concept 20.1 Eukaryotes Acquired Features from Both Archaea and Bacteria

- Early events in the evolution of the eukaryotic cell probably included the loss of the firm cell wall and infolding of the plasma membrane. Such infolding probably led to segregation of the genetic material in a membrane-enclosed nucleus. **Review Figure 20.1**
- Some organelles were acquired by endosymbiosis. Mitochondria evolved by endosymbiosis with a proteobacterium.
- **Primary endosymbiosis** of a eukaryote and a cyanobacterium gave rise to the first chloroplasts. **Secondary endosymbiosis** and **tertiary endosymbiosis** between chloroplast-containing eukaryotes and other eukaryotes gave rise to the distinctive chloroplasts of euglenids, dinoflagellates, and other groups. **Review Figure 20.2 and ANIMATED TUTORIAL 20.1**

concept 20.2 Major Lineages of Eukaryotes Diversified in the Precambrian

- Most eukaryotes can be placed in one of eight major clades that originated in the Precambrian: alveolates, excavates, stramenopiles, rhizaria, amoebozoans, Plantae, fungi, and animals. The first five of these clades are collectively referred to as **protists**. **Review Figure 20.3**
- The term “protist” does not describe a formal taxonomic group, but is shorthand for “all eukaryotes that are not plants, animals, or fungi.” Most, but not all, protists are unicellular.
- **Alveolates** are unicellular organisms with sacs (alveoli) beneath their plasma membranes. Alveolate clades include the marine **dinoflagellates**, the parasitic **apicomplexans**, and the diverse, highly motile **ciliates**. **See WEB ACTIVITY 20.1 and ANIMATED TUTORIAL 20.2**
- The **excavates** include a wide variety of symbiotic as well as free-living species. The **diplomonads** and **parabasalids** lack mitochondria, having apparently lost them during the course of their evolution. **Heteroloboseans** are amoebas with a two-stage life cycle. **Euglenids** are often photosynthetic and have anterior flagella and spiraling strips of protein that support their cell surface. The **kinetoplastids**, which include several human pathogens, have a single, large mitochondrion.
- **Stramenopiles** typically have two flagella of unequal length, the longer one bearing rows of tubular hairs. Among the stramenopiles are the unicellular **diatoms**, the multicellular **brown algae**, and the nonphotosynthetic **oomycetes**, many of which are saprobic.

- **Rhizaria** are unicellular and aquatic. They include the **foraminiferans**, whose shells have contributed to great limestone deposits; the **radiolarians**, which have thin, stiff pseudopods and glassy endoskeletons; and the **cercozoans**, which take many forms and live in diverse habitats.
- The **amoebozoans** move by means of lobe-shaped pseudopods. A **lobosean** consists of a single amoeboid cell. **Plasmodial slime molds** are amoebozoans whose vegetative stage is a **coenocyte** that moves by cytoplasmic streaming. In **cellular slime molds**, the individual cells maintain their identity at all times but aggregate to form fruiting structures.

concept 20.3 Protists Reproduce Sexually and Asexually

- Asexual reproduction gives rise to **clonal lineages** of organisms.
- **Conjugation** in *Paramecium* is a sexual process but not a reproductive one. **Review Figure 20.18**
- **Alternation of generations**, which includes a multicellular diploid phase and a multicellular haploid phase, is a feature of many multicellular protist life cycles (as well as of some fungi and all land plants). The alternating generations may be **heteromorphic** or **isomorphic**.
- In alternation of generations, specialized cells of the diploid organism, called **sporocytes**, divide meiotically to produce haploid spores. Spores give rise to the multicellular, haploid, gamete-producing generation through mitosis. Gametes fuse and give rise to the diploid organism.

concept 20.4 Protists Are Critical Components of Many Ecosystems

- The diatoms are responsible for about one-fifth of the photosynthetic carbon fixation on Earth. They and other members of the phytoplankton are the primary producers in the marine environment.
- Endosymbiotic relationships are common among microbial protists and typically benefit both the endosymbionts and their protist or animal partners. **Review Figure 20.19**
- Some protists are pathogens of humans and other vertebrates. **See ANIMATED TUTORIAL 20.3**
- Ancient diatoms are the major source of today’s petroleum and natural gas deposits.

The Evolution of Plants

21

In the early 1860s, while the United States was entangled in its tragic civil war, much of middle- and upper-class England was caught up in an orchid frenzy. Amateur plant breeders and professional botanists alike were enchanted with raising the beautiful flowers. After *The Origin of Species* appeared in 1859, Charles Darwin wrote his next book on this group of plants, publishing *Fertilisation of Orchids* in 1862.

There are more than 25,000 species of orchids, which makes them one of the most diverse plant groups. Darwin wanted to know why orchids had experienced such rapid diversification and was particularly impressed with the role that insect pollinators might have played in this process. He wanted examples to demonstrate the power of natural selection; he found such examples in abundance among the orchids.

Orchids show an impressive variety of specialized pollination mechanisms, many of which demonstrate that they have coevolved with their pollinators. For example, Darwin observed a South American orchid of the genus *Catasetum* shooting a packet of pollen at an insect that landed on its flower. When he was shown *Angraecum sesquipedale*, an orchid from Madagascar with a nectar tube over a foot long, Darwin hypothesized that there must be a moth with a proboscis of unprecedented length that fed from and pollinated that flower. Many people scoffed at his vision, but the moth he described was eventually discovered—21 years after his death.

In 1836 the explorer Robert Schomburgk shook the botanical world with a report that he had seen flowers described

as belonging to three different genera of orchids—*Catasetum*, *Monachanthus*, and *Myanthus*—growing together on a single plant. The English botanist John Lindley remarked that this observation would “shake to the foundation all our ideas of the stability of genera and species.” Orchid enthusiasts were befuddled by their efforts to grow specimens of *Myanthus*, only to have them flower with the more common blooms of *Catasetum*. Darwin knew that he needed to find the explanation for these odd observations, for otherwise he would have to conclude that individual plants were able to change their specific identity, something that did not fit with his explanations of the evolution of diversity.

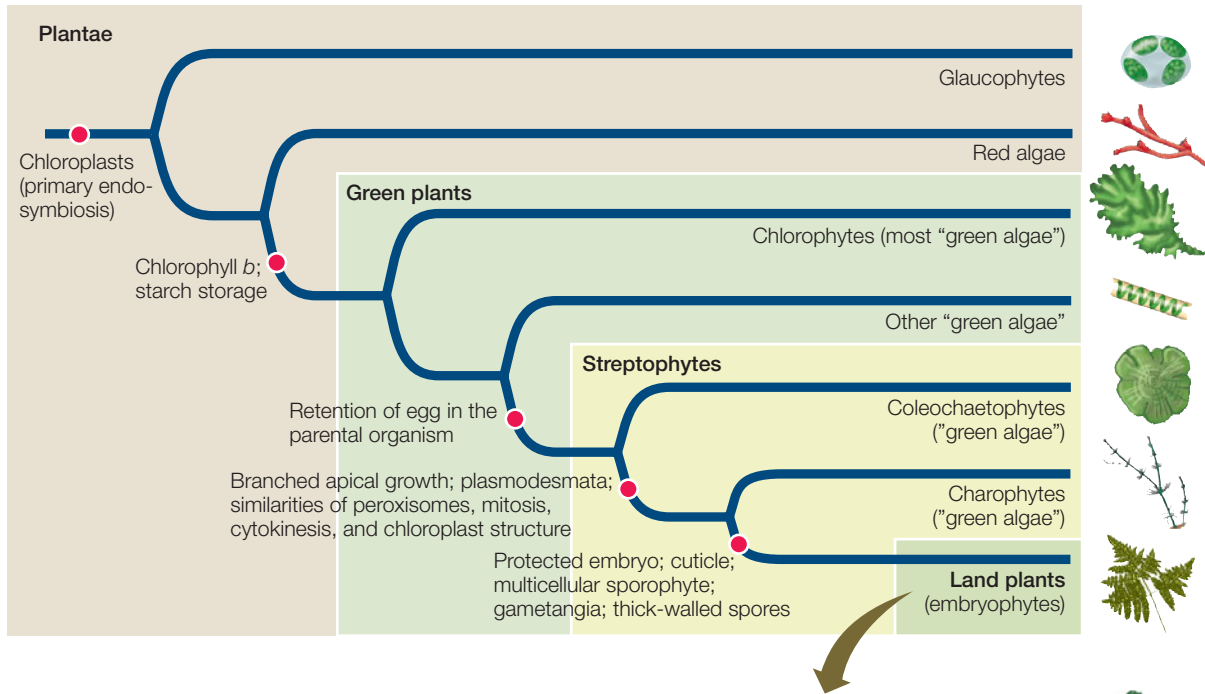

What was Darwin's explanation for the three distinct flowers growing on a single orchid plant?

On examining a specimen of the orchid *Angraecum sesquipedale*, Charles Darwin predicted the existence of a pollinator with an exceptionally long proboscis. This pollinator, the sphinx moth *Xanthopan morgani*, was not discovered until after Darwin's death.

concept 21.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes

Over a billion years ago, when a cyanobacterium was first engulfed by an early eukaryote, the history of life was altered radically. The chloroplasts that resulted from primary endosymbiosis of this cyanobacterium (see Figure 20.2) were obviously important for the evolution of plants and other photosynthetic eukaryotes, but they were also critical to the evolution of all life on land. Until photosynthetic plants were able to move onto land, there was very little on land to support multicellular animals or fungi, and almost all life was restricted to the oceans and fresh waters.

Primary endosymbiosis is a shared derived trait, or *synapomorphy*, of the group known as **Plantae** (FIGURE 21.1). Although *Plantae* is Latin for “plants,” throughout this book and in everyday language the unmodified common name “plants” is usually used to refer only to the land plants. The first several clades to branch off the tree of life after primary endosymbiosis, however, are all aquatic. Aquatic photosynthetic eukaryotes (other than those secondarily derived from land plants) are known by the common name **algae**. This name, however, is just a convenient way to refer to all such groups, which are not all closely related; in other words, the algae are polyphyletic.

Several distinct clades of algae were among the first photosynthetic eukaryotes

The ancestor of Plantae was unicellular and may have been similar in general form to the modern **glaucophytes**. These microscopic, freshwater algae are thought to be the sister group to the rest of Plantae (see Figure 21.1A). The chloroplast of glaucophytes is unique in containing a small amount of peptidoglycan between its inner and outer membranes—the same arrangement found in cyanobacteria. Peptidoglycan has been lost from the remaining photosynthetic eukaryotes.

In contrast to the glaucophytes, almost all **red algae** are multicellular (FIGURE 21.2). Their characteristic color is a result of the accessory photosynthetic pigment *phycoerythrin*, which is found in relatively large amounts in the chloroplasts of many red algae. In addition to phycoerythrin, red algal chloroplasts contain the accessory pigments phycocyanin, carotenoids, and chlorophyll *a*.

The red algae include species that grow in the shallowest tide pools as well as the photosynthesizers found deepest in the ocean (as deep as 260 meters if nutrient conditions are right

Nemalion helminthoides

FIGURE 21.2 A Red Alga The photosynthetic pigment phycoerythrin gives this red alga its rich hue, showing up vividly against a background of green algae.

and the water is clear enough to permit light to penetrate). A few red algae inhabit fresh water. Most grow attached to a substrate by a holdfast.

Despite their name, red algae don’t always appear red in color. The ratio of two pigments—phycoerythrin (red) and chlorophyll *a* (green)—depends largely on the intensity of light that reaches the alga. In deep water, where light is dim, algae accumulate large amounts of phycoerythrin and appear red. But many species growing near the surface contain a higher concentration of chlorophyll *a* and thus appear bright green.

The remaining algal groups in Plantae are the various “green algae.” Like land plants, the green algae contain both chlorophylls *a* and *b* and store their reserve of photosynthetic products as starch in chloroplasts. All the groups that share these features are commonly called **green plants** because of the strong green color of chlorophyll *b*.

Three important clades of green algae are the **chlorophytes**, **coleochaetophytes**, and **charophytes** (FIGURE 21.3). The latter two groups are most closely related to the land plants, and together with the land plants form a group known as **streptophytes**.

FRONTIERS Some human pathologies, such as polycystic kidney disease, are caused by defects in cilia (hence their name, *ciliopathies*). Recent genome analyses have revealed remarkable similarities between the human and green algal proteins involved in cilium assembly and function. The discovery of how little these proteins have changed throughout evolution suggested the use of green algae as experimental organisms for research on diseases that affect human cilia. The single-celled chlorophyte *Chlamydomonas* is now being used for that purpose.

◀ **FIGURE 21.1 The Evolution of Plants** In its broadest definition, the term “plant” includes the green plants, red algae, and glaucophytes—all the groups descended from a common ancestor with chloroplasts. Some biologists restrict the term “plant” to the green plants (those with chlorophyll *b*) or, even more narrowly, to the land plants. Three key characteristics that emerged during the evolution of land plants—protected embryos, vascular tissues, and seeds—led to their success in the terrestrial environment. (See Working with Data 21.1 at yourBioPortal.com.)

One of the key synapomorphies of the **land plants** is development from an embryo that is protected by tissues of the parent plant. For this reason, land plants are sometimes called

(A) *Ulva rigida*(B) *Coleochaete* sp.(C) *Chara* sp.

FIGURE 21.3 “Green Algae” Consist of Several Distantly Related Groups (A) Sea lettuce, a chlorophyte, grows in ocean tidewaters. (B) The coleochaetophytes are thought to be the sister group of charophytes plus land plants. (C) The land plants probably evolved from a common ancestor shared with charophytes such as this one, which displays the branching pattern we associate with land plants.

embryophytes (*phyton*, “plant”). The green plants, the streptophytes, and the land plants each have been called “the plant kingdom” by different authorities; others take an even broader view and include red algae and glaucophytes as “plants.” To avoid confusion in this chapter, we will use modifying terms (“land plants” or “green plants,” for example) to refer to the various clades of Plantae shown in Figure 21.1.

There are ten major groups of land plants

The land plants that exist today fall naturally into ten major clades (**TABLE 21.1**). Members of seven of those clades possess well-developed vascular systems that transport materials throughout the plant body. We call these seven groups, collectively, the **vascular plants**, or **tracheophytes**, because they all possess fluid-conducting cells called *tracheids*.

The remaining three clades (liverworts, hornworts, and mosses) lack tracheids. We refer to these three clades collectively as **nonvascular land plants**. Note, however, that *these three groups do not form a clade*. Some nonvascular land plants have conducting cells, but none have tracheids.

Do You Understand Concept 21.1?

- Explain the different possible uses of the term “plant.”
- What are some of the key differences between glaucophytes, red algae, and the various clades of green algae?
- What evidence supports the phylogenetic relationship between land plants and green algae? Why doesn’t the name “algae” designate a formal taxonomic group?

TABLE 21.1 Classification of Land Plants

GROUP	COMMON NAME	CHARACTERISTICS
Nonvascular Land plants		
Hepatophyta	Liverworts	No filamentous stage; gametophyte flat
Anthoceroophyta	Hornworts	Embedded archegonia; sporophyte grows basally (from the ground)
Bryophyta	Mosses	Filamentous stage; sporophyte grows apically (from the tip)
Vascular plants		
Lycopodiophyta	Lycophytes: Club mosses and allies	Microphylls in spirals; sporangia in leaf axils
Monilophyta	Horsetails, ferns	Megaphylls with a leaf gap (a space in the stem from which the leaf emerges)
SEED PLANTS		
Gymnosperms		
Cycadophyta	Cycads	Compound leaves; swimming sperm; seeds on modified leaves
Ginkgophyta	Ginkgo	Deciduous; fan-shaped leaves; swimming sperm
Gnetophyta	Gnetophytes	Vessels in vascular tissue; opposite, simple leaves
Coniferophyta	Conifers	Seeds in cones; needlelike or scalelike leaves
Angiosperms	Flowering plants	Endosperm; carpels; gametophytes much reduced; seeds within fruit

The green algal ancestors of the land plants lived at the margins of ponds or marshes, ringing them with a mat of dense green. It was from such a marginal habitat, which was sometimes wet and sometimes dry, that early plants made the transition onto land.

concept 21.2 Key Adaptations Permitted Plants to Colonize Land

How did the land plants arise? To address this question, we can compare land plants with their closest relatives among the green algae. The features that differ between the two groups include the adaptations that allowed the first land plants to survive in the terrestrial environment.

Two groups of green algae share many features with land plants

Several microscopic structural features, backed by clear-cut evidence from molecular studies, indicate that the coleochaetophytes and the charophytes are the closest relatives of the land plants. Both of these green algal groups retain their female gametes (eggs) within the parental organism, as do land plants. Of these two candidates, charophytes are thought to be the sister group of land plants. That conclusion is based on the following synapomorphies (as well as studies of DNA sequences):

- Plasmodesmata that join the cytoplasm of adjacent cells
- Growth that is branching and apical (from the tip)
- Similar peroxisome contents, mechanics of mitosis and cytokinesis, and chloroplast structure

Both coleochaetophytes and charophytes have some general features that are similar to those of some groups of land plants. The flattened growth form of coleochaetophytes, represented by the genus *Coleochaete* (see Figure 21.3B), is like the growth form of early land plants such as liverworts. But the charophytes, as represented by stoneworts of the genus *Chara* (see Figure 21.3C), exhibit the branching growth form found among most land plants.

Adaptations to life on land distinguish land plants from green algae

Land plants, or their immediate ancestors in those ancient green mats, first appeared in the terrestrial environment between 400 and 500 million years ago. How did they survive in an environment that differed so dramatically from the aquatic environment of their ancestors? While the water essential for life is everywhere in the aquatic environment, water is difficult to obtain and retain in the terrestrial environment.

No longer bathed in fluid, organisms on land faced potentially lethal desiccation (drying). Large terrestrial organisms had to develop ways to transport water to body parts distant from the source of the water. And whereas water provides aquatic organisms with support against gravity, a plant living

on land must either have some other support system or sprawl unsupported on the ground. A land plant must also use different mechanisms for dispersing its gametes and progeny than its aquatic relatives, which can simply release them into the water.

Survival on land was facilitated by the evolution among plants of numerous adaptations:

- The *cuticle*, a coating of waxy lipids that retards water loss
- *Stomata*, small closable openings in leaves and stems that are used to regulate gas exchange
- *Gametangia*, multicellular organs that enclose plant gametes and prevent them from drying out
- *Embryos*, young plants contained within a protective structure
- Certain *pigments* that afford protection against the mutagenic ultraviolet radiation that bathes the terrestrial environment
- Thick *spore walls* containing *sporopollenin*, a polymer that protects the spores from desiccation and resists decay
- A *mutually beneficial association with fungi* that promotes nutrient uptake from the soil

The **cuticle** may be the most important—and earliest—of these features. Composed of several unique waxy lipids that coat the leaves and stems of land plants, the cuticle has several functions, the most obvious and important of which is to keep water from evaporating from the plant body.

As ancient plants colonized the land, they not only adapted to the terrestrial environment—they modified it by contributing to the formation of soil. Acids secreted by plants help break down rock, and the organic compounds produced by the breakdown of dead plants contribute nutrients to the soil. Such effects are repeated today as plants grow in new areas.

Life cycles of land plants feature alternation of generations

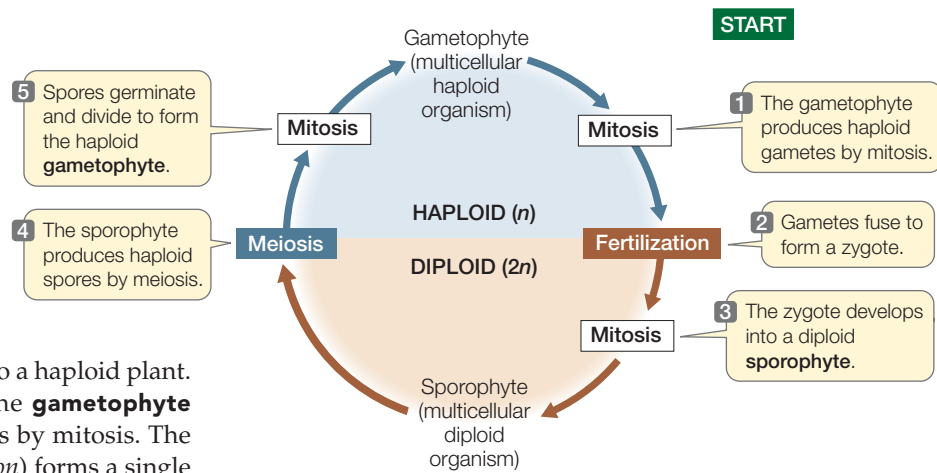

A universal feature of the life cycles of land plants is alternation of generations. Recall from Concept 20.3 the two hallmarks of alternation of generations:

- The life cycle includes both a multicellular diploid stage and a multicellular haploid stage.
- Gametes are produced by mitosis, not by meiosis. Meiosis produces *spores* that develop into multicellular haploid organisms.

If we begin looking at the land plant life cycle at the single-cell stage—the diploid zygote—then the first phase of the cycle is the formation, by mitosis and cytokinesis, of a multicellular embryo, which eventually grows into a mature diploid plant. This multicellular diploid plant is called the **sporophyte** (“spore plant”).

Cells contained within specialized reproductive organs of the sporophyte, called **sporangia** (singular *sporangium*), undergo meiosis to produce haploid, unicellular spores. By

FIGURE 21.4 Alternation of Generations in Land Plants A multicellular diploid sporophyte generation that produces spores by meiosis alternates with a multicellular haploid gametophyte generation that produces gametes by mitosis.

mitosis and cytokinesis, a spore develops into a haploid plant. This multicellular haploid plant, called the **gametophyte** (“gamete plant”), produces haploid gametes by mitosis. The fusion of two gametes (*syngamy*, or *fertilization*) forms a single diploid cell—the zygote—and the cycle is repeated (FIGURE 21.4).

The *sporophyte generation* extends from the zygote through the adult multicellular diploid plant and sporangium formation; the *gametophyte generation* extends from the spore through the adult multicellular haploid plant to the gametes. The transitions between the generations are accomplished by fertilization and by meiosis. In all land plants, the sporophyte and the gametophyte differ genetically: the sporophyte has diploid cells, and the gametophyte has haploid cells.

There is a trend toward reduction of the gametophyte generation in plant evolution. In the nonvascular land plants, the gametophyte is larger, longer-lived, and more self-sufficient than the sporophyte. In those groups that appeared later in plant evolution, however, the sporophyte generation is the larger, more conspicuous, longer-lived, and more self-sufficient one.

Nonvascular land plants live where water is readily available

The living species of nonvascular land plants are the liverworts, mosses, and hornworts. These three groups are thought to be similar in many ways to the earliest land plants. Most of these plants grow in dense mats, usually in moist habitats. Even the largest of these species are only about half a meter tall, and most are only a few centimeters tall or long. Why have they not evolved to be taller? The probable answer is that they lack an efficient vascular system for transporting water and minerals from the soil to distant parts of the plant body.

The nonvascular land plants lack the true leaves, stems, and roots that characterize the vascular plants, although they have structures analogous to each. Their growth form allows water to move through the mats of plants by capillary action. They have leaflike structures that readily catch and hold any water that splashes onto them. They are small enough that minerals can be distributed throughout their bodies by diffusion. As in all land plants, layers of maternal tissue protect their embryos from desiccation. Nonvascular land plants also have a cuticle, although it is often very thin (or even absent in some species) and thus is not highly effective in retarding water loss.

Most nonvascular land plants live on the soil or on vascular plants, but some grow on bare rock, on dead and fallen tree

trunks, and even on buildings. Their ability to grow on such marginal surfaces results from a mutualistic association with fungi. The earliest association of land plants with fungi dates back at least 460 million years. This mutualism probably facilitated the absorption of water and minerals, especially phosphorus, from the first soils.

LINK Land plants of many groups have mutualistic associations with fungi, as described in Concept 22.2

Nonvascular land plants are widely distributed over six continents and even exist (albeit very locally) on the coast of the seventh, Antarctica. Most are terrestrial. Although a few species live in fresh water, these aquatic species are descended from terrestrial ones. None live in the oceans.

LIVERWORTS There are about 9,000 species of **liverworts**. Most liverworts have green, leaflike gametophytes that lie close to or flat on the ground (FIGURE 21.5A). The simplest liverworts are flat plates of cells a centimeter or so long with structures that produce sperm or eggs on their upper surfaces and root-like filaments on their lower surfaces. The sporophyte remains attached to the larger gametophyte and rarely exceeds a few millimeters in length. Most liverworts can reproduce asexually (through simple division of the gametophyte) as well as sexually.

MOSSES The most familiar of the nonvascular land plants are the **mosses** (FIGURE 21.5B). These hardy little plants, of which there are about 15,000 species, are found in almost every terrestrial environment. They are often found on damp, cool ground, where they form thick mats.

The mosses are the sister lineage to the vascular plants plus the hornworts (see Figure 21.1). They share with those lineages an advance over the liverworts in their adaptation to life on land: they have stomata, which are important for both water retention and gas exchange.

Some moss gametophytes are so large that they cannot transport enough water throughout their bodies solely by diffusion. Gametophytes and sporophytes of many mosses contain a type of cell called a *hydroid*, which dies and leaves a

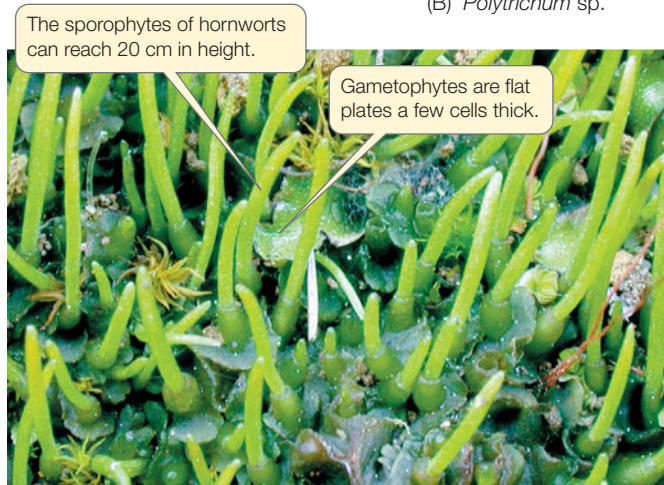

(A) *Marchantia* sp.(B) *Polytrichum* sp.(C) *Anthoceros* sp.

FIGURE 21.5 Diversity among Nonvascular Land Plants (A) Gametophytes of a liverwort. (B) The sporophytes and gametophytes are easily distinguished in this moss. (C) The sporophytes of many hornworts resemble little horns.

all three groups, those of the hornworts come closest to being capable of growth without a set limit. Liverwort and moss sporophytes have a stalk that stops growing as the spore-producing structure matures, so elongation of the sporophyte is strictly limited. The hornwort sporophyte, however, has no stalk. Instead, a basal region remains capable of indefinite cell division, continuously producing new spore-bearing tissue above. The sporophytes of some hornworts growing in mild and continuously moist conditions can grow as tall as 20 centimeters. Eventually, however, the sporophyte's growth is limited by the lack of a transport system.

Hornworts have evolved a symbiotic relationship that promotes their growth by providing them with greater access to nitrogen, which is often a limiting resource for plants. These plants have internal cavities filled with mucilage, and the cavities are often populated by cyanobacteria that convert atmospheric nitrogen gas into a form of nitrogen usable by their host plant.

The sporophytes of nonvascular land plants are dependent on the gametophytes

In the nonvascular land plants, the conspicuous green structure visible to the naked eye is the gametophyte (see Figure 21.6). The gametophyte is photosynthetic and is therefore nutritionally independent; the sporophyte may or may not be photosynthetic, but it is always nutritionally dependent on the gametophyte and remains permanently attached to it.

FIGURE 21.6 illustrates a moss life cycle that is typical of the life cycles of nonvascular land plants. A sporophyte produces unicellular haploid spores as products of meiosis within a sporangium. When a spore germinates, it gives rise to a multicellular haploid gametophyte whose cells contain chloroplasts and are thus photosynthetic. Eventually gametes form within specialized sex organs, called the **gametangia**. The **archegonium** is a multicellular, flask-shaped female sex organ with a long neck and a swollen base; it produces a single egg. The **antheridium** is a male sex organ in which sperm, each bearing two flagella, are produced in large numbers. Both archegonia and antheridia are produced on the same individual, so each individual has both male and female reproductive structures. Adjacent individuals often fertilize one another's gametes, however, which helps maintain genetic diversity in the population.

tiny channel through which water can travel. The hydroid is functionally similar to the tracheid, the characteristic water-conducting cell of vascular plants, but it lacks the lignin and the cell-wall structure that characterize tracheids. The possession of hydroids shows that the term "nonvascular land plant" is somewhat misleading when applied to mosses. Despite their simple systems of internal transport, however, the mosses are not considered vascular plants because of their lack of a well-developed vascular system.

HORNWORTS The **hornworts** are so named because their sporophytes often look like little horns (**FIGURE 21.5C**). The approximately 100 species of hornworts have two characteristics that distinguish them from liverworts and mosses. First, the cells of hornworts each contain a single large, platelike chloroplast, whereas the cells of the other two groups contain numerous small, lens-shaped chloroplasts. Second, of the sporophytes in

FIGURE 21.6 A Moss Life Cycle The life cycles of nonvascular land plants, exemplified here by that of a moss, are dependent on an external source of liquid water. The visible green structure of such plants is the gametophyte.

Once released from the antheridium, the sperm must swim or be splashed by raindrops to a nearby archegonium on the same or a neighboring plant—a constraint that reflects the aquatic origins of the nonvascular land plants' ancestors. The sperm are aided on their journey by chemical attractants released by the egg or the archegonium. Before sperm can enter the archegonium, however, certain cells in the neck of the archegonium must break down, leaving a water-filled canal through which the sperm can swim to complete their journey. Notice that *all of these events require liquid water*.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 21.1**
Life Cycle of a Moss

Once sperm arrive at an egg, the nucleus of a sperm fuses with the egg nucleus to form a diploid zygote. Mitotic divisions of the zygote produce a multicellular, diploid sporophyte embryo. The sporophyte matures and produces a sporangium, within which meiotic divisions produce spores and thus the next gametophyte generation.

Do You Understand Concept 21.2?

- Describe several adaptations of plants to the terrestrial environment, and describe the distribution of those adaptations in liverworts, mosses, and hornworts.
- Explain what is meant by alternation of generations.
- What aspects of the reproductive cycle of nonvascular land plants appear to have been retained from their aquatic ancestors?

Further adaptations to the terrestrial environment appeared as plants continued to evolve. One of the most important of these later adaptations was the appearance of vascular tissues—the characteristic that defines the vascular plants.

concept 21.3 Vascular Tissues Led to Rapid Diversification of Land Plants

The first plants possessing vascular tissues did not arise until tens of millions of years after the earliest plants had colonized the land. But once they arose, their ability to transport water and food throughout their bodies allowed them to spread to new environments and diversify rapidly.

Vascular tissues transport water and dissolved materials

Vascular plants differ from the other land plants in crucial ways, one of which is the possession of a well-developed **vascular system** consisting of tissues specialized for the transport of materials from one part of the plant to another. One type of vascular tissue, the *xylem*, conducts water and minerals from the soil to aerial parts of the plant. Because some of its cell walls contain a stiffening substance called lignin, xylem also provides support against gravity in the terrestrial environment. The other type of vascular tissue, the *phloem*, conducts the products of photosynthesis from sites where they are produced or released to sites where they are used or stored.

LINK The vascular tissues of plants are described in detail in Chapter 24

Although the vascular plants are an extraordinarily large and diverse group, a particular event was critical to their evolution. Sometime during the Paleozoic era, probably in the mid-Silurian (430 mya), a new cell type called a **tracheid** evolved in sporophytes of the earliest vascular plants. The tracheid is the principal water-conducting element of the xylem in all vascular plants except the *angiosperms* (flowering plants), and even in the angiosperms, tracheids persist along with a more specialized and efficient system derived from them.

The evolution of tracheids set the stage for the complete and permanent invasion of land by plants. First, these cells provided

a pathway for the transport of water and mineral nutrients from a source of supply to regions of need in the plant body. And second, the cell walls of tracheids, stiffened by lignin, provided rigid structural support. This support is a crucial factor in a terrestrial environment because it allows plants to grow upward and thus compete for sunlight. A taller plant can intercept more direct sunlight (and thus conduct photosynthesis more readily) than a shorter plant, which may be shaded by the taller one. Increased height also improves the dispersal of spores.

The vascular plants featured another evolutionary novelty: a branching, independent sporophyte. A branching sporophyte body can produce more spores than an unbranched body, and it can develop in complex ways. The sporophyte of a vascular plant is nutritionally independent of the gametophyte at maturity. Among the vascular plants, the sporophyte is the large and obvious plant that one normally pays attention to in nature, in contrast to the relatively small, dependent sporophytes typical of most nonvascular land plants.

Vascular plants have been evolving for almost half a billion years

The evolution of an effective cuticle and protective layers for the gametangia helped make the first vascular plants successful, as did the initial absence of herbivores (plant-eating animals) on land. By the late Silurian period (about 425 mya), vascular plants were being preserved as fossils that we can study today. Their proliferation made the terrestrial environment more hospitable to animals. Arthropods, vertebrates, and other animals moved onto land only after vascular plants became established there.

Trees of various kinds appeared in the Devonian period and dominated the landscape of the Carboniferous period (359–297 mya). Forests of lycophytes (club mosses) up to 40 meters tall, along with horsetails and tree ferns, flourished in the tropical swamps of what would become North America and Europe (**FIGURE 21.7**). Plant parts from those forests sank into the swamps and were gradually covered by layers of sediment. Over millions of years, as the buried plant material was subjected to intense pressure and elevated temperatures, it was transformed into coal. Today that coal provides over half of our electricity. The world's coal deposits, although huge, are not infinite, and they cannot be renewed because the conditions that created coal no longer exist.

In the subsequent Permian period, when the continents came together to form the single gigantic land mass of Pangaea, the continental interior became warmer and drier, but late in the period glaciation was extensive. The 200-million-year reign of the lycophyte–fern forests came to an end as they were replaced by forests of early *gymnosperms*, which were prevalent until angiosperms became the dominant vegetation over much of the landscape about 65 million years ago.

The earliest vascular plants lacked roots

The earliest known vascular plants belonged to a now-extinct group called the **rhyniophytes**. The rhyniophytes were one of

FIGURE 21.7 Reconstruction of an Ancient Forest

Forests of the Carboniferous period were characterized by abundant vascular plants such as club mosses, ferns, and horsetails, some of which reached heights of 40 meters. Huge flying insects (see p. 347) thrived in these forests, which are the source of modern coal deposits.

a very few types of vascular plants in the Silurian period. The landscape at that time probably consisted mostly of bare ground, with stands of rhyniophytes in low-lying moist areas. Early versions of the structural features of all the other vascular plant groups appeared in the rhyniophytes of that time. These shared features strengthen the case for the origin of all vascular plants from a common nonvascular land plant ancestor.

Rhyniophytes did not have roots. Like most modern ferns and lycophytes, they were apparently anchored in the soil by horizontal portions of stem, called **rhizomes**, which bore water-absorbing unicellular filaments called **rhizoids**. These rhizomes also bore aerial branches, and sporangia—homologous to the sporangia of mosses—were found at the tips of those branches. Their branching pattern was *dichotomous*; that is, the apex (tip) of the shoot divided to produce two equivalent new branches, each pair diverging at approximately the same angle from the original stem.

The lycophytes are sister to the other vascular plants

The club mosses and their relatives, the spike mosses and quillworts, are collectively called **lycophytes**. The lycophytes are the sister group to the remaining vascular plants (see Figure 21.1B). There are relatively few surviving species of lycophytes—just over 1,200.

The lycophytes have true roots that branch dichotomously. The arrangement of vascular tissue in their stems is simpler than that in other vascular plants. They bear simple leaflike structures called **microphylls**, which are arranged spirally on the stem. Growth in lycophytes comes entirely from apical cell division. Branching in the stems, which is also dichotomous, occurs by division of an apical cluster of dividing cells.

The sporangia of many club mosses are aggregated in cone-like structures called *strobili* (singular *strobilus*; **FIGURE 21.8A**). The strobilus of a club moss is a cluster of spore-bearing leaves inserted on an axis (a linear supporting structure). Other club mosses lack strobili and bear their sporangia on (or adjacent to) the upper surfaces of specialized leaves.

Horsetails and ferns constitute a clade

The horsetails and ferns were once thought to be only distantly related. As a result of genomic analyses, we now know that they form a clade: the **monilophytes**, or “ferns and fern allies.” Within the monilophytes, the horsetails are monophyletic, but

the ferns are not. However, most ferns do belong to a single clade, the *leptosporangiate ferns*. In the monilophytes—as in the *seed plants*, to which they are the sister group (see Table 21.1)—there is differentiation between a main stem and side branches. This pattern contrasts with the dichotomous branching characteristic of the lycophytes and rhyniophytes, in which each split gives rise to two branches of similar size. A synapomorphy of the monilophytes is the presence of openings in the stem, called *leaf gaps*, from which the leaves emerge.

Today there are only about 15 species of **horsetails**, all in the genus *Equisetum*. The horsetails have reduced true leaves that form in distinct whorls (circles) around the stem (**FIGURE 21.8B**). Horsetails are sometimes called “scouring rushes” because rough silica deposits found in their cell walls once made them useful for cleaning. They have true roots that branch irregularly. Horsetails have a large sporophyte and a small gametophyte, both independent.

The first **leptosporangiate ferns** appeared during the Devonian period; today this group comprises more than 12,000 species. The sporangia of leptosporangiate ferns have walls only one cell thick. The name “leptosporangiate” refers to these thin-walled sporangia (*lepton*, “thin”). Three other small groups that are also called “ferns” evolved independently, even though some are superficially similar to the leptosporangiate ferns.

Although most ferns are terrestrial, a few species live in shallow fresh water (**FIGURE 21.8C**). Terrestrial ferns are

(A) *Lycopodium annotinum*(B) *Equisetum pratense*(C) *Marsilea* sp. *Salvinia* sp.(D) *Dicksonia antarctica*

FIGURE 21.8 Lycophytes and Monilophytes (A) A strobilus is visible at the tip of this club moss. Club mosses have microphylls arranged spirally on their stems. (B) Horsetails have a distinctive growth pattern in which the stem grows in segments above each whorl of leaves. These are fertile shoots with sporangia-bearing structures at the apex. (C) The leaves of two species of water ferns. (D) Tree ferns dominate this forest on the island of Tasmania, Australia.

characterized by large leaves with branching vascular strands (**FIGURE 21.8D**). Some fern leaves become climbing organs and may grow to be as long as 30 meters.

In the alternating generations of a fern, the gametophyte is small, delicate, and short-lived, but the sporophyte can be very large and can sometimes survive for hundreds of years (**FIGURE 21.9**). Ferns require liquid water for the transport of the male gametes to the female gametes, so most ferns inhabit shaded, moist woodlands and swamps. The sporangia of ferns typically are borne on a stalk in clusters called *sori*. The sori are found on the undersurfaces of the leaves, sometimes covering the entire undersurface and sometimes located at the edges.

The vascular plants branched out

Several features that were new to the vascular plants evolved in lycophytes and monilophytes. Roots probably had their evolutionary origins as a branch, either of a rhizome or of the aboveground portion of a stem. That branch presumably penetrated the soil and branched further. The underground portion could anchor the plant firmly, and even in this primitive condition, it could absorb water and minerals.

The microphylls of lycophytes were probably the first leaflike structures to evolve among the vascular plants.

Microphylls are usually small and only rarely have more than a single vascular strand, at least in existing species. Some biologists believe that microphylls had their evolutionary origins as sterile sporangia (**FIGURE 21.10A**). The principal characteristic of a microphyll is a vascular strand that departs from the vascular system of the stem in such a way that the structure of the stem's vascular system is scarcely disturbed. This pattern was evident even in the lycophyte trees of the Carboniferous period, many of which had microphylls many centimeters long.

The monilophytes and seed plants constitute a clade called the **euphyllophytes** (*eu*, "true"; *phyllos*, "leaf"). An important synapomorphy of the euphyllophytes is **overtopping**, a growth pattern in which one branch differentiates from and grows beyond the others (**FIGURE 21.10B**). Overtopping would have given these plants an advantage in the competition for light, enabling them to shade their dichotomously branching competitors. The overtopping growth of the euphyllophytes also allowed a new type of leaflike structure to evolve. This larger, more complex leaf is called a **megaphyll**. The megaphyll is thought to have arisen from the flattening of a portion of a branching stem system that exhibited overtopping growth. This change was followed by the development of photosynthetic tissue between the members of overtopped groups of

The Fern Life Cycle

branches, which had the advantage of increasing the photosynthetic surface area of those branches.

Heterospory appeared among the vascular plants

In the lineages of present-day vascular plants that are most similar to their ancestors, the gametophyte and the sporophyte are independent, and both are usually photosynthetic. The spores produced by the sporophyte are of a single type and develop into a single type of gametophyte that bears both female and male reproductive organs (see Figure 21.9). Such plants, which bear a single type of spore, are said to be **homosporous** (FIGURE 21.11A).

A system with two distinct types of spores evolved somewhat later. Plants of this type are said to be **heterosporous** (FIGURE 21.11B). In heterospory, one type of spore—the **megaspore**—develops into a specifically female gametophyte (a **megagametophyte**) that produces only eggs. The other type, the **microspore**, is smaller and develops into a male gametophyte (a **microgametophyte**) that produces only sperm. The sporophyte produces megaspores in small numbers in *megaspore* and microspores in large numbers in *microsporangia*. Heterospory affects not only the spores and the gametophytes, but also the sporophyte plant itself, which must develop two types of sporangia.

FIGURE 21.10 Evolution of Leaves (A) Microphylls are thought to have evolved from sterile sporangia. (B) The megaphylls of monilophytes and seed plants may have arisen as photosynthetic tissue developed between branches that were “left behind” as dominant branches overtopped them.

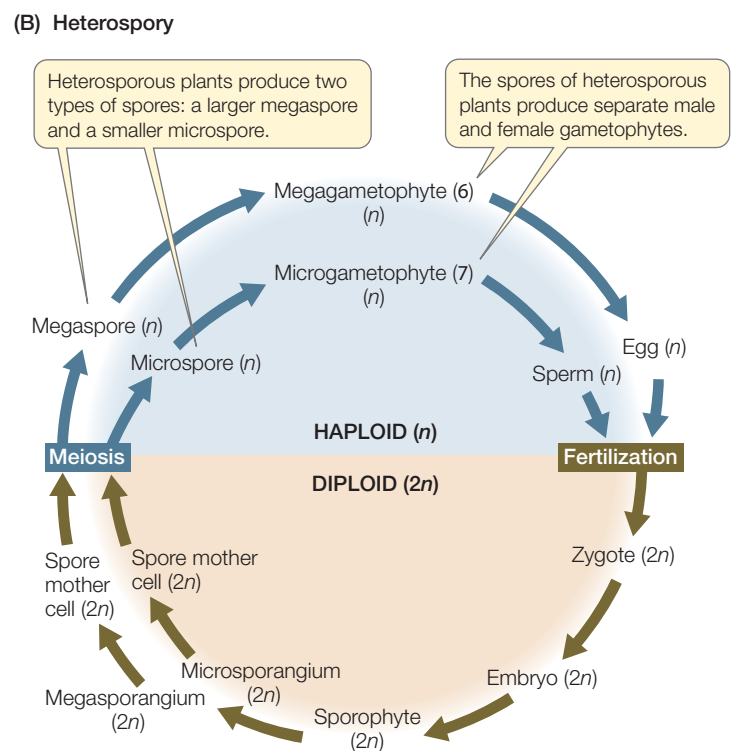

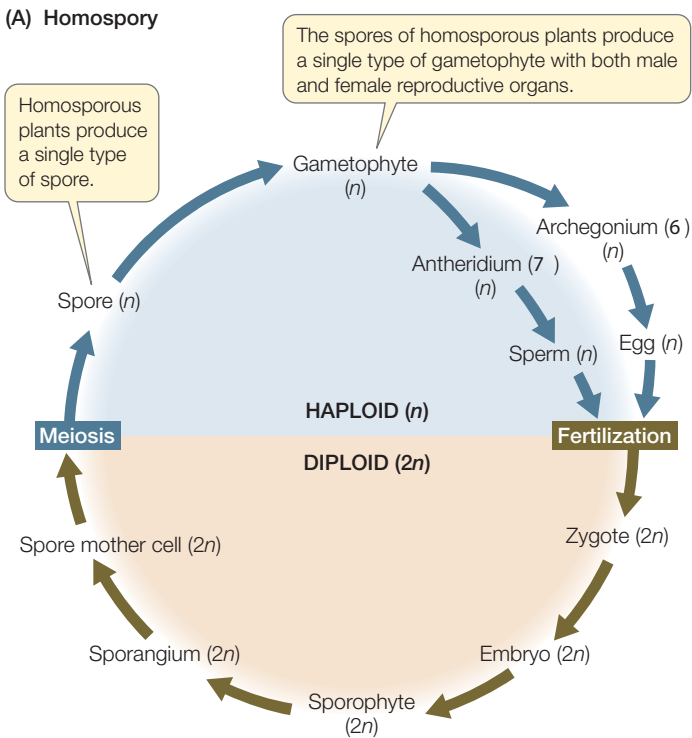

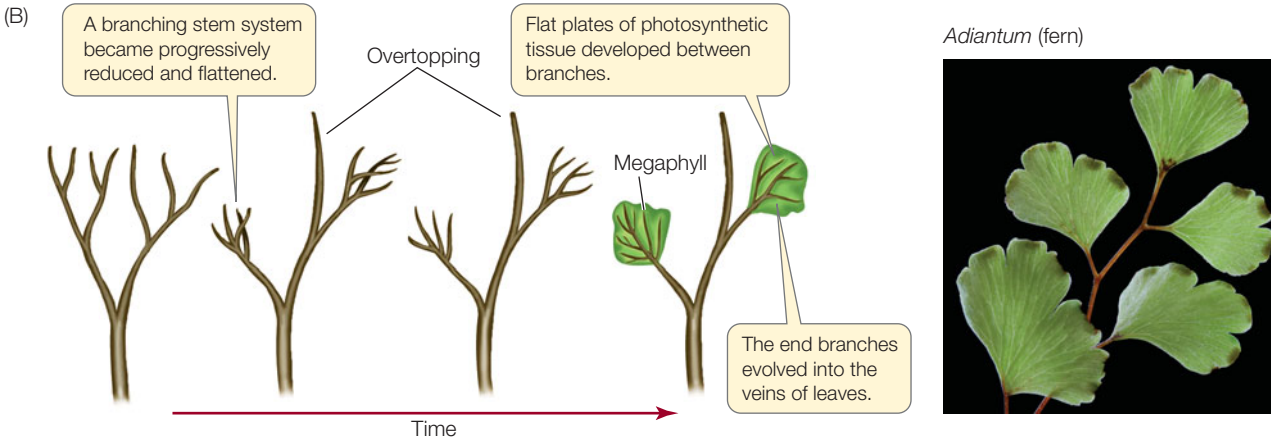

FIGURE 21.11 Homospory and Heterospory (A) Homosporous plants bear a single type of spore. Each gametophyte has two types of sex organs, antheridia (male) and archegonia (female). (B) Heterosporous plants bear two types of spores that develop into distinctly male and female gametophytes.

The earliest vascular plants were all homosporous, but heterospory evidently evolved several times independently among later groups of vascular plants. The fact that heterospory evolved repeatedly suggests that it affords selective advantages. Subsequent evolution in the land plants featured ever greater specialization of the heterosporous condition.

Do You Understand Concept 21.3?

- How do the vascular tissues xylem and phloem serve the vascular plants?
- Describe the evolution and distribution of different kinds of leaves and roots among the vascular plants.
- Explain the concept of heterospory. Why is heterospory thought to provide selective advantages over homospority?

All of the vascular plant groups we have discussed thus far disperse by means of spores. The embryos of these seedless vascular plants develop directly into sporophytes, which either survive or die, depending on environmental conditions. The spores of some seedless plants may remain dormant and viable for long periods, but the embryos of seedless plants are relatively unprotected (see Figure 21.9). Greater protection of the embryo evolved in the seed plants.

concept 21.4 Seeds Protect Plant Embryos

The **seed plants**—the gymnosperms and the angiosperms—provide a secure and lasting dormant stage for the embryo, known as a seed. In seeds, embryos may safely lie dormant, in

some cases for many years (even centuries), until conditions are right for germination. How is this protection provided?

Features of the seed plant life cycle protect gametes and embryos

In Concept 21.2 we described a trend in plant evolution: the sporophyte became less dependent on the gametophyte, which became smaller in relation to the sporophyte. This trend continued with the seed plants, whose gametophyte generation is reduced even further than it is in the ferns (FIGURE 21.12). The haploid gametophyte develops partly or entirely while attached to and nutritionally dependent on the diploid sporophyte.

Among the seed plants, only the earliest diverging groups of gymnosperms (including modern cycads and ginkgos) have swimming sperm. Other groups of gymnosperms and the angiosperms evolved other means of bringing eggs and sperm together. The culmination of this striking evolutionary trend in seed plants was independence from the liquid water that earlier plants needed to assist sperm in reaching the egg. This adaptation, along with the advent of the seed, gave seed plants the opportunity to colonize drier areas and spread over the terrestrial environment.

Seed plants are heterosporous (see Figure 21.11B); that is, they produce two types of spores, one that becomes a microgametophyte and one that becomes a megagametophyte. They form separate microsporangia and megasporangia on structures that are grouped on short axes, such as the stamens and pistils of an angiosperm flower.

FIGURE 21.12 The Relationship between Sporophyte and Gametophyte In the course of plant evolution, the gametophyte (brown) has been reduced and the sporophyte (blue) has become more prominent.

Within the microsporangium, the meiotic products are microspores, which divide mitotically within the spore wall one or a few times to form a multicellular male gametophyte called a **pollen grain**. Pollen grains are released from the microsporangium to be distributed by wind or by an animal pollinator (**FIGURE 21.13**). The spore wall that surrounds the pollen grain contains *sporopollenin*, the most chemically resistant biological compound known, which protects the pollen grain against dehydration and chemical damage—another advantage in terms of survival in the terrestrial environment.

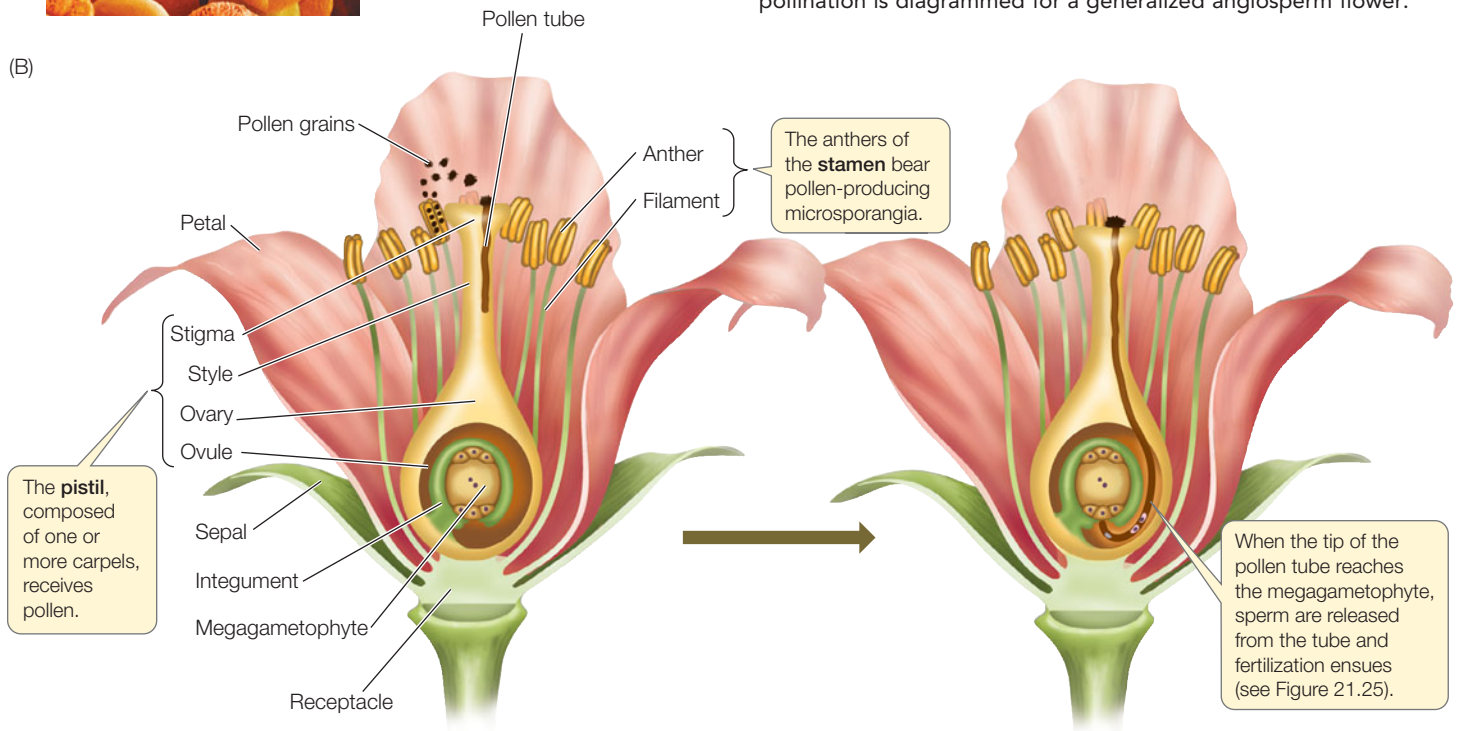

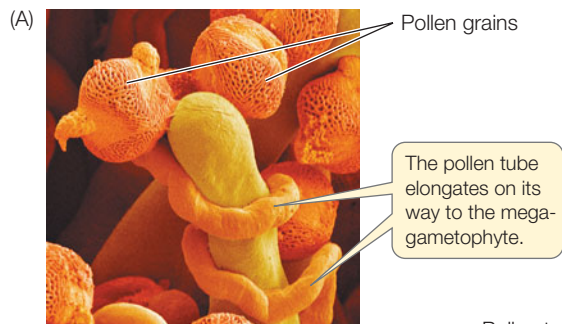

In contrast to the pollen grains produced by the microsporangia, the megaspores of seed plants are not shed. Instead, they develop into female gametophytes within the megasporangia. These megagametophytes are dependent on the sporophyte for food and water.

In most seed plant species, only one of the meiotic products in a megasporangium survives. The surviving haploid nucleus divides mitotically, and the resulting cells divide again to produce a multicellular female gametophyte. The megasporangium is surrounded by sterile sporophytic structures, which form an **integument** that protects the megasporangium and its contents. Together, the megasporangium and integu-

ment constitute the **ovule**, which will develop into a seed after fertilization (**FIGURE 21.14**).

The arrival of a pollen grain at an appropriate landing point, close to a female gametophyte on a sporophyte of the same species, is called **pollination**. A pollen grain that reaches this point develops further. It produces a slender **pollen tube** that

FIGURE 21.14 Pollination in Seed Plants In all seed plants, a pollen tube grows from the pollen grain to the megagametophyte, where sperm are released. APPLY THE CONCEPT

Seeds protect plant embryos

In 1879, W. J. Beal began an experiment that he could not hope to finish in his lifetime. He prepared 20 lots of seeds for long-term storage. Each lot consisted of 50 seeds from each of 23 species. He mixed each lot of seeds with sand and placed the mixture in an uncapped bottle, then buried all the bottles on a sandy knoll. At regular intervals over the next century, several different biologists have excavated a bottle and checked the viability of its contents. The table shows the number of germinating seeds (of the original 50) from three species in years 50–100 of this ongoing experiment.

1. Calculate the percentage of surviving seeds for these three species in years 50–100 and graph seed survivorship as a function of time buried.
2. No seeds of the first two species were viable after 90 years of the experiment. Assume 100% seed viability at the

SPECIES	YEARS AFTER BURIAL					
	50	60	70	80	90	100
<i>Oenothera biennis</i> (Evening primrose)	19	12	7	5	0	0
<i>Rumex crispus</i> (Curly dock)	26	2	7	1	0	0
<i>Verbascum blattaria</i> (Moth mullein)	31	34	37	35	10	21

start of the experiment (year 0), and predict from your graph the approximate year when you think the last of the *Verbascum blattaria* seeds will germinate.

3. What factors do you think might influence the differences in long-term seed viability among the species?

elongates and digests its way toward the megagametophyte (see Figure 21.14). When the tip of the pollen tube reaches the megagametophyte, sperm are released from the tube and fertilization occurs.

The resulting diploid zygote divides repeatedly, forming an embryonic sporophyte. After a period of embryonic development, growth is temporarily suspended (the embryo enters a *dormant* stage). The end product at this stage is the multicellular seed.

The seed is a complex, well-protected package

A **seed** contains tissues from three generations. A *seed coat* develops from the integument—the tissues of the diploid sporophyte parent that surround the megasporangium. Within the megasporangium is haploid tissue from the female gametophyte, which contains a supply of nutrients for the developing embryo. (This tissue is fairly extensive in most gymnosperm seeds. In angiosperm seeds it is greatly reduced, and nutrition for the embryo is supplied instead by a tissue called *endosperm*.) In the center of the seed is the third generation, the embryo of the new diploid sporophyte.

The seed is a well-protected resting stage. The seeds of some species may remain dormant but stay *viable* (capable of growth and development) for many years, germinating only when conditions are favorable for the growth of the sporophyte.

During the dormant stage, the seed coat protects the embryo from excessive drying and may also protect it against potential predators that would otherwise eat the embryo and its nutrient reserves. Many seeds have structural adaptations that promote their dispersal by wind or, more often, by animals. When the young sporophyte resumes growth, it draws on the food reserves in the seed. The possession of seeds is a major reason for

the enormous evolutionary success of the seed plants, which are the dominant life forms of most modern terrestrial floras.

FRONTIERS Seeds of many plant species important to humans are stored at low temperatures in seed banks to ensure their availability for future human populations. These seed banks are themselves subject to destruction by humans, however, as happened in Iraq and Afghanistan in recent wars. To guard against permanent losses of plant species needed for human survival, a multinational global seed vault has been constructed in Norway, deep inside a sandstone mountain. Its features ensure the preservation of the seeds inside in all but the most extreme of possible future scenarios.

A change in anatomy enabled seed plants to grow to great heights

The earliest fossil seed plants were the seed ferns found in late Devonian rocks. These plants had extensively thickened woody stems, which developed through the proliferation of xylem. This type of growth, which increases the diameter of stems and roots in some modern seed plants, is called **secondary growth**, and its product is called secondary xylem, or *wood*.

The younger portion of the wood produced by secondary growth is well adapted for water transport, but older wood becomes clogged with resins or other materials. Although no longer functional in transport, the older wood continues to provide support for the plant. This support allows woody plants to grow taller than other plants around them and thus capture more light for photosynthesis.

Not all seed plants are woody. In the course of seed plant evolution, many groups lost the woody growth habit; however,

other advantageous attributes helped them become established in an astonishing variety of places.

Gymnosperms have naked seeds

The two major groups of living seed plants are the **gymnosperms** (such as pines and cycads) and the **angiosperms** (flowering plants; see Figure 21.1B). We'll discuss the flowering plants in Concept 21.5 and examine the gymnosperms here.

The gymnosperms are seed plants that do not form flowers or fruits. Gymnosperms (which means "naked-seeded") are so named because their ovules and seeds, unlike those of angiosperms, are not protected by ovary or fruit tissue. Although there are probably fewer than 1,200 living species of gymnosperms, these plants are second only to the angiosperms in their dominance of the terrestrial environment. The gymnosperms can be divided into four major groups:

- **Cycads** are palmlike plants of the tropics and subtropics (FIGURE 21.15A). Of the present-day gymnosperms, the cycads are probably the earliest-diverging clade. There are about 300 species, some of which grow as tall as 20 meters. The tissues of many species are highly toxic to humans if ingested.
- **Ginkgos**, common during the Mesozoic era, are represented today by a single genus and species: *Ginkgo biloba*, the maidenhair tree (FIGURE 21.15B). There are both male (microsporangiate) and female (megasporangiate) maidenhair trees. The difference is determined by X and Y sex chromosomes, as in humans; few other plants have distinct sex chromosomes.
- **Gnetophytes** number about 90 species in three very different genera, which share certain characteristics analogous to ones found in the angiosperms. One of the gnetophytes is *Welwitschia* (FIGURE 21.15C), a long-lived desert plant with just two straplike leaves that sprawl on the sand and can grow as long as 3 meters.
- **Conifers** are by far the most abundant of the gymnosperms. There are about 700 species of these cone-bearing plants, including the pines and redwoods (FIGURE 21.15D).

With the exception of the gnetophytes, the living gymnosperm groups have only tracheids as water-conducting and support cells within the xylem; they lack the cells called *vessel*

(A) *Encephalartos transvenosus*

(B) *Ginkgo biloba*

(C) *Welwitschia mirabilis*

(D) *Pinus longaeva*

FIGURE 21.15 Diversity among the Gymnosperms (A) Many cycads have growth forms that resemble both ferns and palms, although cycads are not closely related to either group. (B) The characteristic broad leaves of the maidenhair tree. (C) The straplike leaves of *Welwitschia*, a gnetophyte, grow throughout the life of the plant, breaking and splitting as they grow. (D) Conifers dominate many types of landscapes in the Northern Hemisphere. Bristlecone pines such as these are the longest-lived individual trees known.

elements and *fibers* (specialized for water conduction and support, respectively) that are found in angiosperms. While the gymnosperm water-transport and support system may thus seem somewhat less efficient than that of the angiosperms, it serves some of the largest trees known. The coastal redwoods of California are the tallest gymnosperms; the largest are well over 100 meters tall.

During the Permian, as environments became warmer and dryer, the conifers and cycads flourished. Gymnosperm forests

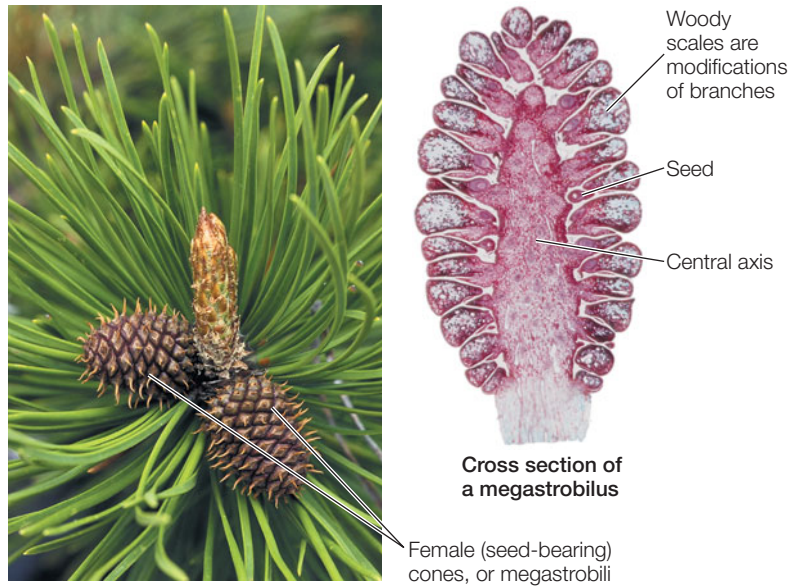

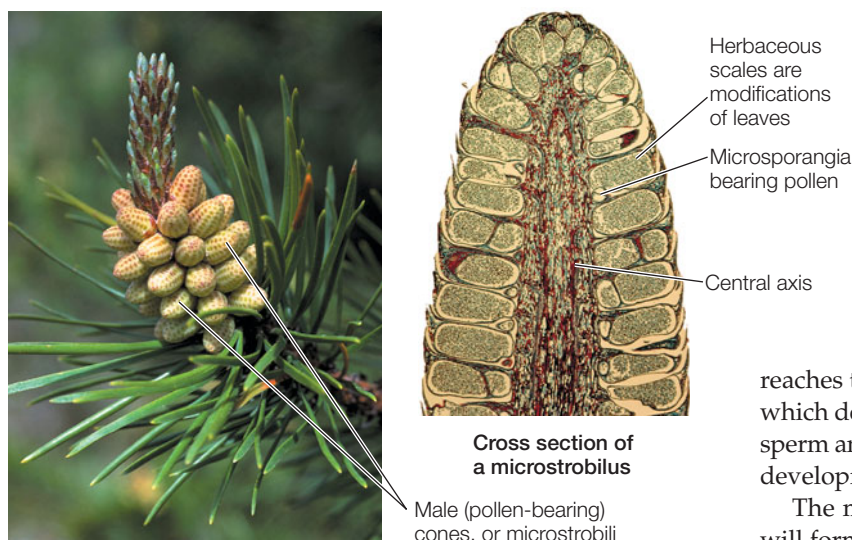

(A) *Pinus contorta*(B) *Pinus contorta*

FIGURE 21.16 Female and Male Cones (A) The scales of female cones (megastrobili) are modified branches. (B) The scales of male cones (microstrobili) are modified leaves.

everywhere, rank among the great forests of the world. All these trees belong to one group of gymnosperms: the conifers, or cone-bearers.

Male and female **cones** contain the reproductive structures of conifers. The female (seed-bearing) cone is known as a **megastrobilus** (plural *megastrobili*); an example is the familiar woody cone of pine trees. The seeds in a megastrobilus are protected by a tight cluster of woody scales, which are modifications of branches extending from a central axis (FIGURE 21.16A). The typically much smaller male (pollen-bearing) cone is known as a **microstrobilus**. The microstrobilus is typically herbaceous rather than woody, as its scales are composed of modified leaves, beneath which are the pollen-bearing microsporangia (FIGURE 21.16B).

The life cycle of a pine illustrates reproduction in gymnosperms (FIGURE 21.17). The production of male gametophytes in the form of pollen grains frees the plant completely from its dependence on liquid water for fertilization. Wind, rather than water, assists conifer pollen grains in their first stage of travel from the microstrobilus to the female gametophyte inside a cone. A pollen tube provides the sperm with the means for the last stage of travel by elongating through maternal sporophytic tissue. When the pollen tube reaches the female gametophyte, it releases two sperm, one of which degenerates after the other unites with an egg. Union of sperm and egg results in a zygote; mitotic divisions and further development of the zygote result in an embryo.

The megasporangium, in which the female gametophyte will form, is enclosed in a layer of sporophytic tissue—the integument—that will eventually develop into the seed coat that protects the embryo. The integument, the megasporangium inside it, and the tissue attaching it to the maternal sporophyte constitute the ovule. The pollen grain enters through a small opening in the integument at the tip of the ovule, the **micropyle**.

Most conifer ovules (which will develop into seeds after fertilization) are borne exposed on the upper surfaces of the scales of the cone (megastrobilus). The only protection of the ovules comes from the scales, which are tightly pressed against one another within the cone. Some pines, such as the lodgepole pine, have such tightly closed cones that only fire suffices to split them open and release the seeds. These species are said to be *fire-adapted*, and fire is essential to their reproduction.

About half of all conifer species have soft, fleshy modifications of cones that envelop their seeds; examples are the fruitlike cones (“berries”) of juniper and yew. Animals may eat these tissues and disperse the seeds in their feces, often carrying them considerable distances from the parent plant.

changed over time as the gymnosperm groups evolved. Gymnosperms dominated the Mesozoic era, during which the continents drifted apart and large dinosaurs lived. Gymnosperms were the principal trees in all forests until about 65 million years ago, and even today conifers are the dominant trees in many forests, especially at high latitudes and altitudes. The oldest living single organism on Earth today is a gymnosperm in California—a bristlecone pine that germinated about 4,800 years ago, at about the time the ancient Egyptians were starting to develop writing (see Figure 21.15D).

Conifers have cones but no motile gametes

yourBioPortal.com

Go to WEB ACTIVITY 21.4 and ANIMATED TUTORIAL 21.2
Life Cycle of a Conifer

The “berries” on some gymnosperms such as juniper and yew are not true fruits but rather are fleshy cones. As we will see next, true fruits are the ripened ovaries of plants. Ovaries are absent in gymnosperms but are characteristic of the plant group that is dominant today: the angiosperms, or flowering plants, which include more than 250,000 species.

Do You Understand Concept 21.4?

- Distinguish between the roles of the megagametophyte and the pollen grain.
- Explain the importance of pollen in freeing seed plants from dependence on liquid water.
- What are some of the advantages afforded by seeds? By wood?
- Do you understand how fire can be necessary for the survival of some plant species?

concept 21.5 Flowers and Fruits Increase the Reproductive Success of Angiosperms

Production of fruits is a unique characteristic of angiosperms. Their most obvious feature, however, is of course their sexual organs: **flowers**. As we will see, both flowers and fruits afford major reproductive advantages to angiosperms.

The female gametophyte of the angiosperms is even more reduced than that of the gymnosperms, usually consisting of just seven cells. Thus the angiosperms represent the current extreme of the trend we have traced throughout the evolution of the vascular plants: the sporophyte generation becomes larger and more independent of the gametophyte, while the gametophyte generation becomes smaller and more dependent on the sporophyte. What else sets the angiosperms apart from other plants?

Angiosperms have many shared derived traits

Several major synapomorphies characterize the angiosperms:

- Double fertilization
- Production of a nutritive tissue called the endosperm
- Ovules and seeds enclosed in a carpel
- Germination of pollen on a stigma
- Flowers
- Fruits
- Phloem with companion cells
- Reduced gametophytes

Most angiosperms are distinguished by the possession of specialized water-transporting cells called **vessel elements** in their xylem. These cells are larger in diameter than tracheids and connect with one another without obstruction, allowing easy water movement. A second distinctive cell type in angiosperm xylem is the **fiber**, which plays an important role in supporting the plant body. Angiosperm phloem possesses another unique cell type, called a *companion cell*. Like the gymnosperms, woody

angiosperms show secondary growth, increasing in diameter by producing secondary xylem and secondary phloem.

Pollination in the angiosperms consists of the arrival of a microgametophyte—a pollen grain—on a receptive surface in a flower (the *stigma*). As in the gymnosperms, pollination is the first in a series of events that result in the formation of a seed. The next event is the growth of a pollen tube extending to the megagametophyte (see Figure 21.14). The third event is a fertilization process that, in detail, is unique to the angiosperms.

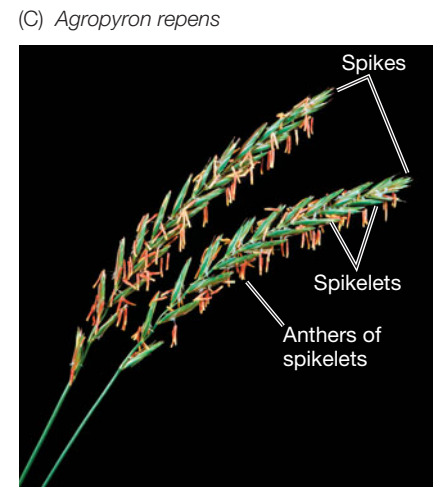

In nearly all angiosperms, *two* male gametes, contained in a single microgametophyte, participate in fertilization. The nucleus of one sperm combines with that of the egg to produce a diploid zygote, the first cell of the sporophyte generation. In most angiosperms, the other sperm nucleus combines with two other haploid nuclei of the female gametophyte to form a cell with a *triploid* ($3n$) nucleus. That cell, in turn, gives rise to triploid tissue, the **endosperm**, which nourishes the embryonic sporophyte during its early development. This process, in which two fertilization events take place, is known as **double fertilization**.

The name *angiosperm* (“enclosed seed”) is drawn from another distinctive characteristic of these plants: the ovules and seeds are enclosed in a modified leaf called a **carpel**. Besides protecting the ovules and seeds, the carpel often interacts with incoming pollen to prevent self-pollination, thus favoring cross-pollination and increasing genetic diversity.

The sexual structures of angiosperms are flowers

Flowers come in an astonishing variety of forms—just think of some of the flowers you recognize. Flowers may be single, or they may be grouped together to form an **inflorescence**.

FIGURE 21.18 Inflorescences (A) The inflorescence of bishop’s goutweed, a member of the carrot family, is a compound umbel. Each umbel bears flowers on stalks that arise from a common center. (B) Zinnias are members of the aster family; their inflorescence is a head. Within the head, each of the long, petal-like structures is a ray flower; the central portion of the head consists of dozens to hundreds of disc flowers. (C) Some grasses, such as quack grass, have inflorescences called spikes, which are composed of many individual flowers, or spikelets.

Different families of flowering plants have characteristic types of inflorescences, such as the compound umbels of the carrot family (FIGURE 21.18A), the heads of the aster family (FIGURE 21.18B), and the spikes of many grasses (FIGURE 21.18C).

If you examine any familiar flower, you will notice that the outer parts look somewhat like leaves. In fact, all the parts of a flower *are* modified leaves.

The diagram in Figure 21.14B represents a generalized flower (for which there is no exact counterpart in nature). The structures bearing microsporangia are called **stamens**. Each stamen is composed of a **filament** bearing an **anther** that contains the pollen-producing microsporangia. The structures bearing megasporangia are the carpels. A structure composed of one carpel or two or more fused carpels is called a **pistil**. The swollen base of the pistil, containing one or more ovules (each containing a megasporangium surrounded by its protective integument), is called the **ovary**. The apical stalk of the pistil is the **style**, and the terminal surface that receives pollen grains is the **stigma**.

Go to WEB ACTIVITY 21.5
Flower Morphology

In addition, many flowers have specialized sterile (non-spore-bearing) leaves. The inner ones are called **petals** (collectively, the **corolla**) and the outer ones **sepals** (collectively, the **calyx**). The corolla and calyx (collectively, the *perianth*) can be quite showy and often play roles in attracting animal pollinators to the flower. The calyx more commonly protects the immature flower in bud. From base to apex, these floral organs—sepals, petals, stamens, and carpels—are usually positioned in circular arrangements or whorls and attached to a central stalk (called the *receptacle*).

The generalized flower in Figure 21.14B has functional megasporangia and microsporangia; such flowers are referred to as **perfect** (or hermaphroditic). Many angiosperms produce two types of flowers, one with only megasporangia and the other with only microsporangia. Consequently, either the stamens or the carpels are nonfunctional or absent in a given flower, and the flower is referred to as **imperfect**.

Species such as corn or birch, in which both megasporangiate (female) and microsporangiate (male) flowers occur on the same plant, are said to be **monoecious** (“one-housed”—but, it must be added, one house with separate rooms). Complete separation of imperfect flowers occurs in some other angiosperm species, such as willows and date palms; in these species, an individual plant produces either

flowers with stamens or flowers with carpels, but never both. Such species are said to be **dioecious** (“two-housed”).

Flower structure has evolved over time

The flowers of the earliest-diverging clades of angiosperms have a large and variable number of *tepals* (undifferentiated sepals and petals), carpels, and stamens (FIGURE 21.19A). Evolutionary change within the angiosperms has included some striking modifications of this early condition: reductions in the number of each type of floral organ to a fixed number, differentiation of petals from sepals, and changes in symmetry from radial (as in a lily or magnolia) to bilateral (as in a sweet pea or orchid), often accompanied by an extensive fusion of parts (FIGURE 21.19B).

According to one hypothesis, the first carpels to evolve were leaves with marginal sporangia, folded but incompletely closed. Early in angiosperm evolution, the carpels fused and became progressively more buried in receptacle tissue, forming the ovary (FIGURE 21.20A). In some flowers, the other floral organs are attached at the top of the ovary, rather than at the bottom as in Figure 21.14B. The stamens of the most ancient flowers may have appeared leaflike (FIGURE 21.20B), little resembling those of the generalized flower in Figure 21.14B.

Why do so many flowers have pistils with long styles and anthers with long filaments? Natural selection has favored length in both of these structures, probably because length increases the likelihood of successful pollination. Long filaments may bring the anthers into contact with insect bodies, or they may place the anthers in a better position to catch the wind. Similar arguments apply to long styles.

A perfect flower represents a compromise of sorts. On the one hand, by attracting a pollinating bird or insect, the plant is attending to both its female and male functions with a single flower type, whereas plants with imperfect flowers must create that attraction twice—once for each type of flower. On the other hand, the perfect flower can favor self-pollination, which is usually disadvantageous. Another potential problem is that the female and male functions might interfere with each other—for example, the stigma might be so placed as to make it

(A) *Nymphaea* sp.

(B) *Viola tricolor*

FIGURE 21.19 Flower Form and Evolution

(A) A water lily shows the major features of early flowers: it is radially symmetrical, and the individual tepals, stamens, and carpels are separate, numerous, and attached at their bases. (B) Violets such as this “Johnny jump-up” have a bilaterally symmetrical structure that evolved much later than radial flower symmetry.

FIGURE 21.20 Carpels and Stamens Evolved from Leaflike Structures (A) Possible stages in the evolution of a carpel from a more leaflike structure. (B) The stamens of three modern plants show three possible stages in the evolution of that organ. (It is not implied that these species evolved from one another; their structures simply illustrate the possible stages.)

difficult for pollinators to reach the anthers, thus reducing the export of pollen to other flowers.

Might there be a way around these problems? One solution is seen in the bush monkeyflower (*Mimulus aurantiacus*), which is pollinated by hummingbirds. Its flower has a stigma that initially serves as a screen, hiding the anthers (**FIGURE 21.21**). Once a hummingbird touches the stigma, one of the stigma's two lobes is retracted, so that subsequent hummingbird visitors pick up pollen from the previously screened anthers. Thus the first bird to visit the flower transfers pollen from another plant to the stigma, eventually leading to fertilization. Later visitors pick up pollen from the now-accessible anthers, fulfilling the flower's male function. **FIGURE 21.22** describes the experiment that revealed the function of this mechanism.

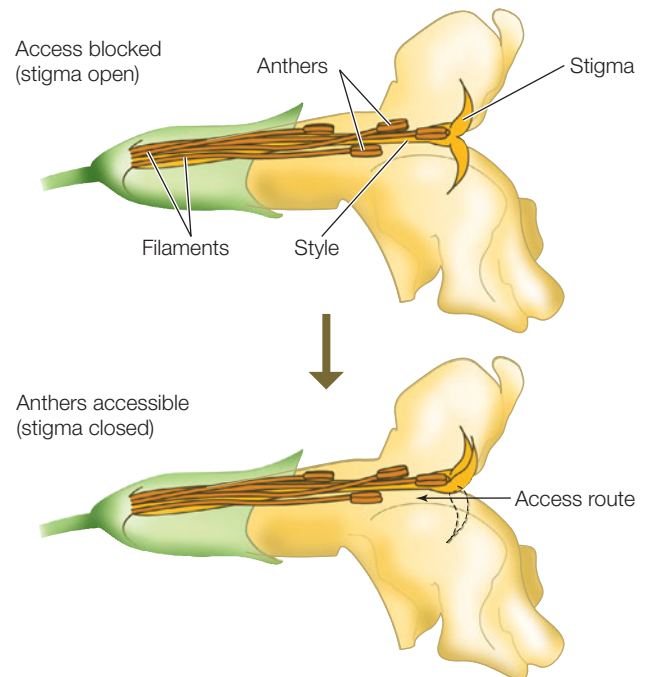

FIGURE 21.21 An Unusual Way to Prevent Selfing Both long stamens and long styles facilitate cross-pollination, but if these male and female structures are too close to each other, the likelihood of (disadvantageous) self-pollination increases. In *Mimulus aurantiacus*, the stigma is initially open, blocking access to the anthers. A hummingbird's touch as it deposits pollen on the stigma causes one lobe of the stigma to retract, creating a path to the anthers and allowing pollen dispersal.

Angiosperms have coevolved with animals

Whereas many gymnosperms are pollinated by wind, most angiosperms are pollinated by animals. The many different pollination mutualisms between plants and animals are vital to both parties. We discussed coevolution of insects and orchids briefly in the opening of this chapter, but we'll consider a few additional aspects of plant-pollinator coevolution here.

Many flowers entice animals to visit them by providing food rewards. Some flowers produce a sugary fluid called nectar, and some of these flowers have specialized structures to store and distribute it, as we saw at the opening of this chapter. Pollen grains themselves sometimes serve as food for animals. In the process of visiting flowers to obtain nectar or pollen, animals often carry pollen from one flower to another or from one plant to another. Thus, in their quest for food, the animals contribute to the genetic diversity of the plant population. Insects, especially bees, are among the most important pollinators; birds and some species of bats are also major pollinators.

For more than 150 million years, angiosperms and their animal pollinators have coevolved in the terrestrial environment. The animals have affected the evolution of the plants, and the plants have affected the evolution of the animals. Flower structure has become incredibly diverse under these selection pressures. Some of the products of coevolution are highly specific; for example, some yucca species are pollinated by only one

INVESTIGATION

FIGURE 21.22 The Effect of Stigma Retraction in Monkeyflowers Elizabeth Fetscher's experiments showed that the unusual stigma retraction response to pollination in monkeyflowers (illustrated in Figure 21.21) enhances the dispersal of pollen to other flowers.

HYPOTHESIS

The stigma-retraction response in *M. aurantiacus* increases the likelihood that an individual flower's pollen will be exported to another flower once pollen from another flower has been deposited on its stigma.

METHOD

1. Set up three groups of monkeyflower arrays. Each array consists of one pollen-donor flower and multiple pollen-recipient flowers (with the anthers removed to prevent pollen donation).
2. In control arrays, the stigma of the pollen donor is allowed to function normally.
3. In one set of experimental arrays, the stigma of the pollen donor is permanently propped open.
4. In a second set of experimental arrays, the stigma of the pollen donor is artificially sealed closed.
5. Allow hummingbirds to visit the arrays, then count the pollen grains transferred from each donor flower to the recipient flowers in the same array.

RESULTS

CONCLUSION

The stigma-retraction response enhances the male function of the flower (dispersal of pollen) once the female function (receipt of pollen) has been performed.

species of yucca moth, and that moth may exclusively pollinate just one species of yucca. Such specific relationships provide plants with a reliable mechanism for transferring pollen only to members of their own species.

Most plant–pollinator interactions are much less specific; that is, many different animal species pollinate the same plant species, and the same animal species pollinates many different plant species. However, even these less specific interactions have developed some specialization. Bird-pollinated flowers

Rubeckia fulgida

FIGURE 21.23 See Like a Bee To normal human vision (above), the petals of a black-eyed Susan appear solid yellow. Ultraviolet photography reveals patterns that attract bees to the central region, where pollen and nectar are located.

are often red and odorless. Many insect-pollinated flowers have characteristic odors, and bee-pollinated flowers may have conspicuous markings, or *nectar guides*, that may be visible only in the ultraviolet region of the spectrum, which is visible to bees (FIGURE 21.23).

Fruits aid angiosperm seed dispersal

The ovary of a flower (together with the seeds it contains) develops into a **fruit** after fertilization. The fruit protects the seeds and can also promote seed dispersal by becoming attached to or being eaten by an animal. Fruits are not necessarily fleshy; they can be hard and woody, or small and have modified structures that allow the seeds to be dispersed by wind or water (FIGURE 21.24).

A fruit may consist of only the mature ovary and its seeds, or it may include other parts of the flower or structures associated with it. A *simple fruit* is one that develops from a single carpel or several fused carpels, such as a plum or peach. A raspberry is an example of an *aggregate fruit*—one that develops from several separate carpels of a single flower. Pineapples and figs are examples of *multiple fruits*, formed from a cluster of flowers (an inflorescence). Fruits derived from parts in addition to the carpel and seeds are called *accessory fruits*; examples are apples, pears, and strawberries.

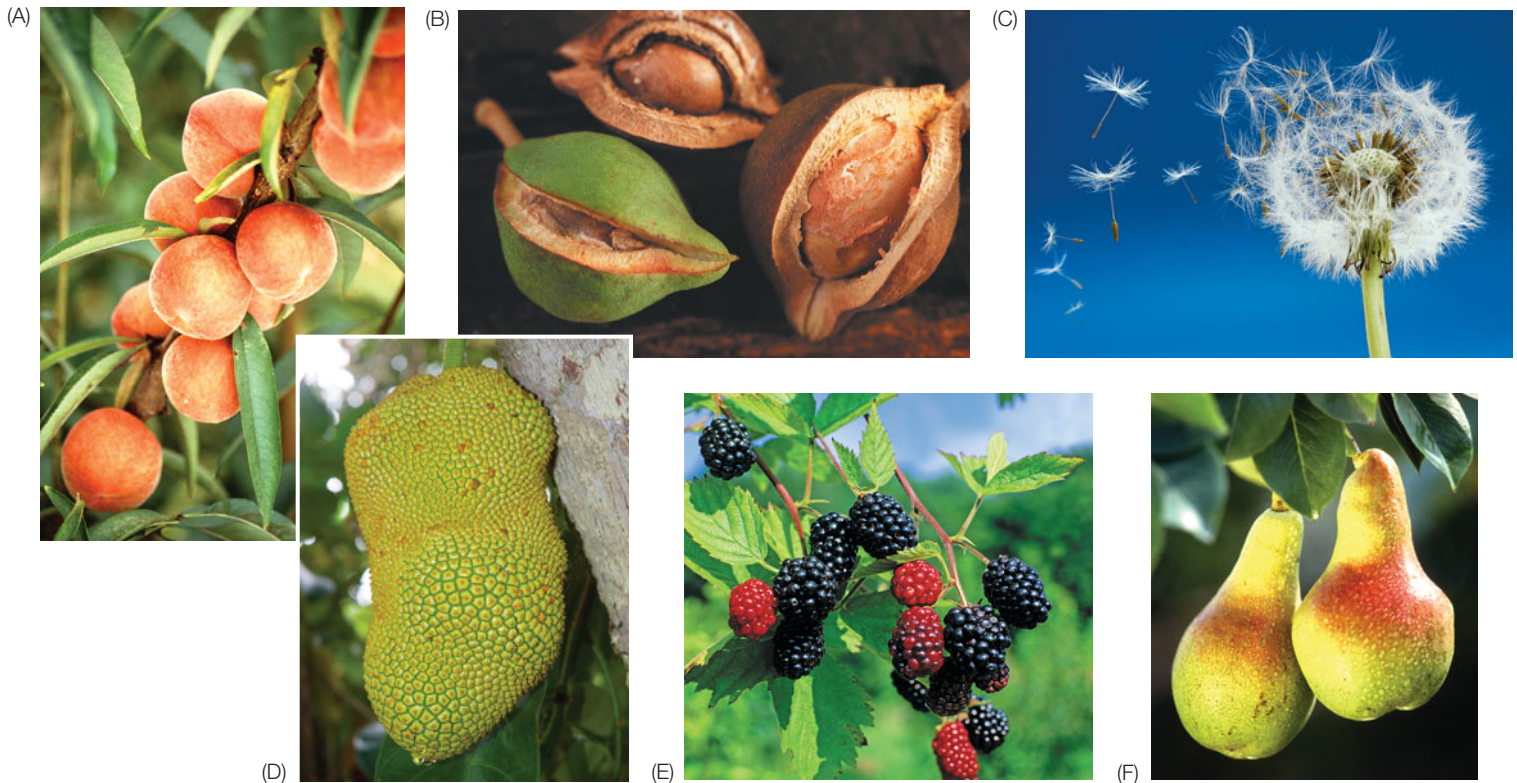

FIGURE 21.24 Fruits Come in Many Forms (A) The single seeds inside the simple fruits of peaches are dispersed by animals. (B) Each macadamia seed is covered by a hard, woody fruit that allows it to survive drought. (C) The highly reduced simple fruits of dandelions are dispersed by wind. (D) A multiple fruit, the jackfruit (*Artocarpus heterophyllus*) of tropical Asia, is the largest tree-borne fruit in the world. (E) An aggregate fruit (blackberry). (F) An accessory fruit (pear).

APPLY THE CONCEPT

Fruits increase the reproductive success of angiosperms

Many fleshy fruits attract animals, which eat the fruit and then disperse the seeds in their feces. If all other factors are equal, large seeds have a better chance of producing a successful seedling than small seeds. So why isn't there selection for larger seeds in the fruits of all plants?

In one study in Peru, the feces of the spider monkey *Ateles paniscus* were found to contain seeds from 71 species of plants. After eating fruit, the monkeys usually travel some distance before defecating, thus dispersing any undigested seeds.

If monkey feces are left undisturbed on the forest floor, rodents eat and destroy the vast majority of the seeds in the feces. To germinate successfully, the seeds in spider monkey feces need to be buried by dung beetles, which makes the discovery and destruction of seeds by rodents much less likely.

Ellen Andresen hypothesized that dung beetles were more likely to remove larger than smaller seeds from spider monkey dung before burying the dung. She added plastic beads of various diameters to spider monkey dung (to simulate seeds) and measured the percentage of beads buried with the dung by the beetles. Use her data to answer the questions at right.

Bead diameter (mm)	2	4	6	8	10	12
Percentage buried	100	76	52	39	20	4

1. Plot bead size (the independent variable) versus percentage of beads buried by dung beetles (the dependent variable).
2. Calculate a regression line for the relationship shown in your graph (see Appendix B). Approximately what percentage of beads with a diameter of 5 mm would you predict would be buried by the beetles? What about beads 14 mm in diameter?
3. What other factors besides size might influence the probability of seed burial by dung beetles? Can you design an experiment to test your hypotheses?
4. Describe how changes in the population sizes of spider monkeys, rodents, and dung beetles would affect the reproductive success of various plant species.

FIGURE 21.25 The Life Cycle of an Angiosperm

Triploid endosperm is produced among many species of angiosperms. One sperm nucleus fertilizes the egg to form the zygote, while the other combines with the two polar nuclei to form the endosperm.

yourBioPortal.com

Go to ANIMATED TUTORIAL 21.3
Life Cycle of an Angiosperm

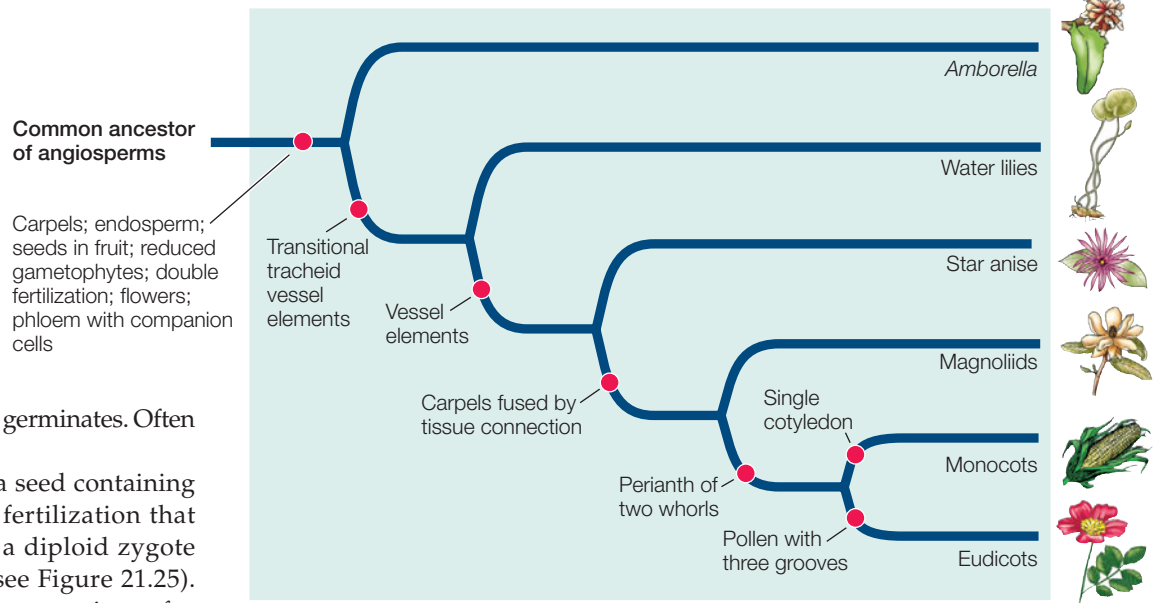

The angiosperm life cycle produces diploid zygotes nourished by triploid endosperms

Like all seed plants, angiosperms are heterosporous. As we have seen, their ovules are contained within carpels rather than being exposed on the surfaces of scales, as in most

gymnosperms. The male gametophytes, as in the gymnosperms, are pollen grains. (Compare the conifer life cycle in Figure 21.17 with Figure 21.25.)

As **FIGURE 21.25** shows, the zygote develops into an embryo, which consists of an embryonic axis (the “backbone” that will become a stem and a root) and one or two **cotyledons**, or “seed leaves.” The cotyledons have different fates in different plants. In many, they serve as absorptive organs that take up and digest the endosperm. In others, they enlarge and become

FIGURE 21.26 Evolutionary Relationships among the Angiosperms Recent analyses of many angiosperm genes have clarified the relationships among the major groups.

photosynthetic when the seed germinates. Often they play both roles.

The ovule develops into a seed containing the products of the double fertilization that characterizes angiosperms: a diploid zygote and a triploid endosperm (see Figure 21.25). The endosperm serves as storage tissue for starch or lipids, proteins, and other substances that will be needed by the developing embryo.

Recent analyses have revealed the phylogenetic relationships of angiosperms

FIGURE 21.26 shows the relationships among the major angiosperm clades. The two largest clades—the **monocots** and the **eudicots**—include

FIGURE 21.27 Monocots and Eudicots Are Not the Only Surviving Angiosperms (A) *Amborella*, a shrub, is sister to the remaining extant angiosperms. Of interest in this photo of a female flower is the pair of false anthers, possibly serving to lure insects that are searching for pollen. (B) The water lily clade was the next to diverge after *Amborella* (see also Figure 21.19A). (C) Star anise and its relatives belong to another early-diverging angiosperm clade. (D,E) The largest clade other than the monocots and eudicots is the magnoliid complex, which includes magnolias and the group known as “Dutchman’s pipe.”

the great majority of angiosperm species. The monocots are so called because they have a single embryonic cotyledon; the eudicots have two. Some familiar angiosperms belong to other clades, among them the water lilies, star anise and its relatives, and the magnoliids (FIGURE 21.27). The **magnoliids** are the sister group to the monocots and eudicots. Although less numerous than the latter two clades, the magnoliids include many familiar and useful plants, such as avocados, cinnamon, black pepper, and magnolias.

The root of the evolutionary tree of flowering plants was once a matter of great controversy. A fundamental challenge was identifying the group that is sister to the remaining angiosperms, and the magnoliid clade was a leading candidate for the position. At the close of the twentieth century, however, an impressive convergence of molecular and morphological evidence led to the conclusion that the sister group to the remaining flowering plants is a clade that today consists of a single species of the genus *Amborella* (see Figure 21.28A). This woody shrub, with cream-colored flowers, lives only on New

FIGURE 21.28 Monocots (A) Monocots include many popular garden flowers such as these hyacinths (*Muscari armeniacum*; blue), tulips (*Tulipa* sp.; red) and daffodils (*Narcissus* sp.; yellow). (B) Monocot grasses such as sugarcane feed the world; wheat, rice, and maize (corn) are also grasses. (C) Seagrasses such as this Neptune's grass form "meadows" in the shallow, sunlit waters of the world's oceans. (D) Palms are among the few monocot trees. Date palms like these are a major food source in some areas of the world.

Caledonia, an island in the South Pacific. Its 5 to 8 carpels are in a spiral arrangement, and it has 30 to 100 stamens. The xylem of *Amborella* lacks vessel elements, which evolved after this deepest split in the angiosperm evolutionary tree.

Representatives of the two largest angiosperm clades are everywhere. The monocots (FIGURE 21.28) include grasses, cattails, lilies, orchids, and palms. The eudicots (FIGURE 21.29) include the vast majority of familiar seed plants, including most herbs (i.e., nonwoody plants), vines, trees, and shrubs. Among the eudicots are such diverse plants as oaks, willows, beans, snapdragons, roses, and sunflowers.

FIGURE 21.29 Eudicots (A) This golden chain tree is a member of the legume clade, an important plant group with a large number of economically important species. (B) Passionflower vines are found throughout the tropics and subtropics. Their flowers are distinguished by elaborate coronas (purple filaments on this flower). (C) The largest flower in the world is *Rafflesia arnoldii*, found in the rainforests of Indonesia. The flower lives as a parasite on tropical vines and has lost its leaf, stem, and even root structures. (D) Cacti comprise a large group of eudicots, with about 1,500 species in the Americas. Many, such as this black lace cactus, bear large flowers for a brief period of each year.

Do You Understand Concept 21.5?

- Explain the difference between pollination and fertilization.
- Give some examples of how animals have affected the evolution of the angiosperms.
- What are the respective roles of the two sperm in double fertilization?
- What are the different functions of flowers, fruits, and seeds?

Once life moved onto land, it was plants that shaped the terrestrial environment. Terrestrial ecosystems could not function without the foods and habitats provided by plants. Plants produce oxygen and remove carbon dioxide from the atmosphere. They play important roles in forming soils and renewing their fertility. Plant roots help hold soil in place, providing protection against erosion by wind and water. Plants also moderate local climates in various ways, such as by increasing humidity, providing shade, and blocking wind. All of these ecosystem services permit a great diversity of fungi and animals to exist on land.

What was Darwin's explanation for the three distinct flowers growing on a single orchid plant?

ANSWER Darwin obtained specimens of the plants in question and dissected the flowers. He was able to demonstrate that the orchid was a single species (*Catasetum macrocarpum*) that bore three distinct types of flowers: megasporangiate (female), microsporangiate (male), and perfect (hermaphroditic). The three types of flowers were remarkable in their morphological differences, which had misled botanists into describing the different flower types as species in different genera. Most plants were either male (specimens identified as *Catasetum*) or female (specimens identified as *Monachanthus*), but some individuals that bore predominately male or female flowers also produced perfect flowers (specimens identified as *Myanthus*).

The case of *C. macrocarpum* demonstrates that some plants blur the lines between strict dioecy (male and female flowers in separate individuals), monoecy (male and female flowers in the same individual), and perfect flowers (flowers with both male and female parts). The flowers on a *C. macrocarpum* are either male or female at any one time, except that plants can bear some perfect flowers as well.

Why do the male and female flowers of *C. macrocarpum* look so different? Part of the explanation is their different roles in pollination. Recall Darwin's observation of a *Catasetum*

flower shooting a packet of pollen at an insect that landed on its flower. The pollinia (pollen packets) and associated structures in male flowers of *Catasetum* are coiled like springs and are released suddenly when disturbed by an insect. This release forcefully propels the pollinia precisely into position on the back of the insect. The insect pollinator of *C. macrocarpum* is a specific bee species, the males of which are attracted to the odor of the flowers. The flowers produce no nectar reward, but the male bee does gather the chemical that produces the scent. The bee then moves on to another flower. When the bee visits a female flower on a different *C. macrocarpum* individual (again attracted by the same scent), no such "loaded spring" awaits. Instead, the morphology of the female flower enhances the removal of the pollinia from the insect's body. In this way, floral morphology makes cross-fertilization more likely and reduces the chances of self-pollination.

Orchids were important in forming Darwin's ideas about the mechanisms of evolution, for they showed that even aspects of the coloration and form of flowers evolved in response to natural selection. This conclusion ran counter to the thinking of the day. For example, Thomas Huxley, one of Darwin's earliest and strongest supporters, doubted that the beauty of color in plants and animals could be explained on the basis of their importance to function. Darwin showed that the beauty of flowers is indeed connected to their reproductive success and is a key element in explaining the great diversity of plants.

21

SUMMARY

concept 21.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes

- Primary endosymbiosis gave rise to chloroplasts and the subsequent diversification of the **Plantae**. The descendants of the first photosynthetic eukaryote include **glaucophytes**, **red algae**, several groups of green algae, and **land plants**, all of which contain chlorophyll *a*. **Review Figure 21.1 and WORKING WITH DATA 21.1**
- **Streptophytes** include the land plants and two groups of green algae. **Green plants**, which include the streptophytes and the remaining green algae, are characterized by the presence of chlorophyll *b* (in addition to chlorophyll *a*). **Review Figure 21.1**
- Land plants, also known as **embryophytes**, arose from an aquatic green algal ancestor related to today's **charophytes**. Land plants develop from embryos that are protected by parental tissue. **Review Figure 21.1**

concept 21.2 Key Adaptations Permitted Plants to Colonize Land

- The acquisition of a **cuticle**, stomata, **gametangia**, a protected embryo, protective pigments, thick spore walls with a protective polymer, and a mutualistic association with a fungus were all adaptations of land plants to terrestrial life.

- All land plant life cycles feature alternation of generations, in which a multicellular diploid **sporophyte** alternates with a multicellular haploid **gametophyte**. **Review Figure 21.4**
- The **nonvascular land plants** comprise the **liverworts**, **hornworts**, and **mosses**. These groups lack specialized vascular tissues for the conduction of water or nutrients through the plant body.
- The life cycles of nonvascular land plants depend on liquid water. The sporophyte is usually smaller than the gametophyte and depends on it for water and nutrition.
- In many land plants, spores form in structures called **sporangia** and gametes form in structures called **gametangia**. Female and male gametangia are, respectively, an **archegonium** and an **antheridium**. **Review Figure 21.6 and ANIMATED TUTORIAL 21.1**

concept 21.3 Vascular Tissues Led to Rapid Diversification of Land Plants

- The **vascular plants** have a **vascular system** consisting of xylem and phloem that conducts water, minerals, and products of photosynthesis through the plant body. The vascular system includes cells called **tracheids**.

- The **rhyniophytes**, the earliest known vascular plants, are known to us only in fossil form. They lacked true roots and leaves but apparently possessed **rhizomes** and **rhizoids**.
- Among living vascular plant groups, the **lycophytes** (club mosses and relatives) have only small, simple leaflike structures (**microphylls**). True leaves (**megaphylls**) are found in **monilophytes** (which include **horsetails** and **leptosporangiate ferns**). The monilophytes and the seed plants are collectively called **euphyllophytes**. **Review WEB ACTIVITY 21.1**
- Roots may have evolved either from rhizomes or from stems. Microphylls probably evolved from sterile sporangia, and megaphylls may have resulted from the flattening and reduction of a portion of a stem system with **overtopping** growth. **Review Figure 21.10**
- The earliest-diverging groups of vascular plants are **homosporous**, but **heterospory**—the production of distinct **megaspores** and **microspores**—has evolved several times. Megaspores develop into female **megagametophytes**; microspores develop into male **microgametophytes**. **Review Figure 21.11 and WEB ACTIVITIES 21.2 and 21.3**

concept 21.4 Seeds Protect Plant Embryos

- All **seed plants** are heterosporous, and their gametophytes are much smaller than (and dependent on) their sporophytes. **Review Figure 21.12**
 - Seed plants do not require liquid water for fertilization. **Pollen grains**, the microgametophytes of seed plants, are carried to a megagametophyte by wind or by animals. Following **pollination**, a **pollen tube** emerges from the pollen grain and elongates to deliver gametes to the megagametophyte. **Review Figure 21.14**
 - An **ovule** consists of the seed plant megagametophyte and the **integument** of sporophytic tissue that protects it. The ovule develops into a **seed**. **Review Figure 21.14B**
 - Seeds are well protected, and they are often capable of long periods of dormancy, germinating when conditions are favorable.
 - Fossils of woody seed ferns are the earliest evidence of seed plants. The surviving groups of seed plants are the **gymnosperms** and **angiosperms**. **Review Figure 21.1**
 - The gymnosperms produce ovules and seeds that are not protected by ovary or fruit tissues. The major gymnosperm groups are the **cycads**, **ginkgos**, **gnetophytes**, and **conifers**. **Review Figure 21.15**
- The megaspores of conifers are produced in woody **cones** called **megastrobili**; the microspores are produced in herbaceous cones called **microstrobili**. Pollen reaches the megagametophyte by way of the **micropyle**, an opening in the integument of the ovule. **Review Figures 21.16 and 21.17, WEB ACTIVITY 21.4, and ANIMATED TUTORIAL 21.2**

concept 21.5 Flowers and Fruits Increase the Reproductive Success of Angiosperms

- **Flowers** and **fruits** are unique to the angiosperms, distinguishing them from the gymnosperms.
- The xylem of angiosperms is more complex than that of the gymnosperms. It contains two specialized cell types: **vessel elements**, which function in water transport, and **fibers**, which play an important role in structural support.
- The ovules and seeds of angiosperms are enclosed in and protected by **carpels**.
- The floral organs, from the base to the apex of the flower, are the **sepals**, **petals**, **stamens**, and **pistil**. Stamens bear microsporangia in **anthers**. The pistil (consisting of one or more carpels) includes an **ovary** containing ovules. The **stigma** is the receptive surface of the pistil. **Review Figure 21.14B and WEB ACTIVITY 21.5**
- The structure of flowers has evolved over time. A flower with both megasporangia and microsporangia is referred to as **perfect**; a flower with only one or the other is **imperfect**. Some plants with perfect flowers have adaptations to prevent self-fertilization. **Review Figures 21.21 and 21.22**
- A **monoecious** species has megasporangiate and microsporangiate flowers on the same plant. A **dioecious** species is one in which megasporangiate and microsporangiate flowers occur on different plants.
- Flowers may be pollinated by wind or by animals. Many angiosperms have coevolved with their animal pollinators.
- Nearly all angiosperms exhibit **double fertilization**, resulting in the production of a diploid zygote and an **endosperm** (which is triploid in most species). **Review Figure 21.25 and ANIMATED TUTORIAL 21.3**
- The oldest evolutionary split among the angiosperms is between the clade represented by the single species in the genus *Amborella* and all the remaining flowering plants. **Review Figure 21.26**
- The most species-rich angiosperm clades are the **monocots** and the **eudicots**. The **magnoliids** are the sister group to the monocots and eudicots.

The Evolution and Diversity of Fungi

22

Alexander Fleming was already a famous scientist in 1928, but his laboratory was often a mess. That year he was studying the properties of *Staphylococcus* bacteria, the agents of dangerous staph infections. In August, he took a long vacation with his family. When he returned in early September, he found that some of his petri dishes of *Staphylococcus* had become infested with a fungus that killed many of the bacteria.

Many scientists would have sighed at the loss, thrown out the petri dishes, and started new cultures of bacteria. But when Fleming looked at the dishes, he saw something exciting. Around each colony of fungi was a ring within which all the bacteria were dead.

Fleming hypothesized that the bacteria-free rings around the fungal colonies were produced by a substance excreted from the fungi, which he initially called “mould juice.” He identified the fungi as members of the genus *Penicillium* and eventually named the antibacterial substance produced by these fungi penicillin. Fleming published his discovery in 1929, but initially, the finding received very little attention.

Over the next decade, Fleming produced small quantities of penicillin for testing as an antibacterial agent. Some of the tests showed promise, but many were inconclusive, and eventually Fleming gave up on the research. But his tests had shown enough promise to attract the attention of several chemists, who worked out the practical problems of producing a stable form of the substance. Clinical trials of this stable form of penicillin were extremely successful, and by 1945 it was being produced and distributed as an antibiotic on a large scale. That same

year, Fleming and two of the chemists, Howard Florey and Ernst Chain, won the Nobel Prize in Medicine for their work on penicillin.

The development of penicillin was one of the most important achievements in modern medicine. Until the introduction of modern antibiotics, the most widespread agents of human death included bacterial infections such as gangrene, tuberculosis, and syphilis. Penicillin proved to be highly effective in curing such infections, and its success led to the creation of the modern pharmaceutical industry. Soon many additional antibiotic compounds were isolated from other fungi or synthesized in the laboratory, leading to a “golden age” of human health.

Have antibiotics derived from fungi eliminated the danger of bacterial diseases in human populations?

All species of the fungus *Penicillium* are recognizable by their dense spore-bearing structures (see Figure 22.17).

KEY CONCEPTS

- 22.1 Fungi Live by Absorptive Heterotrophy
- 22.2 Fungi Can Be Saprobic, Parasitic, Predatory, or Mutualistic
- 22.3 Major Groups of Fungi Differ in Their Life Cycles
- 22.4 Fungi Can Be Sensitive Indicators of Environmental Change

concept 22.1 Fungi Live by Absorptive Heterotrophy

Fungi are organisms that digest their food outside their bodies. They secrete digestive enzymes to break down large food molecules in the environment, then absorb the breakdown products through the plasma membranes of their cells in a process known as **absorptive heterotrophy**. This mode of nutrition is successful in a wide variety of environments. Many fungi are *saprobes*, which absorb nutrients from dead organic matter. Others are *parasites*, which absorb nutrients from living hosts. Still others are *mutualists* living in intimate associations with other organisms that benefit both partners.

Modern fungi are believed to have evolved from a unicellular protist ancestor that had a flagellum. The probable common ancestor of the animals was also a flagellated protist much like the living choanoflagellates (see Figure 23.2). Current evidence, including the sequences of many genes, suggests that the fungi, choanoflagellates, and animals share a common ancestor not shared by other eukaryotes. These three lineages are often grouped together as the *opisthokonts* (FIGURE 22.1). A synapomorphy of the opisthokonts is a flagellum that, if present, is posterior, as in animal sperm. The flagella of all other eukaryotes are anterior.

Synapomorphies that distinguish the fungi as a group among the opisthokonts include absorptive heterotrophy and the presence of chitin in their cell walls. The fungi represent one of four large, independent evolutionary origins of multicellular organisms (plants, brown algae, and animals are the other three).

Unicellular yeasts absorb nutrients directly

Most fungi are multicellular, but single-celled species are found in most fungal groups. Unicellular, free-living fungi are referred to as **yeasts** (FIGURE 22.2). Some fungi that have yeast life stages also have multicellular life stages. Thus the term “yeast” does not refer to a single taxonomic group, but rather to a lifestyle that has evolved multiple times. Yeasts live in liquid or moist environments and absorb nutrients directly across their cell surfaces.

The ease with which many yeasts can be cultured, combined with their rapid growth rates, has made them ideal model

FIGURE 22.1 Fungi in Evolutionary Context Absorptive heterotrophy and the presence of chitin in their cell walls distinguish the fungi from other opisthokonts.

Saccharomyces cerevisiae

FIGURE 22.2 Yeasts Unicellular, free-living fungi are known as yeasts. Many yeasts reproduce by budding—mitosis followed by asymmetrical cell division—as those shown here are doing.

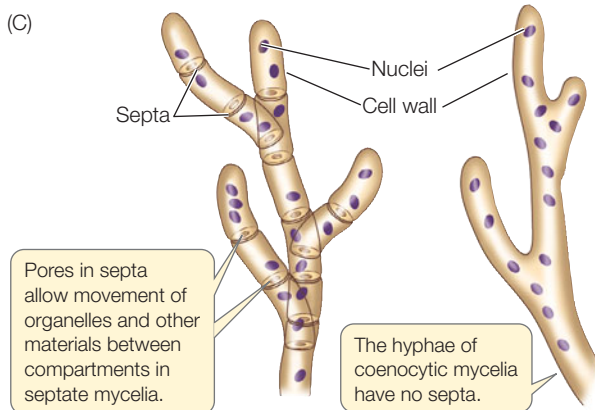

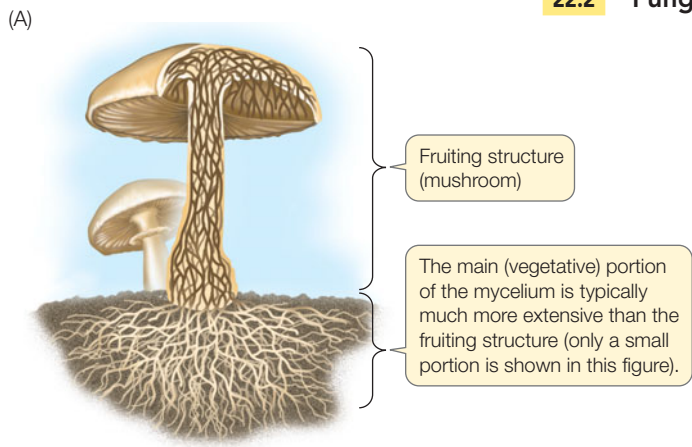

organisms for study in the laboratory. They present many of the same advantages to laboratory investigators as do many bacteria, but because they are eukaryotes, their genome structures and cells are much more like those of humans and other eukaryotes than are those of bacteria.

Multicellular fungi use hyphae to absorb nutrients

The body of a multicellular fungus is called a **mycelium** (plural *mycelia*). A mycelium is composed of a mass of individual tubular filaments called **hyphae** (singular *hypha*; FIGURE 22.3A,B), in which absorption of nutrients takes place. The cell walls of the hyphae are greatly strengthened by microscopic fibrils of *chitin*, a nitrogen-containing structural polysaccharide. In some species of fungi, the hyphae are subdivided into cell-like compartments by *incomplete* cross-walls called **septa** (singular *septum*); these hyphae are referred to as **septate**. Septa do not completely close off compartments in the hyphae. Gaps at the centers of the septa known as *pores* allow organelles—sometimes even nuclei—to move in a controlled way between compartments (FIGURE 22.3C). In other species of fungi, the hyphae lack septa, but may contain hundreds of nuclei; these hyphae are referred to as **coenocytic**. The coenocytic condition results from repeated nuclear divisions without cytokinesis.

The total hyphal growth of a fungal mycelium (not the growth of an individual hypha) may exceed 1 kilometer a day! The hyphae may be widely dispersed to forage for nutrients over a large area, or they may clump together in a cottony mass to exploit a rich nutrient source. Some species of fungi produce sexual spores, in which case portions of the mycelium become reorganized into a reproductive *fruiting structure*, such as a mushroom. The mycelial mass is often far larger than the mushroom alone. The mycelium of one individual fungus in Michigan covers 15 hectares underground and weighs more than a blue whale (the largest animal). Aboveground, this individual is evident only as isolated clumps of mushrooms.

Certain modified hyphae, called *rhizoids*, anchor some fungi to their substrate (i.e., the dead organism or other matter on which they feed). These rhizoids are not homologous to the

rhizoids of plants, and they are not specialized to absorb nutrients and water.

Fungi are in intimate contact with their environment

The filamentous hyphae of a fungus give it a unique relationship with its physical environment. The fungal mycelium has an enormous surface area-to-volume ratio compared with that of most large multicellular organisms. This large ratio is a marvelous adaptation for absorptive heterotrophy. Throughout the mycelium (except in fruiting structures), all of the hyphae are very close to their food source.

FIGURE 22.3 Mycelia Are Made Up of Hyphae (A) The fruiting structure of a club fungus is short-lived, but the filamentous, nutrient-absorbing mycelium can be long-lived and cover large areas. (B) The minute individual hyphae of fungal mycelia can penetrate small spaces. In this artificially colored micrograph, hyphae (yellow structures) of a dry-rot fungus are penetrating the xylem tissues of a log. (C) The hyphae of septate fungal species are divided into organelle-containing compartments by porous septa, while coenocytic hyphae have no septa.

The downside of the large surface area-to-volume ratio of the mycelium is its tendency to lose water rapidly in a dry environment. Thus fungi are most common in moist environments. You have probably observed the tendency of molds, toadstools, and other fungi to appear in damp places.

Another characteristic of some fungi is a tolerance for highly hypertonic environments (those with a solute concentration higher than their own; see Concept 5.2). Many fungi are more resilient than bacteria in hypertonic surroundings. Jelly in the refrigerator, for example, will not become a growth medium for bacteria because it is too hypertonic to those organisms, but it may eventually harbor mold colonies. Mold in the refrigerator illustrates yet another trait of many fungi: tolerance of temperature extremes. Many fungi grow in temperatures as low as -6°C , and some tolerate temperatures above 50°C .

Do You Understand Concept 22.1?

- Describe the relationship between fungal structure and absorptive heterotrophy.
- What are the advantages and disadvantages to multicellular fungi of the large surface-to-volume ratio of the mycelium?

Fungi are important components of healthy ecosystems. They interact with other organisms in many ways, some of which are harmful and some beneficial to those other organisms.

concept 22.2 Fungi Can Be Saprobic, Parasitic, Predatory, or Mutualistic

Without the fungi, our planet would be very different. Picture Earth with only a few stunted plants and watery environments choked with the remains of dead organisms. Fungi do much of Earth's garbage disposal. Fungi not only help clean up the landscape and form soil, but also play a key role in recycling mineral nutrients. Furthermore, the colonization of the terrestrial environment was made possible in large part by associations fungi formed with land plants and other organisms.

Saprobic fungi are critical to the planetary carbon cycle

Saprobic fungi, along with bacteria, are the major decomposers on Earth, contributing to the decay of nonliving organic

matter and thus to recycling of the elements used by living things. In forests, for example, the mycelia of fungi absorb nutrients from fallen trees, thus decomposing their wood. Fungi are the principal decomposers of cellulose and lignin, the main components of plant cell walls (most bacteria cannot break down these materials). Other fungi produce enzymes that decompose keratin and thus break down animal structures such as hair and nails.

Were it not for the fungal decomposers, Earth's carbon cycle would fail: great quantities of carbon atoms would remain trapped forever on forest floors and elsewhere. Instead, those carbon atoms are returned to the atmosphere in the form of CO₂ by fungal respiration, where they are again available for photosynthesis by plants.

LINK Earth's carbon cycle is described in Concept 46.3

In fact, there was a time in Earth's history when populations of saprobic fungi declined dramatically. Vast tropical swamps existed during the Carboniferous period, as we saw in Chapter 21. When plants in these swamps died, they began to form peat. Peat formation led to acidification of the swamps; that acidity, in turn, drastically reduced the fungal population. The result? With the decomposers largely absent, large quantities of peat remained on the swamp floor and over time were converted into coal.

In contrast to their decline during the Carboniferous, fungi did very well at the end of the Permian, a quarter of a billion years ago, when the aggregation of continents produced volcanic eruptions that triggered a planetwide mass extinction of many other organisms (see Chapter 18). The fossil record shows that even as 96 percent of all multicellular species became extinct, fungi flourished—demonstrating both their hardiness and their role in recycling the elements in dead plants and animals.

Simple sugars and the breakdown products of complex polysaccharides are the favored source of carbon for saprobic fungi. Most fungi obtain nitrogen from proteins or the products of protein breakdown. Many fungi can use nitrate (NO₃⁻) or ammonium (NH₄⁺) ions as their sole source of nitrogen. No known fungus can get its nitrogen directly from inorganic nitrogen gas, however, as can some bacteria and plant–bacteria associations (that is, fungi cannot fix nitrogen; see Concept 19.3).

What happens when a fungus faces a dwindling food supply? A common strategy is to reproduce rapidly and abundantly. When conditions are good, fungi produce great quantities of spores, but the rate of spore production is commonly even higher when nutrient supplies go down. The spores may then remain dormant until conditions improve, or they may be dispersed to areas where nutrient supplies are higher.

Not only are fungal spores abundant in number, but they are extremely tiny and easily spread by wind or water (FIGURE 22.4). These attributes virtually ensure that they will be scattered over great distances, and that at least some of them will find conditions suitable for growth. No wonder we find fungi just about everywhere.

Lycoperdon perlatum

FIGURE 22.4 Spores Galore Puffballs (a type of club fungus) disperse trillions of spores in great bursts. Few of the spores travel very far, however; some 99 percent of them fall within 100 meters of the parent puffball.

Some fungi engage in parasitic or predatory interactions

Whereas saprobic fungi obtain their energy, carbon, and nitrogen directly from dead organic matter, other species of fungi obtain their nutrition from parasitic—and even predatory—interactions.

PARASITIC FUNGI Mycologists distinguish between two classes of parasitic fungi based on their degree of dependence on their host. *Facultative* parasites can grow on living organisms, but can also grow by themselves (including on artificial media). *Obligate* parasites can grow only on their specific living host, often a plant or insect species. The fact that their growth depends on a living host shows that obligate parasites have specialized nutritional requirements.

The filamentous structure of fungal hyphae is especially well suited to a life of absorbing nutrients from living plants. The slender hyphae of a parasitic fungus can invade a plant through stomata, through wounds, or in some cases, by direct penetration of epidermal cell walls (FIGURE 22.5A). Once inside the plant, the hyphae branch out to expand the mycelium. Some hyphae produce **haustoria**, branching projections that push through cell walls into living plant cells, absorbing the nutrients within those cells. The haustoria do not break through the plasma membranes inside the cell walls; they simply invaginate into the membranes, so that the plasma membrane fits them like a glove (FIGURE 22.5B). Fruiting structures may form, either within the plant body or on its surface. Some parasitic fungi live in a close physical (*symbiotic*) relationship with their host that is usually not lethal to the plant. Others,

however, are *pathogenic*, sickening or even killing the host from which they derive nutrition.

PATHOGENIC FUNGI Although most human diseases are caused by bacteria or viruses, fungal pathogens are a major cause of death among people with compromised immune systems. Most people with AIDS die of fungal diseases, such as the pneumonia caused by *Pneumocystis jirovecii* or incurable diarrhea caused by other fungi. *Candida albicans* and certain other yeasts also cause severe diseases, such as esophagitis (which impairs swallowing), in individuals with AIDS and in individuals taking immunosuppressive drugs. Fungal diseases are a growing international health problem, requiring vigorous research. Our limited understanding of the basic biology of these fungi still hampers our ability to treat the diseases they cause. Various fungi cause other, less threatening human diseases, such as ringworm and athlete's foot.

The worldwide decline of amphibian species has been linked to the spread of a chytrid fungus, *Batrachochytrium dendrobatidis*. Genetic analyses indicate that the fungus populations attacking amphibian populations around the world are genetically almost identical, which suggests a recent introduction of the fungus across the globe. This chytrid appears to be endemic to southern Africa, and its spread around the world may have been initiated in the 1930s with exports of the African clawed frog (*Xenopus laevis*), which was once widely used in human pregnancy tests.

Fungi are by far the most important plant pathogens, causing crop losses amounting to billions of dollars. Bacteria and viruses are less important than fungi as plant pathogens. Major fungal diseases of crop plants include black stem rust of wheat and other diseases of wheat, corn, and oats. The agent of black stem rust is *Puccinia graminis*, which has a complicated life cycle that involves two plant hosts (wheat and barberry). In an epidemic in 1935, *P. graminis* was responsible for the loss of about one-fourth of the wheat crop in Canada and the United States.

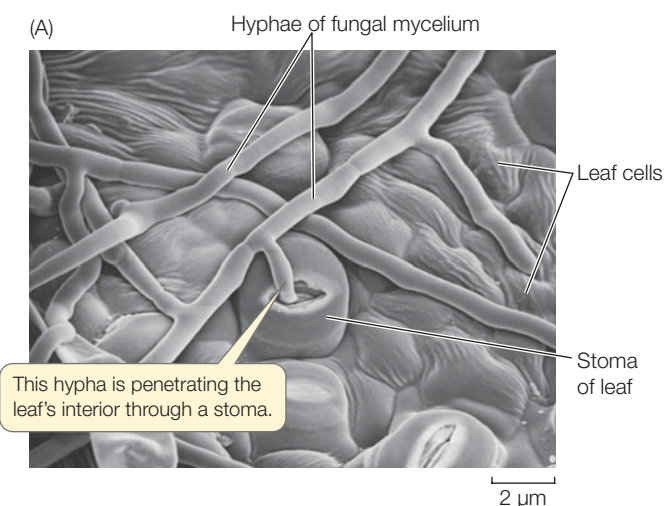

FIGURE 22.5 Invading a Leaf (A) Hyphae of the mildew *Phyllactinia guttata* growing on the surface of a hazel leaf. (B) Haustoria are fungal hyphae that push into the living cells of plants, from which they absorb nutrients.

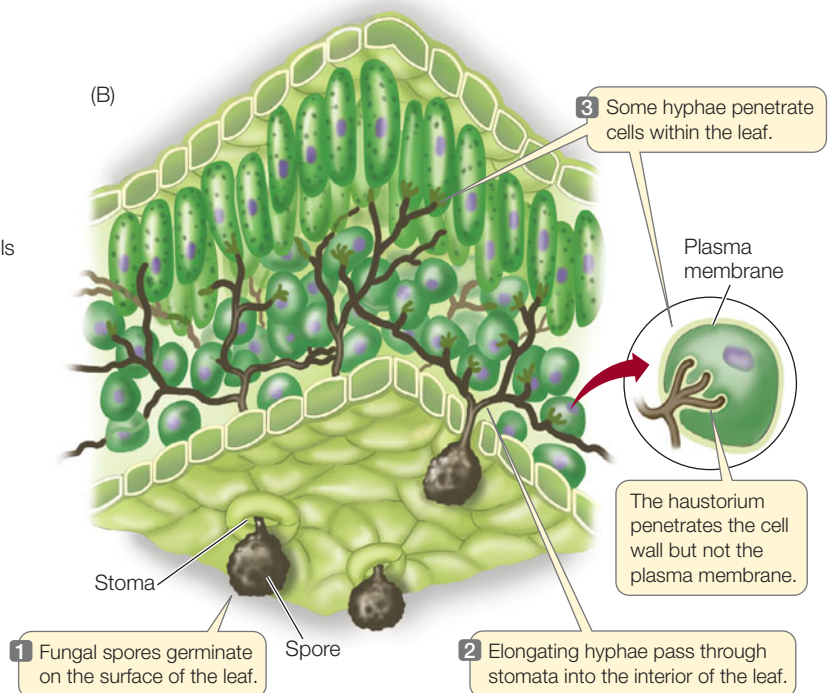

FRONTIERS Although many pathogenic fungi cause problems when they attack agricultural crops, pathogenic fungi of the genus *Fusarium* can benefit agriculture by killing certain weed species, such as witchweed, a serious pest of cereal crops. Another strain of *Fusarium* has been proposed as a tool in the war against cocaine. The fungus could be applied to kill coca plants, the source of the drug. The use of *Fusarium* to kill coca plants is highly controversial, however, as the fungus may not be specific to this target species.

PREDATORY FUNGI Some fungi have adaptations that enable them to function as active predators, trapping nearby microscopic protists or animals. The most common predatory strategy seen in fungi is to secrete sticky substances from the hyphae so that passing organisms stick to them. The hyphae then quickly invade the trapped prey, growing and branching within it, spreading through its body, absorbing nutrients, and eventually killing it.

A more dramatic adaptation for predation is the constricting ring formed by some species of soil fungi (**FIGURE 22.6**). When nematodes (tiny roundworms) are present in the soil, these fungi form three-celled rings with a diameter that just fits a nematode. A nematode crawling through one of these rings stimulates the fungus, causing the cells of the ring to swell and trap the worm. Fungal hyphae quickly invade and digest the unlucky victim.

Mutualistic fungi engage in relationships beneficial to both partners

Certain kinds of relationships between fungi and other organisms have nutritional consequences for both partners. Two relationships of this type are highly specific and are **sympiotic** (the

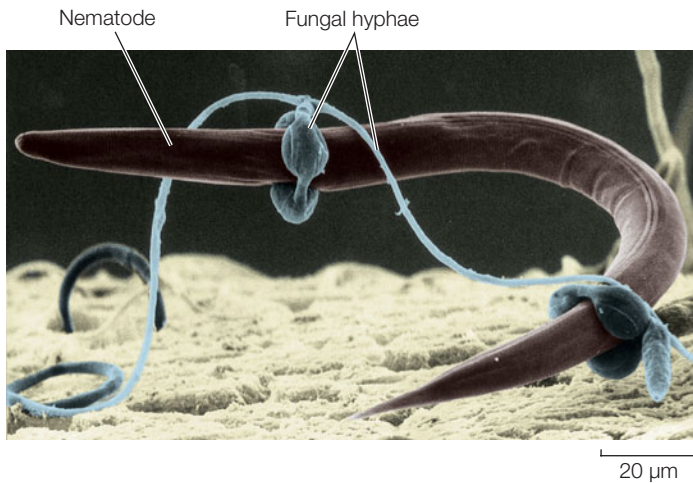

FIGURE 22.6 Fungus as Predator A nematode is trapped by hyphal rings of the soil-dwelling fungus *Arthrobotrys dactyloides*.

partners live in close, permanent contact with each other) as well as **mutualistic** (the relationship benefits both partners; see Chapter 44).

Lichens are associations of a fungus with a cyanobacterium, a unicellular photosynthetic alga, or both. **Mycorrhizae** (singular *mycorrhiza*) are associations between fungi and the roots of plants. In these associations, the fungus obtains organic compounds from its photosynthetic partner and provides it with minerals and water in return, so that the partner's nutrition is also promoted.

LICHENS A lichen is not a single organism, but rather a meshwork of two radically different species: a fungus and a photosynthetic microorganism. Together the organisms that constitute a lichen can survive some of the harshest environments on Earth (although they are sensitive to poor air quality; see Concept 22.4). The biota of Antarctica, for example, features more than a hundred times as many species of lichens as of plants. Relatively little experimental work has focused on lichens, perhaps because they grow so slowly—typically less than 1 centimeter in a year.

There are nearly 30,000 described “species” of lichens, each of which is assigned the name of its fungal component. These fungal components may constitute as many as 20 percent of all fungal species. Most of them are sac fungi (Ascomycota). Some of them are able to grow independently without a photosynthetic partner, but most have never been observed in nature other than in a lichen association. The photosynthetic component of a lichen is most often a unicellular green alga, but it can be a cyanobacterium, or may even include both.

Lichens are found in all sorts of exposed habitats: on tree bark, on open soil, and on bare rock. Reindeer moss (not a moss at all, but the lichen *Cladonia subtenuis*) covers vast areas in Arctic, sub-Arctic, and boreal regions, where it is an important part of the diets of reindeer and other large mammals. The body forms of lichens fall into three principal categories: *Crustose* (crustlike) lichens look like colored powder dusted over their substrate (**FIGURE 22.7A**). *Foliose* (leafy) and *fruticose* (shrubby) lichens may have complex forms (**FIGURE 22.7B**).

(A) Crustose (*Caloplaca* sp.)

(B) Fruticose (*Cladonia* sp.)

Foliose (*Parmotrema* sp.)

FIGURE 22.7 Lichen Body Forms Lichens fall into three principal categories—crustose, fruticose, or foliose—based on their body form. (A) A crustose lichen growing on the surface of an exposed rock. (B) Fruticose lichens (above) appear “shrubby,” whereas foliose lichens (below) look “leafy.”

Visible in a cross section of a typical foliose lichen are a tight upper region of fungal hyphae, a layer of photosynthetic cyanobacteria or algae, a looser hyphal layer, and finally hyphal rhizoids that attach the entire structure to its substrate (**FIGURE 22.8**). The meshwork of fungal hyphae takes up some mineral nutrients needed by the photosynthetic cells and provides a suitably moist environment for them by holding water tenaciously. The fungi obtain fixed carbon from the photosynthetic products of the algal or cyanobacterial cells.

Within the lichen, the fungal hyphae are tightly pressed against the algal or cyanobacterial cells and sometimes even invade them without breaching the plasma membrane (as we described earlier for haustoria in parasitic fungi; see Figure 22.5). The bacterial or algal cells not only survive these indignities, but continue their growth and photosynthesis. In fact, the algal cells in a lichen “leak” photosynthetic products at a greater rate than do similar cells growing on their own, and photosynthetic cells taken from lichens grow more rapidly on their own than when associated with a fungus. On this basis, we could consider lichen fungi to be parasitic on their photosynthetic

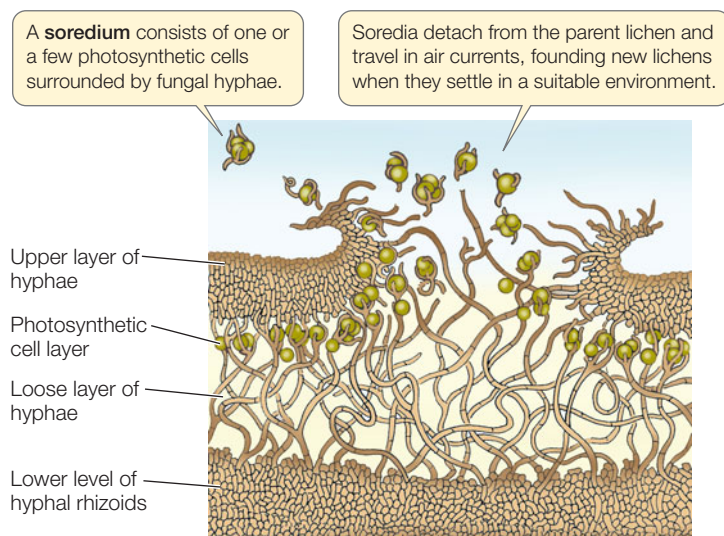

FIGURE 22.8 Lichen Anatomy Cross section showing the layers of a foliose lichen and the release of soredia.

partners. In many places where lichens grow, however, the photosynthetic cells could not grow at all on their own.

Lichens can reproduce simply by fragmentation of the vegetative body (the *thallus*), or by means of specialized structures called *soredia* (singular *soredium*). Soredia consist of one or a few photosynthetic cells bound by fungal hyphae. The soredia become detached from the lichen, are dispersed by air currents, and upon arriving at a favorable location, develop into a new lichen thallus. Alternatively, the fungal partner may go through its sexual cycle, producing haploid spores. When these spores are discharged, however, they disperse alone, unaccompanied by the photosynthetic partner.

Lichens are often the first colonists on new areas of bare rock. They get most of the mineral nutrients they need from the air and rainwater, augmented by minerals absorbed from dust. A lichen begins to grow shortly after a rain, as it begins to dry. As it grows, the lichen acidifies its environment slightly, and this acidity contributes to the slow breakdown of rocks, an early step in soil formation. With further drying, the lichen's photosynthesis ceases. The water content of the lichen may drop to less than 10 percent of its dry weight, at which point it becomes highly insensitive to extremes of temperature.

MYCORRHIZAE Many vascular plants depend on a symbiotic association with fungi. Unassisted, the root hairs of such plants often do not take up enough water or minerals to sustain growth. However, their roots usually do become infected with fungi, forming an association called a mycorrhiza. Mycorrhizae are of two types, distinguished by whether or not the fungal hyphae penetrate the plant cell walls.

In *ectomycorrhizae*, the fungus wraps around the root, and its mass is often as great as that of the root itself

(**FIGURE 22.9A**). The fungal hyphae wrap around individual cells in the root, but do not penetrate the cell walls. An extensive web of hyphae penetrates the soil in the area around the root, so that up to 25 percent of the soil volume near the root may be fungal hyphae. The hyphae attached to the root increase the surface area for the absorption of water and minerals, and the mass of hyphae in the soil acts like a sponge to hold water in the neighborhood of the root. Infected roots are short, swollen, and club-shaped, and they lack root hairs.

The fungal hyphae of *arbuscular mycorrhizae* enter the root and penetrate the cell walls of the root cells, forming arbuscular (treelike) structures inside the cell wall but outside the plasma membrane. These structures, like the haustoria of parasitic fungi and the contact regions of fungal hyphae and photosynthetic cells in lichens, become the primary site of exchange between plant and fungus (**FIGURE 22.9B**). As in the ectomycorrhizae, the fungus forms a vast web of hyphae leading from the root surface into the surrounding soil.

LINK Concept 25.2 contains a detailed description of the role of arbuscular mycorrhizae in plant nutrition

The mycorrhizal association is important to both partners. The fungus obtains needed organic compounds, such as sugars and amino acids, from the plant. In return, the fungus, because of its very high surface area-to-volume ratio and its ability to penetrate the fine structure of the soil, greatly increases the plant's ability to absorb water and minerals (especially phosphorus). The fungus may also provide the plant with certain growth hormones and may protect it against attack

FIGURE 22.9 Mycorrhizal Associations (A) Ectomycorrhizal fungi wrap themselves around a plant root, increasing the area available for absorption of water and minerals. (B) Hyphae of arbuscular mycorrhizal fungi infect the root internally and penetrate the root cell walls, branching within the cells and forming a treelike structure, the arbuscule. (For purposes of this scanning electron micrograph, the cell cytoplasm was removed to better visualize the arbuscule.)

by disease-causing microorganisms. Plants that have active arbuscular mycorrhizae typically are a deeper green and may resist drought and temperature extremes better than plants of the same species that have little mycorrhizal development.

Attempts to introduce some plant species to new areas have failed until a bit of soil from the native area (presumably containing the fungus necessary to establish mycorrhizae) was provided. Trees without ectomycorrhizae do not grow well in the absence of abundant nutrients and water, so the health of our forests depends on the presence of ectomycorrhizal fungi. Many agricultural crops require inoculation of seeds with appropriate mycorrhizal fungi prior to planting. Without these fungi, the plants are unlikely to grow well, or in some cases at all. Certain plants that live in nitrogen-poor habitats, such as cranberry bushes and orchids, invariably have mycorrhizae. Orchid seeds will not germinate in nature unless they are already infected by the fungus that will form their mycorrhizae. Plants that lack chlorophyll always have mycorrhizae, which they often share with the roots of green, photosynthetic plants. In effect, these plants without chlorophyll are feeding on nearby green plants, using the fungus as a bridge.

Endophytic fungi protect some plants from pathogens, herbivores, and stress

In a tropical rainforest, 10,000 or more fungal spores may land on a single leaf each day. Some are plant pathogens, some do not affect the plant at all, and some invade the plant in a beneficial way. Fungi that live within aboveground parts of plants without causing obvious deleterious symptoms are called **endophytic fungi**. Recent research has shown that endophytic fungi are abundant in plants in all terrestrial environments.

Among the grasses, individual plants with endophytic fungi are more resistant to pathogens and to insect and mammalian herbivores than are plants lacking endophytes. The fungi produce alkaloids (nitrogen-containing compounds) that are toxic to animals. The alkaloids do not harm the host plant; in fact, some plants produce alkaloids (such as nicotine) themselves. The fungal alkaloids also increase the ability of grasses to resist stress of various types, including drought (water shortage) and salty soils. Such resistance is useful in agriculture.

The role, if any, of endophytic fungi in most broad-leaved plants is unclear. They may convey protection against pathogens, or they may simply occupy space within leaves without conferring any benefit, but also without doing harm. The benefit, in fact, might be all for the fungus.

Do You Understand Concept 22.2?

- What is the role of fungi in Earth's carbon cycle?
- Describe the nature and benefits of the lichen association.
- Why do plants grow better when infected with mycorrhizal fungi?

Before molecular techniques clarified the phylogenetic relationships among fungi, one criterion used for assigning fungi to taxonomic groups was the nature of their life cycles. The next section takes a closer look at life cycles in the six major groups of fungi.

concept 22.3 Major Groups of Fungi Differ in Their Life Cycles

Major fungal groups were originally defined by their structures and processes for sexual reproduction and also, to a lesser extent, by other morphological differences. Although fungal life cycles are even more diverse than was once realized, specific types of life cycles generally distinguish the six major groups of fungi—microsporidia, chytrids, zygospor fungi (Zygomycota), arbuscular mycorrhizal fungi (Glomeromycota), sac fungi (Ascomycota), and club fungi (Basidiomycota). **FIGURE 22.10** diagrams the evolutionary relationships of these groups as they are understood today.

The chytrids and the zygospor fungi may not represent monophyletic groups, as they each consist of several distantly

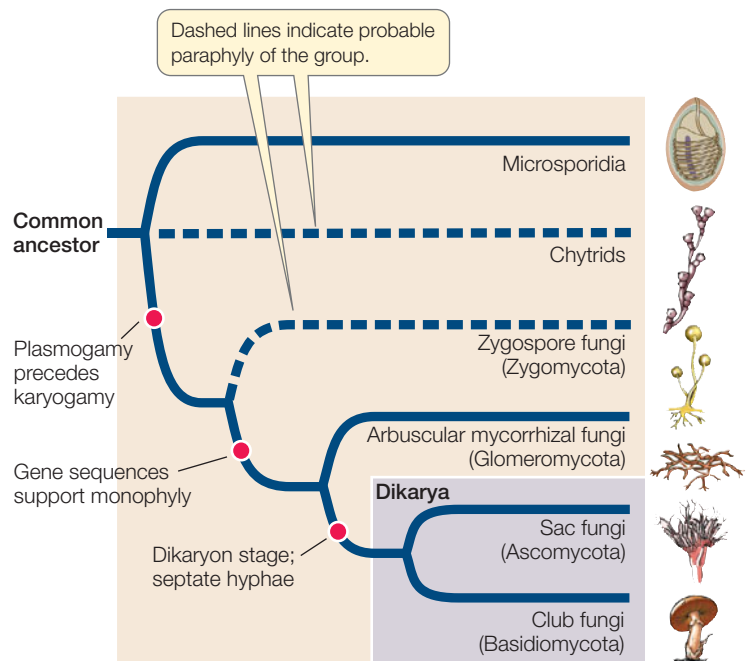

FIGURE 22.10 A Phylogeny of the Fungi Microsporidia are reduced, parasitic fungi whose relationships among the fungi are uncertain. They may be the sister group of most other fungi or more closely related to particular groups of chytrids or zygospor fungi. The dashed lines indicate that chytrids and zygospor fungi are thought to be paraphyletic; the relationships of the lineages within these two informal groups (see Table 22.1) are not yet well resolved. The sac fungi and club fungi together form the clade Dikarya.

yourBioPortal.com

Go to WEB ACTIVITY 22.1
Fungal Phylogeny

related lineages that retain some ancestral features. The clades that are thought to be monophyletic within these two informal groupings are listed in **TABLE 22.1**. Recent evidence from DNA analyses has established the placement of the microsporidia among the fungi, the likely paraphyly of the chytrids and the zygosporic fungi, the independence of arbuscular mycorrhizal fungi from the other fungal groups, and the monophyly of sac fungi and club fungi.

Fungi reproduce both sexually and asexually

Both asexual and sexual reproduction occur among the fungi (**FIGURE 22.11**). Asexual reproduction takes several forms:

- The production of (usually) haploid spores within structures called *sporangia*
- The production of haploid spores (not enclosed in sporangia) at the tips of hyphae; such spores are called *conidia* (Greek *konis*, “dust”)
- Cell division by unicellular fungi—either a relatively equal division of one cell into two (*fission*) or an asymmetrical division in which a smaller daughter cell is produced (*budding*)
- Simple breakage of the mycelium

Asexual reproduction in fungi can be spectacular in terms of spore quantity. A 2.5-centimeter colony of *Penicillium*, the mold that produces the antibiotic penicillin, can produce as many as 400 million conidia. The air we breathe contains as many as 10,000 fungal spores per cubic meter.

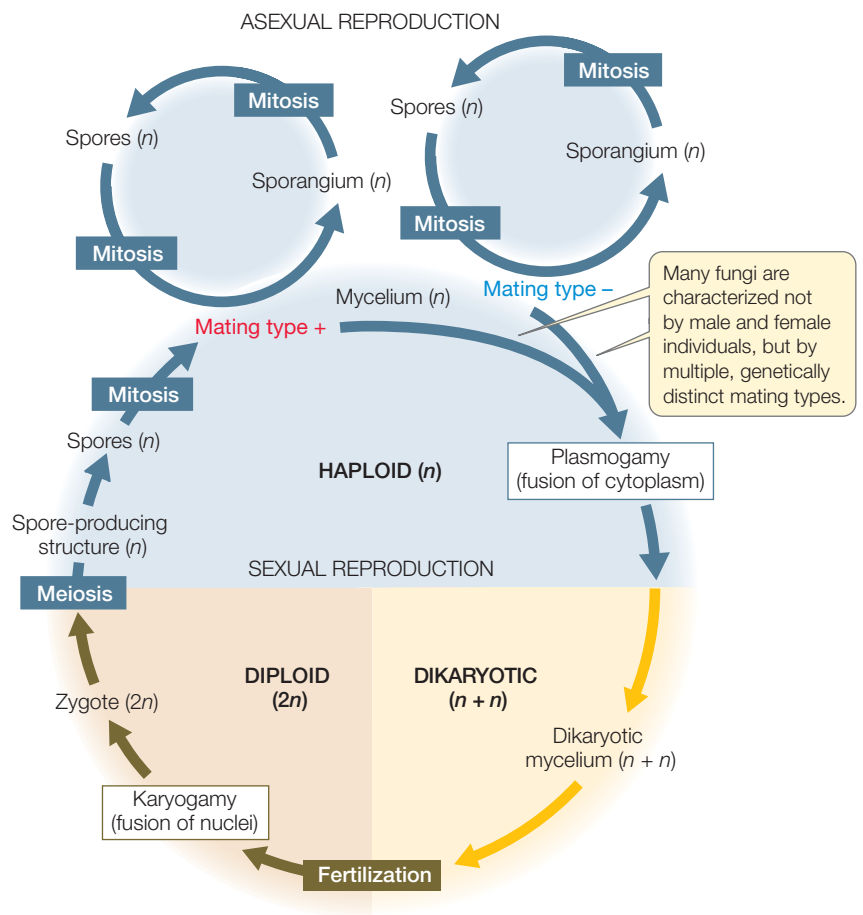

FIGURE 22.11 A Fungal Life Cycle Environmental conditions may determine which mode of reproduction—sexual or asexual—takes place at a given time.

TABLE 22.1 Classification of the Fungi

GROUP	COMMON NAME	FEATURES
Microsporidia	Microsporidia	Intracellular parasites of animals; greatly reduced, among smallest eukaryotes known; polar tube used to infect hosts
Chytrids (paraphyletic) ^a Chytridiomycota Neocallimastigomycota Blastocladiomycota	Chytrids	Mostly aquatic and microscopic; zoospores have flagella
Zygomycota (paraphyletic) ^a Entomophthoromycotina Kickxellomycotina Mucoromycotina Zoopagomycotina	Zygosporic fungi	Reproductive structure is a unicellular zygospore with many diploid nuclei in a zygosporangium; hyphae coenocytic; usually no fleshy fruiting body
Glomeromycota	Arbuscular mycorrhizal fungi	Form arbuscular mycorrhizae on plant roots; only asexual reproduction is known
Ascomycota	Sac fungi	Sexual reproductive saclike structure known as an ascus, which contains haploid ascospores; hyphae septate; dikaryon
Basidiomycota	Club fungi	Sexual reproductive structure is a basidium, a swollen cell at the tip of a specialized hypha that supports haploid basidiospores; hyphae septate; dikaryon

^aThe formally named groups within the chytrids and Zygomycota are each thought to be monophyletic, but their relationships to one another (and to Microsporidia) are not yet well resolved.

Sexual reproduction is rare (or even unknown) in some groups of fungi, but common in others. Sexual reproduction may not occur in some species, or it may occur so rarely that biologists have never observed it. Species in which no sexual stage has been observed were once placed in a separate taxonomic group because knowledge of the sexual life cycle was considered necessary for classifying fungi. Now, however, these species can be related to other species of fungi through analysis of their DNA sequences.

Sexual reproduction in some fungi features an interesting twist: There is no morphological distinction between female and male structures, or between female and male individuals. Rather, there is a genetically determined distinction between two or more **mating types**. Individuals of the same mating type cannot mate with each another, but they can mate with individuals of another mating type within the same species, thus avoiding self-fertilization. Individuals of different mating types differ genetically, but are often visually and physiologically indistinguishable.

Microsporidia are highly reduced, parasitic fungi

Microsporidia are unicellular parasitic fungi. They are among the smallest eukaryotes known, with infective spores that are only 1–40 μm in diameter. About 1,500 species have been described, but many more species are thought to exist. Their relationships among the eukaryotes have puzzled biologists for many decades.

Microsporidia lack true mitochondria, although they have reduced structures known as *mitosomes* that are derived from mitochondria. Unlike mitochondria, however, mitosomes contain no DNA; the mitochondrial genome has been completely transferred to the nucleus. Because microsporidia lack mitochondria, biologists initially suspected that they represented an early lineage of eukaryotes that diverged before the endosymbiotic event from which mitochondria evolved. The presence of mitosomes, however, indicates that this hypothesis is incorrect. DNA sequence analysis, along with the fact that their cell walls contain chitin, has confirmed that the microsporidia are in fact highly reduced, parasitic fungi, although their exact placement among the fungal lineages is still being investigated.

Microsporidia are obligate intracellular parasites of animals, especially of insects, crustaceans, and fishes. Some species are known to infect mammals, including humans. Most infections by microsporidia cause chronic diseases in the host, with effects that include weight loss, reduced fertility, and shortened life span. The host cell is penetrated by a *polar tube* that grows from the microsporidian spore, and the contents of the spore, called the *sporoplasm*, are injected into the host (**FIGURE 22.12**). The sporoplasm then replicates within the host cell and produces new infective spores. The life cycle of some species is complex and involves multiple hosts, whereas other species infect a single host. In some insects, parasitic microsporidia are transmitted vertically (i.e., from parent to offspring). Reproduction is thought to be strictly asexual in some microsporidians, but includes poorly understood asexual and sexual cycles in other species.

FIGURE 22.12 Invasion of the Microsporidia Spores The polar tubes of microsporidian spores transfer the contents of the spores into the host's cells. The species shown here infects many animals, including humans.

Most chytrids have an aquatic life cycle

The **chytrids** include several distinct lineages of aquatic microorganisms once classified with the protists. However, morphological evidence (cell walls that consist primarily of chitin) and molecular evidence support their classification as early-diverging fungi. In this book we use the term “chytrid” to refer to all three of the formally named clades listed as chytrids in Table 22.1, but some mycologists use this term to refer to only one of those clades, the Chytridiomycota. There are fewer than one thousand described species among the three groups of chytrids.

Like the animals (and many other eukaryotes), most chytrids possess flagellated gametes. The retention of this trait reflects the aquatic environment in which fungi first evolved. Chytrids are the only fungi that have flagella at any life cycle stage.

Chytrids reproduce both sexually and asexually. The alternation between multicellular haploid (n) and multicellular diploid ($2n$) generations that evolved in plants and certain protist groups is seen in some chytrids as well (**FIGURE 22.13A**). Alternation of generations is not usual in the life cycles of other fungal groups. These chytrids have flagellated spores as well as flagellated gametes.

Chytrids may be parasitic (on organisms such as algae, mosquito larvae, nematodes, and amphibians) or saprobic. Some have complex mutualistic relationships with foregut-fermenting animals such as cattle and deer. Many chytrids live in freshwater habitats or in moist soil, but some are marine. Some chytrids are unicellular, others have rhizoids, and still others have coenocytic hyphae.

Some fungal life cycles feature separate fusion of cytoplasm and nuclei

Most members of the remaining four groups of fungi are terrestrial. Although the terrestrial fungi grow in moist places, they do not have motile gametes, and they do not release gametes

(A) Chytrids

The life cycle of some aquatic chytrids features alternation of generations.

(B) Zygosporangium fungi (Zygomycota)

The sporangium of zygosporangium fungi contains haploid nuclei that are incorporated into spores.

FIGURE 22.13 Sexual Life Cycles of Chytrids and Zygosporangium Fungi (A) These chytrids are the only fungi that possess flagella at any stage of the life cycle. Their flagellated gametes and zoospores link them to the animals. (B) The unicellular zygospore, which contains multiple diploid nuclei, is a resting structure unique to the zygosporangium fungi.

into the environment. Instead, the cytoplasm of two individuals of different mating types fuse (a process called **plasmogamy**) before their nuclei fuse (a process called **karyogamy**). Therefore, liquid water is not required for fertilization. Sexual species of terrestrial fungi include some zygosporangium fungi, sac fungi, and club fungi.

Zygosporangium fungi reproduce sexually when adjacent hyphae of two different mating types release chemical signals called *pheromones*, which cause them to grow toward each other. These hyphae produce gametangia, in which the nuclei replicate without cell division, resulting in multiple haploid nuclei in both gametangia. The two gametangia then fuse to form a *zygosporangium* with many haploid nuclei from each mating type (FIGURE 22.13B). Pairs of haploid nuclei then form multiple diploid nuclei within a unicellular **zygospore**, which is the basis of the name of the zygosporangium fungi. A thick, multilayered cell wall develops to protect the zygospore. The zygospore is a resting stage that may remain dormant for months before its nuclei undergo meiosis and a stalked **sporangiophore** sprouts, bearing one or many *sporangia*. Each sporangium contains the products of meiosis: haploid nuclei that are incorporated into spores. These spores disperse and germinate to form a new generation of haploid hyphae.

The zygosporangium fungi include four major lineages of terrestrial fungi that live on soil as saprobes, as parasites of insects and spiders, or as mutualists of other fungi and invertebrate animals. They produce no cells with flagella, and only one diploid cell—the zygospore—appears in the entire life cycle. Their hyphae are coenocytic. Most species do not form a fleshy fruiting structure; rather, the hyphae spread in a radial pattern from the spore, with occasional stalked sporangiophores reaching up into the air (FIGURE 22.14).

More than a thousand species of zygosporangium fungi have been described. One species you may have seen is *Rhizopus stolonifer*, the black bread mold. *Rhizopus* produces many stalked sporangiophores, each bearing a single sporangium containing hundreds of minute spores (see Figure 22.13B).

Life Cycle of a Zygomycete

Arbuscular mycorrhizal fungi form symbioses with plants

Arbuscular mycorrhizal fungi (Glomeromycota) are terrestrial fungi that associate with plant roots in a symbiotic, mutualistic relationship (see Figure 22.9B). As we noted earlier in this chapter, these associations are important for most species of plants, which benefit from absorption of water and mineral nutrients through the large surface area of the fungal mycelium. Many of the fungi found in soils are arbuscular mycorrhizal fungi. Fewer than 200 species have been described, but 80–90 percent of all plants have associations with them. Molecular systematic studies have suggested that arbuscular mycorrhizal fungi are the sister group to the Dikarya (sac fungi and club fungi).

FIGURE 22.14 Zygosporangium Fungi Produce Sporangiophores

The transparent structures are sporangiophores growing on decomposing animal dung. The sporangiophores grow toward the light and end in tiny sporangia, which the stalked sporangiophores can eject as far as 2 meters. Animals ingest sporangia that land on grass and then disseminate the spores in their feces.

The hyphae of arbuscular mycorrhizal fungi are coenocytic. These fungi use glucose from their plant partners as their primary energy source, converting it into other, fungus-specific sugars that cannot return to the plant. Arbuscular mycorrhizal fungi reproduce asexually; there is not yet any direct evidence that they reproduce sexually.

The dikaryotic condition is a synapomorphy of sac fungi and club fungi

In the two remaining groups of fungi—the sac fungi and the club fungi—certain hyphae have a nuclear configuration other than the familiar haploid or diploid states (FIGURES 22.15A, B). In these fungi, sexual reproduction begins in two distinct steps: karyogamy (fusion of nuclei) occurs long after plasmogamy (fusion of cytoplasm), so that *two genetically different haploid nuclei coexist and divide within the each cell of the mycelium*. This stage of the fungal life cycle is called a **dikaryon** (“two nuclei”) and its ploidy is indicated as $n + n$. The dikaryon is a synapomorphy of these two groups, which are placed together in a clade called Dikarya.

Eventually, specialized fruiting structures form, within which pairs of genetically dissimilar nuclei—one from each parent—fuse, giving rise to zygotes long after the original “mating.” The diploid zygote nucleus undergoes meiosis, producing four haploid nuclei. The mitotic descendants of those nuclei become spores, which germinate to give rise to the next haploid generation.

A life cycle with a dikaryon stage has several unusual features. First, there are no gamete *cells*, only gamete *nuclei*. Second, the

(A) Sac fungi (Ascomycota)

In sac fungi, the products of meiosis are borne in a microscopic sac called an ascus. The fleshy fruiting bodies consist of both dikaryotic and haploid hyphae.

FIGURE 22.15 Sexual Life Cycles among the Dikarya (A) The fruiting structure of sexually reproducing sac fungi is the ascoma, often a cup-shaped structure. (B) The sexual species of club fungi produce fruiting structures known as basidiomata, which include many familiar mushrooms, puffballs, and bracket fungi.

(B) Club fungi (Basidiomycota)

In club fungi, the products of meiosis are borne on the surface of the gills on pedestals called basidia. Fruiting bodies consist solely of dikaryotic hyphae, and the dikaryotic phase can last a long time.

(A) *Aleuria aurantia***FIGURE 22.16 Sac Fungi**

(A) These brilliant red cups are the ascomata of a cup fungus. (B) Morels, which have a spongelike ascoma and a subtle flavor, are considered a culinary delicacy by humans.

only true diploid structure is the zygote, although for a long period the genes of both parents are present in the dikaryon and can be expressed. In effect, the dikaryon is neither diploid ($2n$) nor haploid (n); rather, it is *dikaryotic* ($n + n$). Therefore, a harmful recessive mutation in one nucleus may be compensated for by a normal allele on the same chromosome in the other nucleus, and dikaryotic hyphae often have characteristics that are different from their n or $2n$ products. The dikaryotic condition is perhaps the most distinctive of the genetic peculiarities of the fungi.

Go to WEB ACTIVITY 22.2
Life Cycle of a Dikaryotic Fungus

The sexual reproductive structure of sac fungi is the ascus

The **sac fungi** (Ascomycota) are a large and diverse group of fungi found in marine, freshwater, and terrestrial habitats. There are approximately 64,000 known species, nearly half of which are the fungal partners in lichens. The hyphae of sac fungi are segmented by more or less regularly spaced septa. A pore in each septum permits extensive movement of cytoplasm and organelles (including nuclei) from one segment to the next.

Sac fungi are distinguished by the production of sacs called **asci** (singular *ascus*), which after meiosis and spore cleavage contain sexually produced haploid *ascospores* (see Figure 22.15A). The ascus is the characteristic sexual reproductive structure of the sac fungi. In the past, the sac fungi were classified on the basis of whether or not the asci are contained within a specialized fruiting structure known as an **ascoma** (plural *ascomata*) and the morphology of that fruiting structure. DNA sequence analyses have resulted in a revision of these traditional groupings, however.

Some species of sac fungi are unicellular yeasts. The thousand or so species in this group are among the most important domesticated fungi. Perhaps the best known is baker's, or brewer's, yeast (*Saccharomyces cerevisiae*; see Figure 22.2), which metabolizes glucose obtained from its environment into ethanol and carbon dioxide by fermentation. It forms carbon dioxide bubbles in bread dough and gives baked bread its light texture. Although they are baked away in bread making (which produces the

pleasant aroma of baking bread), the ethanol and carbon dioxide are both retained when the yeast ferments grain into beer. Other sac fungus yeasts live on fruits such as figs and grapes and play an important role in the making of wine. Many others are associated with insects; in the guts of some insects, they provide enzymes that break down materials that are otherwise difficult for the insects to digest, especially cellulose.

Sac fungus yeasts reproduce asexually by budding. Sexual reproduction takes place when two adjacent haploid cells of opposite mating types fuse. In some species, the resulting zygote buds to form a diploid cell population. In others, the zygote nucleus undergoes meiosis immediately; when this happens, the entire cell becomes an ascus. Depending on whether the products of meiosis then undergo mitosis, a yeast ascus usually contains either eight or four ascospores. Ascospores germinate to become haploid cells. The sac fungus yeasts have lost the dikaryon stage.

Most sac fungi are filamentous species, such as the cup fungi (FIGURE 22.16), in which the ascomata are cup-shaped and can be as large as several centimeters across (although most are much smaller). The inner surfaces of the cups, which are covered with a mixture of specialized hyphae and asci, produce huge numbers of spores. The edible ascomata of some species, including morels and truffles, are regarded by humans as gourmet delicacies (and can sell at prices higher than gold). The underground ascomata of truffles have a strong odor that attracts mammals such as pigs, which then eat and disperse the fungus.

The sac fungi also include many of the filamentous fungi known as *molds*. Many of these species are parasites of flowering plants. Chestnut blight and Dutch elm disease are both caused by molds. The chestnut blight fungus, which was introduced to the United States in the 1890s, had destroyed the American chestnut as a commercial species by 1940. Before the blight, this species accounted for more than half the trees in the eastern U.S. forests. Another familiar story is that of the American elm. Sometime before 1930, the Dutch elm disease fungus (first discovered in the Netherlands, but native to Asia) was introduced into the U.S. on infected elm logs from Europe. Spreading rapidly—sometimes by way of connected root systems—the fungus destroyed great numbers of American elm trees.

Other plant pathogens among the sac fungi include the powdery mildews that infect cereal crops, lilacs, and roses, among many other plants. Mildews can be a serious problem

*Penicillium roquefortii*5 μ m

FIGURE 22.17 Conidia Chains of conidia (yellow) are developing at the tips of specialized hyphae arising from a *Penicillium* mold; compare the conidia of this species (which is used to produce “bleu” cheese) with the species shown on p. 437.

to farmers and gardeners, and a great deal of research has focused on ways to control these agricultural pests.

Brown molds of the genus *Aspergillus* are important in some human diets. *A. tamarii* acts on soybeans in the production of soy sauce, and *A. oryzae* is used in brewing the Japanese alcoholic beverage sake. Some species of *Aspergillus* that grow on grains and on nuts such as peanuts and pecans produce extremely carcinogenic (cancer-inducing) compounds called *aflatoxins*. In the United States and most other industrialized countries, moldy grain infected with *Aspergillus* is thrown out. In Africa, where food is scarcer, the grain gets eaten, moldy or not, and causes severe health problems, including high levels of certain cancers.

Penicillium is a genus of green molds, of which some species produce the antibiotic penicillin, presumably for defense against

competing bacteria. Two species, *P. camembertii* and *P. roquefortii*, are the organisms responsible for the characteristic strong flavors of Camembert and Roquefort cheeses, respectively.

The filamentous sac fungi reproduce asexually by means of conidia that form at the tips of specialized hyphae (FIGURE 22.17). Small chains of conidia are produced by the millions and can survive for weeks in nature. The conidia are what give molds their characteristic colors.

The sexual reproductive cycle of filamentous sac fungi includes the formation of a dikaryon, although this stage is relatively brief compared with that in club fungi. Many filamentous sac fungi form multinucleate mating structures (see Figure 22.15A). Mating structures of two different mating types fuse and produce a dikaryotic mycelium, with nuclei from both mating types. The dikaryotic mycelium typically forms a cup-shaped ascoma, which bears the asci. Only with the formation of asci do the nuclei from the two mating types finally fuse. Both nuclear fusion and the subsequent meiosis that produces haploid ascospores take place within individual asci. The ascospores are ultimately released (sometimes shot off forcefully) by the ascus to begin the new haploid generation.

The sexual reproductive structure of club fungi is the basidium

Club fungi (Basidiomycota) produce some of the most spectacular fruiting structures found among the fungi. These fruiting structures, called **basidiomata** (singular *basidioma*), include puffballs (see Figure 22.4), some of which may be more than half a meter in diameter, mushrooms of all kinds, and the bracket fungi often encountered on trees and fallen logs in a damp forest. About 30,000 species of club fungi have been described. They include about 4,000 species of mushrooms, including both poisonous and edible species (FIGURE 22.18A). Bracket fungi (FIGURE 22.18B) do great damage to both cut

(A) *Armillaria* sp.(B) *Coriolus versicolor*

FIGURE 22.18 Club Fungus Basidiomata (A) These edible mushrooms are the fruiting structures of a honey fungus; mycelia of this genus form connected underground masses that cover many hectares and, if considered as one organism, are among the largest and longest-lived organisms in the world. (B) Saprophytic bracket fungi are agents of decay on dead wood.

lumber and timber stands; by breaking down wood, they also play an important role in the carbon cycle. Some of the most damaging plant pathogens are club fungi, including the rust fungi and smut fungi that parasitize cereal grains. In contrast, other club fungi contribute to the survival of plants as fungal partners in ectomycorrhizae.

The hyphae of club fungi characteristically have septa with small, distinctive pores. The **basidium** (plural *basidia*), a swollen cell at the tip of a specialized hypha, is the characteristic sexual reproductive structure of the club fungi. In mushroom-forming club fungi, the basidia typically form on specialized structures known as *gills*. The basidium is the site of nuclear fusion and meiosis and thus plays the same role in the club fungi as the ascus does in the sac fungi and the zygosporangium does in the zygosporangium fungi.

After nuclei fuse in the basidium, the resulting diploid nucleus undergoes meiosis, and the four resulting haploid nuclei are incorporated into haploid *basidiospores*, which form on tiny stalks on the outside of the basidium (see Figure 22.15B). A single basidioma of the common bracket fungus *Ganoderma applanatum* can produce as many as 4.5 trillion basidiospores in one growing season. Basidiospores typically are forcibly discharged from their basidia and then germinate, giving rise to hyphae with haploid nuclei. As these hyphae grow, haploid hyphae of different mating types meet and fuse, forming dikaryotic hyphae, each cell of which contains two nuclei, one from each parent hypha. The dikaryotic mycelium grows and eventually, when triggered by rain or another environmental cue, produces a basidioma. The dikaryon stage may persist for years—some club fungi live for decades or even centuries. This pattern contrasts with the life cycle of the sac fungi, in which the dikaryon is found only in the stages leading up to formation of the asci.

Do You Understand Concept 22.3?

- Explain the concept of mating types. How are they different from male and female sexes?
- Explain how the microsporidia infect the cells of their animal hosts.
- What feature of the chytrids suggests that the fungi had an aquatic ancestor?
- What is the role of the zygospore in the life cycle of zygospore fungi?
- What distinguishes the fruiting structures of sac fungi from those of club fungi?

Fungi are of interest to biologists because the roles they play in interactions with other organisms. But they can also be useful as tools for studying environmental problems and for finding solutions to those problems.

concept 22.4

Fungi Can Be Sensitive Indicators of Environmental Change

We've already noted the important roles that fungi play in ecosystems, from decomposers to pathogens to plant mutualists. These diverse ecological roles have led to their use in studies of environmental change and in environmental remediation.

Lichen diversity and abundance indicate air quality

Lichens can live in many harsh environments where few other species can survive, as we saw in Concept 22.2. In spite of their hardiness, however, lichens are highly sensitive to air pollution because they are unable to excrete any toxic substances they absorb. This sensitivity means that lichens are good biological indicators of air pollution levels. It also explains why they are not commonly found in heavily industrialized regions or in large cities.

Monitoring the diversity and abundance of lichens growing on trees is a practical and inexpensive system for gauging air quality around cities (FIGURE 22.19). Maps of lichen diversity provide environmental biologists with a tool for tracking the distribution of air pollutants and their effects. Sensitive biological indicators of pollution, such as lichen growth, allow biologists to monitor air quality without the use of specialized equipment. Lichens are naturally distributed across the environment, and they can also provide a long-term measure of the effects of air pollution across many seasons and years.

Fungi contain historical records of pollutants

Biologists deposit samples of many groups of organisms in the collections of natural history museums. These museum collections serve many purposes. Biologists borrow specimens from these museums to study many aspects of evolution and ecology, and the collections document changes in the biota of our planet over time.

Collections of fungi made over many decades or centuries provide a record of the environmental pollutants that were present when the fungi were growing. Biologists can analyze these historical samples to see how different sources of pollutants were affecting our environment before anyone thought to take direct measures. These long-term records are also useful for analyzing the effectiveness of cleanup efforts and regulatory programs for controlling environmental pollutants.

Reforestation may depend on mycorrhizal fungi

When a forest is cut down, it is not just the trees that are lost. A forest is an ecosystem that depends on the interaction of many species. As we have discussed, many plants depend on close relationships with mycorrhizal fungal partners. When trees are removed from a site, the populations of mycorrhizal fungi

FIGURE 22.19 More Lichens, Better Air Lichen abundance and diversity are excellent indicators of air quality. (A) Many lichen species show luxuriant growth on trees in suitable environments with few pollutants in the air. (B) As air quality declines, so do the number and diversity of lichens.

APPLY THE CONCEPT

Fungi can be sensitive indicators of environmental change

Biologists analyzed museum samples of lace lichens (*Ramalina menziesii*) collected near San Francisco, California from 1892 to 2006 for evidence of lead contamination. They measured concentrations of lead (Pb) as well as the ratios of its isotopes ^{206}Pb and ^{207}Pb . The latter measurement was used to determine the source of lead contamination. Possible sources included a lead smelter that operated in the area from 1885 to 1971 (which produced emissions with a $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of about 1.15–1.17); leaded gasoline in use from the 1930s to the early 1980s, peaking in 1970 (with a $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of 1.18–1.23); and resuspension of historic lead contamination as atmospheric aerosols in recent decades (with an intermediate $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of about 1.16–1.19).

Before analyzing the data, use the information provided above to formulate hypotheses about these questions: What trends in atmospheric lead concentrations would you expect to see? What $^{206}\text{Pb}/^{207}\text{Pb}$ ratios would you expect to find at different times from the late 1800s to the early 2000s?

1. Plot lead concentration in the lichen samples against year of sample collection. Make a second plot of $^{206}\text{Pb}/^{207}\text{Pb}$ ratio against year of sample collection.
2. Do your analyses support the hypotheses you formulated? Are your hypotheses consistent with your analyses of both lead concentrations and $^{206}\text{Pb}/^{207}\text{Pb}$ ratios through time? If not, how would you modify your hypotheses, and what additional tests can you design to test your ideas?

SAMPLE	YEAR COLLECTED	LEAD CONCENTRATION (μg OF Pb/g OF LICHEN)	$^{206}\text{Pb}/^{207}\text{Pb}$ RATIO
1	1892	11.9	1.165
2	1894	4.0	1.155
3	1906	13.7	1.154
4	1907	22.9	1.157
5	1945	49.9	1.187
6	1957	34.2	1.185
7	1978	50.9	1.221
8	1982	10.0	1.215
9	1983	4.6	1.224
10	1987	1.0	1.198
11	1988	1.3	1.199
12	1995	1.9	1.202
13	2000	0.4	1.184
14	2006	1.8	1.184

there decline rapidly. If we wish to restore the forest on the site, we cannot simply replant it with trees and other plants and expect them to survive. The mycorrhizal fungal community must be reestablished as well. For large forest restoration projects, a planned succession of plant growth and soil improvement is often necessary before forest trees can be replanted. As the community of soil fungi gradually recovers, trees that have been inoculated with appropriate mycorrhizal fungi in tree nurseries can be planted to reintroduce greater diversity to the soil fungal community.

Do You Understand Concept 22.4?

- What are some advantages of using surveys of lichen diversity and museum collections of lichens to measure long-term changes in air quality, compared with direct measurements of atmospheric pollutants?
- Can you develop a strategy for tree harvest that would ease the difficulty and expense of reforestation projects by retaining viable communities of mycorrhizal fungi?
- What distinguishes the fruiting structures of sac fungi from those of club fungi?

Whether living on their own or in symbiotic associations, fungi have spread successfully over much of Earth since their origin from a protist ancestor. An earlier ancestor of fungi also gave rise to the choanoflagellates and the animals, as we will describe in Chapter 23.

Have antibiotics derived from fungi eliminated the danger of bacterial diseases in human populations?

ANSWER Beginning in the 1940s, antibiotics derived from fungi ushered in a “golden age” of freedom from bacterial infections. Today, however, that golden age may be coming to an end. Many antibiotics are losing their effectiveness as pathogenic bacteria evolve resistance to these drugs (**FIGURE 22.20**). Some bacterial diseases, such as tuberculosis, are increasingly serious health problems because of the evolution of new strains that are resistant to most classes of antibiotics.

Why do bacteria evolve resistance to antibiotics? Mutations that allow bacteria to survive in the presence of an antibiotic are favored by selection in a bacterial population whenever an antibiotic is used. Such mutations often carry a cost to the bacteria, so they may be selected against in the absence of regular antibiotic use. To reduce the rate of evolution of

FIGURE 22.20 Penicillin Resistance In a petri dish similar to those in Alexander Fleming’s lab, four strains of a pathogenic bacterium have been cultured along with *Penicillium* mold. One strain is resistant to the mold’s antibiotic substance, as is evidenced by its growth up to the mold.

antibiotic resistance, antibiotics should be used only for the treatment of appropriate bacterial diseases, and then used to completely clear the bacterial infection.

Most medical antibiotics are semisynthetic, meaning that they are chemically modified forms of the substances that are found naturally in fungi and other organisms. Fungi naturally produce antibiotic compounds to defend themselves against bacterial growth and to reduce competition from bacteria for nutritional resources. These naturally occurring compounds are usually chemically modified to increase their stability, to improve their effectiveness, and to facilitate synthetic production.

From the late 1950s to the late 1990s, no new major classes of antibiotics were discovered. In recent years, however, three new classes of antibiotics have been synthesized based on the information learned from naturally occurring antibiotics, leading to improved treatment of some formerly resistant strains of bacteria.

Fungi have also been used to combat non-bacterial diseases. One of the more unusual applications of fungi is in the war against malaria, one of the biggest killers of humans in sub-Saharan Africa. Biologists have discovered that two species of fungi, *Beauveria bassiana* and *Metarhizium anisopliae*, can kill malaria-causing mosquitoes when applied to mosquito netting. Mosquitoes have not yet shown evidence of developing resistance to these biological pathogens, unlike most chemical pesticides.

22

SUMMARY

concept
22.1

Fungi Live by Absorptive Heterotrophy

- Fungi are opisthokonts with **absorptive heterotrophy** and with chitin in their cell walls. Fungi have various nutritional modes: some are saprobes, others are parasites, and some are mutualists. **Yeasts** are unicellular, free-living fungi. **Review Figure 22.1**
- The body of a multicellular fungus is a **mycelium**—a meshwork of filaments called **hyphae**. Hyphae may be **septate** (having **septa**) or **coenocytic** (multinucleate). **Review Figure 22.3**
- Fungi are often tolerant of hypertonic environments, and many are tolerant of extreme temperatures.

concept
22.2

Fungi Can Be Saprobic, Parasitic, Predatory, or Mutualistic

- Saprobic fungi, as decomposers, make crucial contributions to the recycling of elements, especially carbon.
- Many fungi are parasites of plants, harvesting nutrients from plant cells by means of **haustoria**. **Review Figure 22.5**
- Certain fungi have relationships with other organisms that are both **symbiotic** and **mutualistic**.
- Some fungi associate with unicellular green algae, cyanobacteria, or both to form **lichens**, which live on exposed surfaces of rocks, trees, and soil. **Review Figure 22.8**
- **Mycorrhizae** are mutualistic associations of fungi with plant roots. They improve a plant's ability to take up nutrients and water.
- **Endophytic fungi** live within plants and may provide protection to their hosts from herbivores and pathogens.

concept
22.3

Major Groups of Fungi Differ in Their Life Cycles

- The microsporidia, chytrids, and zygosporangium fungi diversified early in fungal evolution. The mycorrhizal fungi, sac fungi, and club fungi form a monophyletic group, and the latter two groups form the clade Dikarya. **Review Figure 22.10 and Table 22.1; see WEB ACTIVITY 22.1**
- Many species of fungi reproduce both sexually and asexually. In many fungi, sexual reproduction occurs between individuals of different **mating types**. **Review Figure 22.11**

- The **microsporidia** are highly reduced unicellular fungi. They are obligate intracellular parasites that infect several animal groups.
- The three distinct lineages of **chytrids** all have flagellated gametes. **Review Figure 22.13A**
- In the sexual reproduction of terrestrial fungi, hyphae fuse, allowing "gamete" nuclei to be transferred. **Plasmogamy** (fusion of cytoplasm) precedes **karyogamy** (fusion of nuclei).
- **Zygosporangium fungi** have a resting stage with many diploid nuclei, known as a **zygosporangium**. Their fruiting structures are simple stalked **sporangiophores**. **Review Figure 22.13B and ANIMATED TUTORIAL 22.1**
- **Arbuscular mycorrhizal fungi** form symbiotic associations with plant roots. They are only known to reproduce asexually. Their hyphae are coenocytic.
- In sac fungi and club fungi, a mycelium containing two genetically different haploid nuclei, called a **dikaryon**, is formed. The dikaryotic ($n + n$) condition is unique to the fungi. **Review Figures 22.15 and WEB ACTIVITY 22.2**
- **Sac fungi** have septate hyphae; their sexual reproductive structures are **asci**. Many sac fungi are partners in lichens. Filamentous sac fungi produce fleshy fruiting structures called **ascomata**. The dikaryon stage in the sac fungus life cycle is relatively brief. **Review Figure 22.15A**
- **Club fungi** have septate hyphae. Many club fungi are plant pathogens, although mushroom-forming species are more familiar to most people. Their fruiting structures are called **basidiomata**, and their sexual reproductive structures are **basidia**. The dikaryon stage may last for years. **Review Figure 22.15B**

concept
22.4

Fungi Can Be Sensitive Indicators of Environmental Change

- The diversity and abundance of lichen growth on trees provide sensitive indications of air quality. **Review Figure 22.19**
- Museum collections of fungi provide a historical record of atmospheric pollutants that were present when the fungi were growing.
- Reforestation projects require restoration of the mycorrhizal fungal community.

Animal Origins and Diversity

23

Almost 1.5 million species of animals have been discovered and named by biologists. One group of animals, the insects, accounts for about 1 million of these species, or more than half of all known species of living organisms. Although these numbers may seem incredibly large, they represent a relatively small fraction of the total animal diversity that is thought to exist on Earth.

As recently as the 1980s, many biologists thought that about half of existing insect species had been described, but today they think that the number of described insect species may be a much smaller fraction of the total number of living species. Why did they change their minds?

A simple but important field study published in 1988 suggested that the number of existing insect species had been significantly underestimated. Knowing that the insects of tropical forests—the most species-rich habitat on Earth—were poorly known, entomologist Terry Erwin made a comprehensive sample of one group of insects, the beetles, in the canopies of a single species of tropical forest tree, *Luehea seemannii*, in Panama. Erwin fogged the canopies of 19 large *L. seemannii* trees with a pesticide and collected the insects that fell from the trees in collection nets. His sample contained about 1,200 species of beetles—many of them undescribed—from this one species of tree.

Erwin then used a set of assumptions to estimate the total number of insect species in tropical evergreen forests. His assumptions included estimates of the number of species of host trees in these forests; the proportion of beetles that specialized on a specific species of host tree; the relative proportion of beetles to other

insect groups; and the proportion of beetles that live in trees versus leaf litter. From this and similar studies, Erwin estimated that there may be 30 million or more species of insects on Earth. Although recent tests of Erwin's assumptions suggest 30 million was an overestimate, it is clear that the vast majority of insect species remain to be discovered by biologists.

Erwin's pioneering study highlighted the fact that we live on a poorly known planet, most of whose species have yet to be named and described. Much of the undiscovered diversity occurs among several groups of physically small yet biologically diverse animal groups, although even many larger species of animals continue to be discovered.

Entomologists collecting insects from a tree canopy in the Yungas rainforest of Argentina. Such research illuminates the vast number of insect species that remain undescribed by science.

Besides the insects, which other groups of animals are thought to contain many more species than are known at present?

concept 23.1 Distinct Body Plans Evolved among the Animals

How do we recognize an animal? The answer may seem obvious for familiar animals, but consider the sponges, which were once thought to be plants, or the rotifers, which are smaller than some protists.

The general characteristics often used to recognize animals include multicellularity, heterotrophy (using nutrients produced by other organisms), internal digestion, and motility (independent movement). Although these features are useful, none is diagnostic for all animals. Some animals do not move independently (at least during certain life stages), and some plants and fungi do have limited movement. Many parasitic animals lack a gut for internal digestion, and many other

organisms (notably the fungi) are multicellular and heterotrophic. So what evidence leads us to group the animals in a monophyletic clade?

Animal monophyly is supported by gene sequences and cellular morphology

The most convincing evidence that all the organisms considered to be animals share a common ancestor comes from phylogenetic analyses of their gene sequences. Relatively few complete animal genomes are available, but more are being sequenced each year. Analyses of these genomes and of many individual gene sequences have shown that all animals are indeed monophyletic. A currently well-supported phylogenetic tree of the animals is shown in **FIGURE 23.1**.

Surprisingly few morphological features are shared across all animal species. The morphological *synapomorphies* that are present are evident primarily at the cellular level. They include

FIGURE 23.1 Animal Phylogeny This tree presents the best-supported current hypotheses of the evolutionary relationships among major groups of animals. The traits highlighted by red circles will be explained as you read this chapter. (See Working with Data 23.1 at yourBioPortal.com.)

several unique features of the junctions between animal cells and a common set of extracellular matrix molecules, including collagen and proteoglycans. Although some animals in a few groups lack one or another of these cellular characteristics, it is believed that these traits were possessed by the ancestor of all animals and were subsequently lost in those groups.

LINK Animal cell junctions and extracellular matrix molecules are described in Concept 4.5

Similarities in the organization and function of Hox and other developmental genes provide additional evidence of developmental mechanisms shared by a common animal ancestor. The Hox genes specify body pattern and axis formation, leading to developmental similarities across animals (see Chapter 14).

The common ancestor of animals was probably a colonial flagellated protist similar to existing colonial choanoflagellates, which have similarities to the multicellular sponges (FIGURE 23.2). The best-supported hypothesis postulates a choanoflagellate lineage in which certain cells in the colony began to be specialized—some for movement, others for nutrition, others for reproduction, and so on. Once this *functional specialization* had begun, cells could have continued to differentiate. Coordination among groups of cells could have improved by means of specific regulatory and signaling molecules that guided differentiation and migration of cells in developing embryos. Such coordinated groups of cells eventually evolved into the larger and more complex organisms that we call animals.

Nearly 80 percent of the 1.8 million named species of living organisms are animals, and millions of additional animal species await discovery. Evidence about the evolutionary relationships among animal groups can be found in fossils, in patterns of embryonic development, in the morphology and physiology of living animals, in the structure of animal proteins, and in gene sequences. Increasingly, studies of higher-level relationships have come to depend on genomic sequence comparisons, as genomes are ultimately the source of all inherited trait information.

Basic developmental patterns and body plans differentiate major animal groups

Distinct layers of cells form during the early development of most animals. These cell layers differentiate into specific organs and organ systems as development continues. The embryos of **diploblastic** animals have two cell layers: an outer *ectoderm* and an inner *endoderm*. Embryos of **triploblastic** animals have, in addition to ectoderm and endoderm, a third distinct cell layer, *mesoderm*, between the ectoderm and the endoderm. The existence of three cell layers in embryos is a synapomorphy of triploblastic animals, whereas the diploblastic animals (placozoans, ctenophores, and cnidarians) exhibit the ancestral condition. Some biologists consider sponges to be diploblastic, but since they do not have clearly differentiated tissue types or embryonic cell layers, the term is not usually applied to them.

During early development in many animals, in a process known as *gastrulation*, a hollow ball one cell thick indents to

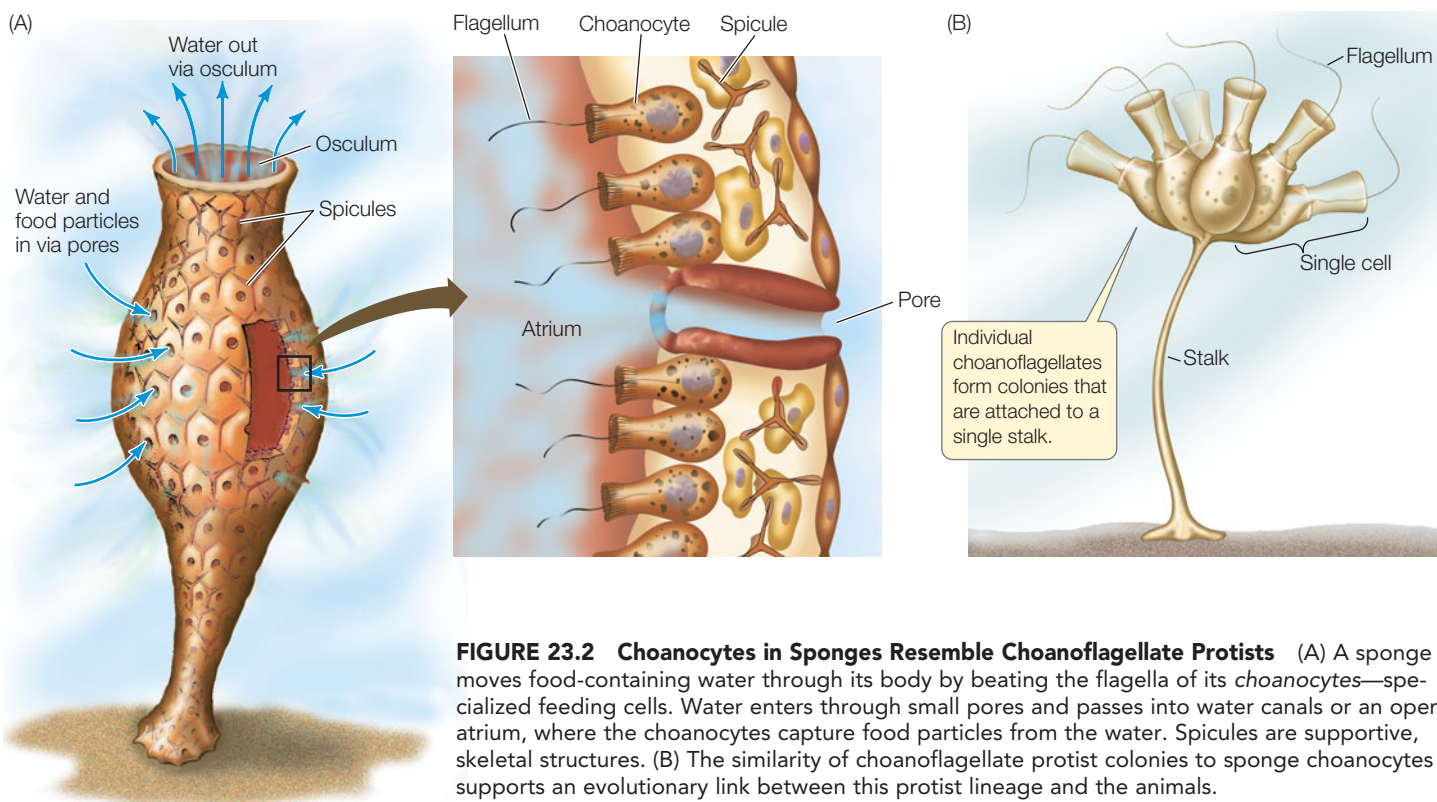

FIGURE 23.2 Choanocytes in Sponges Resemble Choanoflagellate Protists (A) A sponge moves food-containing water through its body by beating the flagella of its *choanocytes*—specialized feeding cells. Water enters through small pores and passes into water canals or an open atrium, where the choanocytes capture food particles from the water. Spicules are supportive, skeletal structures. (B) The similarity of choanoflagellate protist colonies to sponge choanocytes supports an evolutionary link between this protist lineage and the animals.

form a cup-shaped structure. The opening of the cavity formed by this indentation is called the *blastopore*:

Blastopore

Gastrulation is covered in detail in Chapter 33; the point to remember here is that the *overall pattern* of gastrulation immediately after the blastopore forms divides the triploblastic animals into two major groups:

- In the **protostomes** (Greek, “mouth first”), the mouth arises from the blastopore, and the anus forms later.
- In the **deuterostomes** (“mouth second”), the blastopore becomes the anus, and the mouth forms later.

Although the developmental patterns of animals are more varied than suggested by this simple dichotomy, phylogenies based on DNA sequences indicate that the protostomes and deuterostomes are distinct clades. These groups are known as the *bilaterians* (named for their usual bilateral symmetry), and they account for the vast majority of animal species.

The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts are referred to as its **body plan**. As Chapter 14 describes, the regulatory and signaling genes that govern the development of body symmetry, body cavities, segmentation, and appendages are widely shared among the different animal groups. Although the myriad animal body plans cover a wide range of morphologies, they can be seen as variations on four key features:

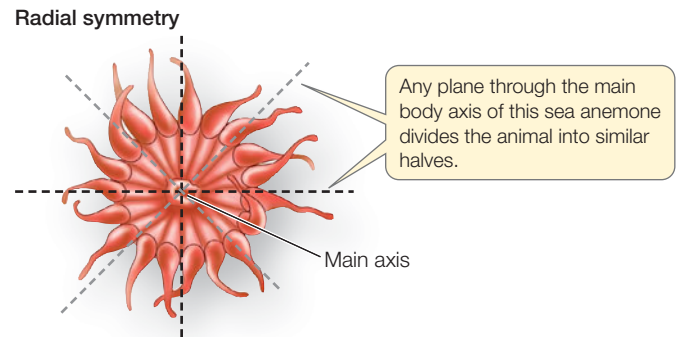

- The *symmetry* of the body
- The structure of the *body cavity*
- The *segmentation* of the body
- The existence and location of *external appendages* that are used for sensing, chewing, locomotion, mating, and other functions

Each of these features affects how an animal interacts with its environment.

Most animals are symmetrical

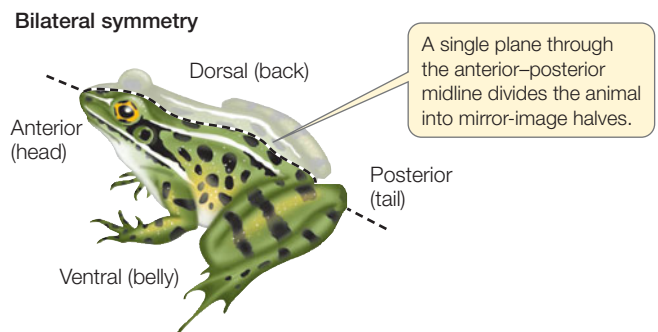

The overall shape of an animal can be described by its **symmetry**. An animal is said to be *symmetrical* if it can be divided along at least one plane into similar halves. Animals that have no plane of symmetry are *asymmetrical*. Placozoans and many sponges are asymmetrical, but most other animals have some kind of symmetry, which is governed by the expression of regulatory genes during development.

In organisms with **radial symmetry**, body parts are arranged around a single axis at the body’s center:

A perfectly radially symmetrical animal can be divided into similar halves by any plane that contains the central axis. However, most radially symmetrical animals are slightly modified, so fewer planes can divide them into identical halves. Some radially symmetrical animals are sessile (sedentary) or drift with water currents. Others move slowly but can move equally well in any direction.

Bilateral symmetry is characteristic of animals that have a distinct front end, which typically precedes the rest of the body as the animal moves. A bilaterally symmetrical animal can be divided into mirror-image (left and right) halves by a single plane that passes through the midline of its body. This plane runs from the front, or *anterior*, end of the body, to the rear, or *posterior*, end:

A plane at right angles to the midline divides the body into two dissimilar sides, its *dorsal* and *ventral* surfaces.

Bilateral symmetry is strongly correlated with **cephalization**, which is the concentration of sensory organs and nervous tissues in an anterior head. Cephalization has been evolutionarily favored because the anterior end of a bilaterally symmetrical animal typically encounters new environments first.

The structure of the body cavity influences movement

Animals with three embryonic cell layers (see Figure 23.1) can be divided into three types—*acoelomate*, *pseudocoelomate*, and *coelomate*—based on the presence and structure of an internal, fluid-filled body cavity.

- **Acoelomate** animals such as flatworms lack an enclosed, fluid-filled body cavity. Instead, the space between the gut (derived from endoderm) and the muscular body wall

(derived from mesoderm) is filled with masses of cells called *mesenchyme* (FIGURE 23.3A). These animals typically move by beating cilia.

- **Pseudocoelomate** animals have a body cavity called a *pseudocoel*, a fluid-filled space in which many of the internal organs are suspended. A pseudocoel is enclosed by muscles

FIGURE 23.3 Animal Body Cavities (A) Acoelomates do not have enclosed body cavities. (B) Pseudocoelomates have a body cavity bounded by endoderm and mesoderm. (C) Coelomates have a peritoneum surrounding the internal organs in a region bounded by mesoderm.

(mesoderm) only on its outside; there is no inner layer of mesoderm surrounding the internal organs (FIGURE 23.3B).

- **Coelomate** animals have a *coelom*, a body cavity that develops within the mesoderm. It is lined with a layer of muscular tissue called the *peritoneum*, which also surrounds the internal organs. The coelom is thus enclosed on both the inside and the outside by mesoderm (FIGURE 23.3C). A coelomate animal has more refined control over the movement of the fluids in its body cavity than a pseudocoelomate animal does.

The structure of an animal's body cavity strongly influences the ways in which it can move, and the body cavities of many animals function as *hydrostatic skeletons* (see Figure 36.12). Fluids are relatively incompressible, so when the muscles surrounding them contract, fluids shift to another part of the cavity. If the body tissues around the cavity are flexible, fluids squeezed out of one region can cause another region to expand. The moving fluids can thus move specific body parts. (You can see how a hydrostatic skeleton works by watching a snail emerge from its shell.) An animal with both *circular muscles* (encircling the body cavity) and *longitudinal muscles* (running along the length of the body) has even greater control over its movement.

In terrestrial environments, the hydrostatic function of fluid-filled body cavities applies mostly to relatively small, soft-bodied organisms. Most larger animals (as well as many smaller ones) have hard skeletons that provide protection and facilitate movement. Muscles are attached to those firm structures, which may be inside the animal or on its outer surface (in the form of a shell or cuticle).

Segmentation improves control of movement

Many animal bodies are divided into segments. **Segmentation** facilitates specialization of different body regions. It also allows an animal to alter the shape of its body in complex ways and to control its movements precisely. If an animal's body is segmented, muscles in each individual segment can change the shape of that segment independently of the others. In only a few segmented animals is the body cavity separated into discrete compartments, but even partly separated compartments allow better control of movement. Segmentation occurs in several groups of protostomes and deuterostomes.

In some animals, segments are not apparent externally (e.g., the segmented vertebrae of vertebrates). In other animals, similar body segments are repeated many times (FIGURE 23.4A). And in yet other animals, including most arthropods, the visible segments differ strikingly (FIGURE 23.4B). The dramatic evolutionary radiation of the arthropods (including the insects, spiders, centipedes, and crustaceans) was based on changes in a segmented body plan that features muscles attached to the inner surface of an external skeleton, including a variety of external *appendages* that move these animals.

Appendages have many uses

Getting around under their own power allows animals to obtain food, to avoid predators, and to find mates. Even some

FIGURE 23.4 Body Segmentation (A) All of the segments of this marine fireworm, an annelid, are similar. Its appendages are tipped with bristles that are used for locomotion and (in this species) for protection, since they contain a noxious toxin. (B) Segmentation allows the evolution of differentiation among the segments. The segments of this scorpion, an arthropod, differ in their form, function, and the appendages they bear.

sedentary species, such as sea anemones, have larval stages that use cilia to swim, thus increasing the animal's chances of finding a suitable habitat. Appendages that project externally from the body greatly enhance an animal's ability to move around.

Highly controlled, rapid movement is greatly enhanced in animals whose appendages have become modified into specialized *limbs*. In the arthropods and vertebrates, the presence of *jointed limbs* has been a prominent factor in their evolutionary success. In four independent instances—among the arthropod insects and among the vertebrate pterosaurs, birds, and bats—body plans emerged in which limbs were modified into wings, allowing these animals to take to the air.

Appendages also include many structures that are not used for locomotion. Many animals have antennae, which are specialized appendages used for sensing the environment. Other appendages (such as claws and mouthparts of many arthropods) are adaptations for capturing prey or chewing food. In some species, appendages are used for reproductive purposes, such as sperm transfer or egg incubation.

Do You Understand Concept 23.1?

- Describe the difference between diploblastic and triploblastic embryos, and between protostomes and deuterostomes.
- Describe the main types of symmetry found in animals. How can an animal's symmetry influence the way it moves?
- Explain several ways in which body cavities and segmentation improve control over movement.

Variations in body symmetry, body cavity structure, life cycles, patterns of development, and survival strategies differentiate millions of animal species. TABLE 23.1 summarizes the living members of the major animal groups we will describe in the rest of this chapter.

concept 23.2 Some Animal Groups Fall Outside the Bilateria

Looking at Figure 23.1, you can see that the protostome and deuterostome animals together comprise a monophyletic group known as the **Bilateria**. Some major traits that support the monophyly of bilaterians (in addition to genomic analyses) are strong bilateral symmetry, the presence of three distinct cell layers in embryos (*triploblasty*), and the presence of at least seven Hox genes (see Chapter 14). There are, however, four animal groups—the sponges, placozoans, ctenophores, and cnidarians—that are not bilaterians.

The simplest animals, the **sponges**, have no distinct tissue types. The **placozoans** have four cell types and weakly differentiated tissue layers. All other animal groups, including the bilaterians, are known as **eumetazoans**; eumetazoans have obvious body symmetry, a gut, a nervous system, and tissues organized into distinct organs (although there have been secondary losses of some of these structures in some eumetazoans). Sponges and placozoans lack all of these features.

yourBioPortal.com

Go to WEB ACTIVITY 23.2
Sponge and Diploblast Classification

Sponges and placozoans are weakly organized animals

Sponges have hard skeletal elements called **spicules**, which may be small and simple or large and complex. The three major groups of sponges separated soon after the split between sponges and the rest of the animals. Members of two groups (*glass sponges* and *demosponges*) have skeletons composed of spicules made of hydrated silicon dioxide (FIGURE 23.5A,B). These siliceous spicules have greater flexibility and toughness than synthetic glass rods of similar length. Members of the third group, the *calcareous sponges*, take their name from their

FIGURE 23.5 Sponge Diversity (A) The great majority of sponge species are demosponges, such as these Pacific barrel sponges. (B) Like the demosponges, the supporting structures of glass sponges are siliceous spicules. The pores and water canals “typical” of the sponge body plan are apparent in both (A) and (B). (C) The spicules of calcareous sponges, prominent in this photo, are made of calcium carbonate.

TABLE 23.1 Summary of Living Members of the Major Animal Groups

APPROXIMATE NUMBER OF LIVING SPECIES DESCRIBED			APPROXIMATE NUMBER OF LIVING SPECIES DESCRIBED		
		MAJOR GROUPS			MAJOR GROUPS
Sponges	9,000	Demosponges, glass sponges, calcareous sponges	Ecdysozoans		
Placozoans	2		Kinorhynchs	150	
Ctenophores	150		Loriciferans	100	
Cnidarians	11,000	Anthozoans: Corals, sea anemones	Priapulids	16	
		Hydrozoans: Hydras and hydroids	Horsehair worms	320	
		Scyphozoans: Jellyfishes	Nematodes	25,000	
PROTOSTOMES			Onychophorans	150	
Arrow worms	100		Tardigrades	800	
Lophotrochozoans			Arthropods:		
Bryozoans	4,500		Crustaceans	52,000	Crabs, shrimps, lobsters, barnacles, copepods
Flatworms	25,000	Free-living flatworms; flukes and tapeworms (all parasitic); monogeneans (ectoparasites of fishes)	Hexapods	1,000,000	Insects and relatives
Rotifers	1,800		Myriapods	14,000	Millipedes, centipedes
Ribbon worms	1,000		Chelicerates	98,000	Horseshoe crabs, arachnids (scorpions, harvestmen, spiders, mites, ticks)
Phoronids	20		DEUTEROSTOMES		
Brachiopods	335		Echinoderms	7,000	Crinoids (sea lilies and feather stars); brittle stars; sea stars; sea urchins; sea cucumbers
Annelids	16,500	Polychaetes (all marine)	Hemichordates	100	Acorn worms and pterobranchs
		Clitellates: Earthworms, freshwater worms, leeches	Urochordates	3,000	Ascidians (sea squirts)
Mollusks	100,000	Monoplacophorans	Cephalochordates	30	Lancelets
		Chitons	Vertebrates	62,000	Hagfish; lampreys
		Bivalves: Clams, oysters, mussels			Cartilaginous fishes
		Gastropods: Snails, slugs, limpets			Ray-finned fishes
		Cephalopods: Squids, octopuses, nautiloids			Coelacanths; lungfishes
					Amphibians
					Reptiles (including birds)
					Mammals

FIGURE 23.6 Placozoan Simplicity (A) As seen in this artist's rendition, adult placozoans are tiny, flattened, asymmetrical animals with only four cell types. (B) Recent studies have found a weakly swimming pelagic stage of placozoan to be abundant in many warm tropical and subtropical seas.

skeletons composed of calcium carbonate spicules (**FIGURE 23.5C**).

The body plan of all sponges—even large ones, which may reach a meter or more in length—is an aggregation of cells built around a water canal system. Water, along with any food particles it contains, enters the sponge by way of small pores and passes into the water canals or a central atrium, where choanocytes capture food particles (see Figure 23.2).

A skeleton of simple or branching spicules, and often a complex network of elastic fibers, supports the body of most sponges. Sponges also have an extracellular matrix, composed of collagen, adhesive glycoproteins, and other molecules, that holds the cells together. Most species are filter feeders; a few species are carnivores that trap prey on hook-shaped spicules that protrude from the body surface.

Most of the 9,000 species of sponges are marine; only about 50 species live in fresh water. The wide varieties of sponge sizes and shapes are adapted to different movement patterns of water. Sponges living in intertidal or shallow subtidal environments are subject to strong wave action and attach firmly to the substrate. Most sponges that live in slowly flowing water are flattened and are oriented at right angles to the direction of current flow, allowing them to intercept water and the food it contains as it flows past them.

Sponges reproduce both sexually and asexually. In most species, a single individual produces both eggs and sperm, but individuals do not self-fertilize. Water currents carry sperm from one individual to another. Asexual reproduction is by budding and regeneration (see Concept 32.1).

Placozoans are structurally very simple animals with only four distinct cell types (**FIGURE 23.6A**). Individuals in the mature life stage are usually observed adhering to surfaces (such as the glass of aquariums, where they were first discovered, or to rocks and other hard substrata in nature). Their structural simplicity—they have no mouth, gut, or nervous system—initially led biologists to suspect they might be the sister group of all other animals. Most phylogenetic analyses have not supported this hypothesis, however, and some aspects of the placozoans' structural simplicity may be secondarily derived. They are generally considered to have a diploblastic body plan, with upper and lower epithelial (surface) layers that sandwich a layer of contractile fiber cells.

Recent studies have found that placozoans have a pelagic (open-ocean) stage that is capable of swimming (**FIGURE**

23.6B), but the life history of placozoans is incompletely known. It is known that placozoans can reproduce both asexually as well as sexually, although we know almost none of the details of their sexual reproduction. Most studies have focused on the larger adherent stages that can be found in aquariums, where they appear after being inadvertently collected with other marine organisms. The transparent nature and small size of placozoans make them very difficult to observe in nature.

Ctenophores are radially symmetrical and diploblastic

Ctenophores, also known as *comb jellies*, lack most of the Hox genes found in all other eumetazoans. Ctenophores have a radially symmetrical, diploblastic body plan. The two cell layers are separated by an inert, gelatinous extracellular matrix called **mesoglea**. Ctenophores have a *complete gut*: food enters through a mouth, and wastes are eliminated through two anal pores.

Ctenophores move by beating cilia rather than by muscular contractions. Most of the 150 known species have eight comb-like rows of cilia-bearing plates, called **ctenes** (**FIGURE 23.7**). The feeding tentacles of ctenophores are covered with cells that discharge adhesive material when they contact prey. After capturing its prey, a ctenophore retracts its tentacles to bring the food to its mouth. In some species, the entire surface of the body is coated with sticky mucus that captures prey. Most ctenophores eat small planktonic organisms, although some eat other ctenophores. Ctenophores are common in open seas and can become abundant in protected bodies of water, where large populations can damage local ecosystems.

Ctenophore life cycles are uncomplicated. Gametes are released into the body cavity and then discharged through the mouth or the anal pores. Fertilization takes place in open seawater. In nearly all species, the fertilized egg develops directly into a miniature ctenophore that gradually grows into an adult.

Cnidarians are specialized carnivores

The **cnidarians** (jellyfishes, sea anemones, corals, and hydrozoans) may be the sister group of the ctenophores, although some biologists think they are more closely related to the bilaterians. The mouth of a cnidarian is connected to a blind sac called the **gastrovascular cavity** (a cnidarian thus does not have a complete gut). The gastrovascular cavity functions in digestion, circulation, and gas exchange, and it also acts as a hydrostatic skeleton. The single opening serves as both mouth and anus.

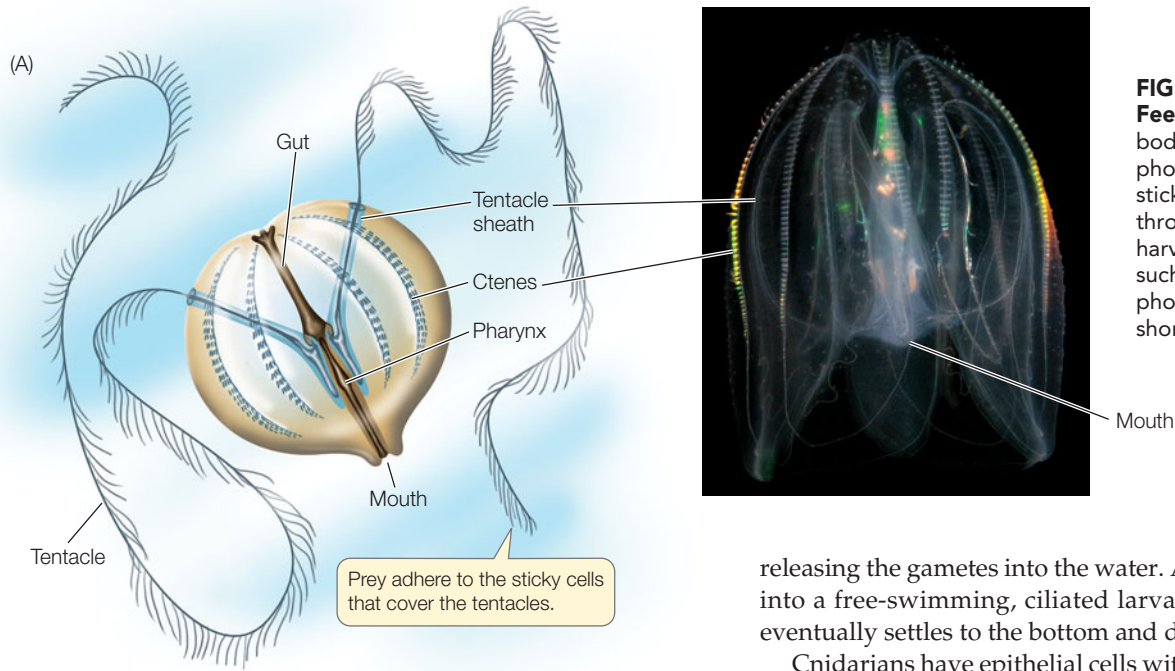

FIGURE 23.7 Comb Jellies Feed with Tentacles The body plan of a typical ctenophore. In many species, long, sticky tentacles sweep through the water, efficiently harvesting small prey. Others, such as the species in the photograph at right, have short tentacles.

The life cycle of many cnidarians has two distinct stages, one sessile and the other motile (**FIGURE 23.8**), although one or the other of these stages is absent in some groups. In the sessile **polyp** stage, a cylindrical stalk is attached to the substrate. The motile **medusa** (plural *medusae*) is a free-swimming stage shaped like a bell or an umbrella. It typically floats with its mouth and feeding tentacles facing downward. Mature polyps produce medusae by asexual budding. Medusae then reproduce sexually, producing eggs or sperm by meiosis and

releasing the gametes into the water. A fertilized egg develops into a free-swimming, ciliated larva called a **planula**, which eventually settles to the bottom and develops into a polyp.

Cnidarians have epithelial cells with muscle fibers that contract and enable the animals to move, as well as simple *nerve nets* that integrate their body activities. They are specialized carnivores, using the toxin in harpoonlike structures called *cnematocysts* to capture relatively large and complex prey. Some cnidarians, including many corals and anemones, gain additional nutrition from photosynthetic endosymbionts that live in their tissues.

FIGURE 23.8 The Cnidarian Life Cycle Typically Has Two Stages The life cycle of a scyphozoan (jellyfish) exemplifies the typical cnidarian body forms: the sessile, asexual polyp; and the motile, sexual medusa.

(C)

LINK The importance of protist endosymbionts in coral colonies is discussed in Concept 20.4

Of the roughly 11,000 living cnidarian species, all but a few live in the oceans. The smallest cnidarians can hardly be seen without a microscope. The largest known jellyfish is 2.5 meters in diameter, and some colonial species can reach lengths in excess of 30 meters. Three clades of cnidarians have many species, some of which are shown in **FIGURE 23.9**. The *anthozoans* include sea anemones, sea pens, and corals; the *scyphozoans* are commonly known as jellyfishes or sea jellies. The less familiar *hydrozoans* include both freshwater and marine species.

Do You Understand Concept 23.2?

- Why are sponges and placozoans considered to be animals, even though they lack the complex body structures found among most other animal groups?
- How does feeding differ between ctenophores and cnidarians?
- Can you think of any advantages to the biphasic life cycle (sessile polyp and motile medusa) of many cnidarians?

In Concept 23.1 we noted that the name protostome means “mouth first,” a developmental synapomorphy that links all these animals. The protostomes can be divided into two major clades—the lophotrochozoans and the ecdysozoans—largely on the basis of DNA sequence analysis.

concept 23.3 There are Two Major Groups of Protostomes

The protostomes are a highly diverse group of animals. Nearly all protostomes can be readily classified as either *lophotrochozoans* or *ecdysozoans*. Although their body plans are extremely varied, they are all bilaterally symmetrical animals whose bodies exhibit two major derived traits:

- An anterior *brain* that surrounds the entrance to the digestive tract
- A ventral *nervous system* consisting of paired or fused longitudinal nerve cords

Other aspects of protostome body organization differ widely from group to group. Although the common ancestor of the protostomes had a coelom, subsequent modifications of the coelom distinguish many protostome lineages. In at least one protostome lineage (the flatworms), the coelom has been lost (that is, the flatworms reverted to an acoelomate state). Some lineages are characterized by a pseudocoel (see Figure 23.3B). In two of the most prominent protostome groups, the coelom has been highly modified.

- The *arthropods* lost the ancestral condition of the coelom over the course of evolution. Their internal body cavity has become a *hemocoel*, or “blood chamber,” in which fluid from an open circulatory system bathes the internal organs before returning to blood vessels.
- Most *mollusks* have an open circulatory system with some of the attributes of the hemocoel, but they retain vestiges of an enclosed coelom around their major organs.

The evolutionary relationships of one small group of protostomes, the **arrow worms** (see Figure 23.1), have been debated for many years. Although recent gene sequence studies clearly identify arrow worms as protostomes, there remains some question as to whether they are the closest relatives of the lophotrochozoans, or possibly the sister group of all other protostomes.

The 100 or so living species of arrow worms are small (3 mm–12 cm) marine predators of planktonic protists and small fish.

Go to WEB ACTIVITIES 23.3 and 23.4
Features of the Protostomes and
Protostome Classification

Cilia-bearing lophophores and trochophore larvae evolved among the lophotrochozoans

Lophotrochozoans derive their name from two different features that involve cilia: a feeding structure known as a *lophophore* and a free-living larva known as a *trochophore*. Neither feature is universal for all lophotrochozoans, however.

Several distantly related groups of lophotrochozoans (including bryozoans, brachiopods, and phoronids) have a **lophophore**, a circular or U-shaped ring of ciliated, hollow tentacles around the mouth (**FIGURE 23.10A**). This complex structure is an organ for both food collection and gas exchange. The lophophore appears to have evolved independently several times, although it may be an ancestral feature that has been lost in many groups. Nearly all animals with a lophophore are sessile as adults, using the lophophore's tentacles and cilia to capture small floating organisms from the water.

Some lophotrochozoans, especially in their larval form, use cilia for locomotion. The larval form known as a **trochophore** moves by beating a band of cilia:

This movement of cilia also brings plankton closer to the larva, where the plankton can be captured and ingested (similar in function to the cilia of the lophophore). Trochophore larvae are found among many of the major groups of lophotrochozoans, including the mollusks, annelids, ribbon worms, and bryozoans. This larval form was probably present in the common ancestor of lophotrochozoans, although it has been subsequently lost in several lineages.

Lophotrochozoans range from relatively simple animals with a blind gut (that is, a gut with a single opening that both takes in food and expels wastes) and no internal transport system to animals with a complete gut (having separate entrance and exit openings) and a complex internal transport system. A number of these groups exhibit wormlike bodies, but the

lophotrochozoans encompass a wide diversity of morphologies, including a few groups with external shells. Included among the lophotrochozoans are species-rich groups such as flatworms, annelids, and mollusks, along with many less well known groups, some of which have only recently been discovered.

BRYOZOANS The 4,500 species of **bryozoans** (“moss animals”) are colonial animals that live in a “house” made of material secreted by the external body wall. Almost all bryozoans are marine, although a few species occur in fresh or brackish water. A bryozoan colony consists of many small (1–2 mm) individuals connected by strands of tissue along which nutrients can be moved (**FIGURE 23.10B**). The colony is created by the asexual reproduction of its founding member, and a single colony may contain as many as 2 million individuals. Rocks in coastal regions in many parts of the world are covered with luxuriant growths of bryozoans. Some bryozoans create miniature reefs in shallow waters. In some species, the individual colony members are differentially specialized for feeding, reproduction, defense, or support.

(A) *Cristatella mucedo*

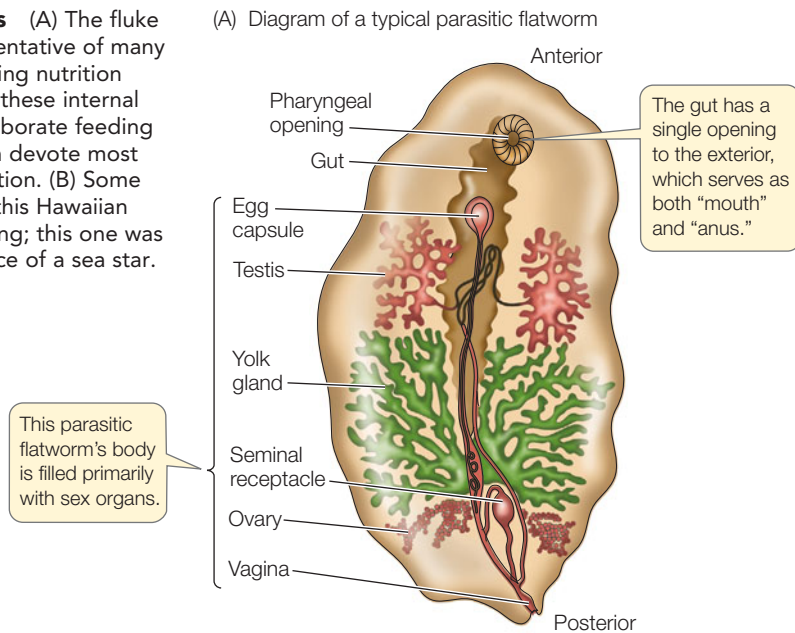

(B) *Cabera boryi*

FIGURE 23.10 Bryozoans Form Colonies (A) The extended lophophores of its individual members dominate the anatomy of this colonial bryozoan. (B) The rigid orange tissue of this marine bryozoan colony connects and supplies nutrients to thousands of individual animals.

FIGURE 23.11 Flatworms (A) The fluke diagrammed here is representative of many parasitic flatworms. Absorbing nutrition from the host animal's gut, these internal parasites do not require elaborate feeding or digestive organs and can devote most of their bodies to reproduction. (B) Some flatworms species, such as this Hawaiian marine species, are free-living; this one was photographed on the surface of a sea star.

(B) *Pseudobiceros* sp.

Bryozoans can also reproduce sexually by releasing sperm into the water, which carries the sperm to other individuals. Eggs are fertilized internally; developing embryos are brooded before they exit as larvae to seek suitable sites for attachment to the substrate.

FLATWORMS Most of the 25,000 species of **flatworms** are *tapeworms* and *flukes*; members of these two groups are internal parasites, particularly of vertebrates (**FIGURE 23.11A**). Because they absorb digested food from the guts of their hosts, many parasitic flatworms lack digestive tracts of their own. Some cause serious human diseases, such as schistosomiasis, which is common in parts of Asia, Africa, and South America. The species that causes this devastating disease has a complex life cycle involving both freshwater snails and mammals as hosts. Other flatworms are external parasites of fishes and other aquatic vertebrates. The *turbellarians* include most of the free-living species (**FIGURE 23.11B**).

Flatworms lack specialized organs for transporting oxygen to their internal tissues. Lacking a gas transport system, each cell must be near a body surface, a requirement met by the dorsoventrally flattened body form. In flatworms that have a digestive tract, this consists of a mouth opening into a blind sac. The sac is often highly branched, forming intricate patterns that increase the surface area available for the absorption of nutrients. Some small free-living flatworms are cephalized, with a head bearing chemoreceptor organs, two simple eyes, and a tiny brain composed of anterior thickenings of the longitudinal nerve cords. Free-living flatworms glide over surfaces, powered by broad bands of cilia.

ROTIFERS Most **rotifers** are tiny—50–500 μm long, smaller than some ciliate protists—but they have

specialized internal organs (**FIGURE 23.12**). A complete gut passes from an anterior mouth to a posterior anus; the body cavity is a pseudocoel that functions as a hydrostatic skeleton. Rotifers typically propel themselves through the water by means of rapidly beating cilia rather than by muscular contraction.

(B) *Philodina* sp.

FIGURE 23.12 Rotifers (A) The individual diagrammed here reflects the general structure of many rotifers. (B) A light micrograph reveals the internal complexity of these tiny animals.

FIGURE 23.13 Ribbon Worms (A) The proboscis is the ribbon worm's feeding organ. (B) Although most nemerteans are small, some marine species such as this one can reach several meters in length.

The most distinctive organ of rotifers is a conspicuous ciliated organ called the *corona*, which surmounts the head of many species. Coordinated beating of the cilia sweeps particles of organic matter from the water into the animal's mouth and down to a complicated structure called the *mastax*, in which food is ground into small pieces. By contracting muscles around the pseudocoel, a few rotifer species that prey on protists and small animals can protrude the mastax through their mouth and seize small objects with it.

Most of the 1,800 known species of rotifers live in fresh water. Some species rest on the surfaces of mosses or lichens in a desiccated, inactive state until it rains. When rain falls, they absorb water and become mobile, feeding in the films of water that temporarily cover the plants. Most rotifers live no longer than a few weeks.

Both males and females are found in some species of rotifers, but only females are known among the *bdelloids* (the *b* is silent). Biologists have concluded that the bdelloid rotifers may have existed for tens of millions of years without regular sexual reproduction. In general, lack of genetic recombination leads to the buildup of deleterious mutations, so long-term asexual reproduction typically leads to extinction (see Concept 15.6). However, recent studies indicate that bdelloid rotifers may avoid this problem by taking up fragments of genes directly from the environment during the desiccation–rehydration cycle; such a mechanism would allow genetic recombination among individuals in the absence of direct sexual exchange.

RIBBON WORMS The *nemerteans*, or **ribbon worms**, have simple nervous and excretory systems similar to those of flatworms. Unlike flatworms, however, they have a complete digestive tract with a mouth at one end and an anus at the other. Small ribbon worms move slowly by beating their cilia. Larger ones employ waves of muscle contraction to move over the surface of sediments or to burrow into them.

(B) *Tubulanus annulatus*

Within the body of nearly all of the 1,000 species of ribbon worms is a fluid-filled cavity called the *rhynchocoel*, within which lies a hollow, muscular *proboscis*. The proboscis, which is the worm's feeding organ, may extend much of the length of the body. Contraction of the muscles surrounding the rhynchocoel causes the proboscis to evert explosively through an anterior pore (**FIGURE 23.13A**). The proboscis may be armed with sharp stylets that pierce prey and discharge paralytic toxins into the wound.

Ribbon worms are largely marine, although there are some freshwater and terrestrial species. Most ribbon worms are less than 20 centimeters long, but individuals of some species

(A) *Phoronopsis californica*

FIGURE 23.14 Phoronids (A) The tentacles of this species' lophophores form two spirals. (B) The phoronid gut is U-shaped, as seen in this generalized diagram.

reach 20 meters or more. Some genera feature species that are conspicuous and brightly colored (FIGURE 23.13B).

PHORONIDS AND BRACHIOPODS Like bryozoans (see Figure 23.10A), phoronids and brachiopods also feed using a lophophore, but this structure may have evolved more than once among these groups. Although neither the phoronids nor the brachiopods are represented by many living species, the brachiopods—which have shells and thus leave an excellent fossil record—are known to have been much more abundant during the Paleozoic and Mesozoic eras.

The 20 known species of **phoronids** are small (5–25 cm long), sessile worms that live in muddy or sandy sediments or attached to rocky substrata. Phoronids are found in marine waters, from the intertidal zone to about 400 meters deep. They secrete tubes made of chitin, within which they live (FIGURE 23.14). Their cilia drive water into the top of the lophophore, and the water exits through the narrow spaces between the tentacles. Suspended food particles are caught and transported to the mouth by ciliary action. Eggs are fertilized internally, and the embryos are either released into the water or, in species with large embryos, retained in the parent's body, where they are brooded until they hatch.

Brachiopods are solitary marine animals with a rigid shell that is divided into two parts connected by a ligament (FIGURE

FIGURE 23.15 Brachiopods The lophophores of these North Atlantic brachiopods can be seen between their shells; although their shells resemble those of the bivalve mollusks (see Figure 23.18D), they evolved independently.

23.15). Although brachiopods superficially resemble bivalve mollusks, shells evolved independently in the two groups. The two halves of the brachiopod shell are dorsal and ventral, rather than lateral as in bivalves. The lophophore is located within the shell. Most brachiopods are 4–6 centimeters long. More than 26,000 fossil brachiopod species have been described, but only about 335 species survive.

ANNELIDS As discussed in Concept 23.1, segmentation allows an animal to move different parts of its body independently of one another, giving it much better control of its movement. A clear and obvious example of segmentation is seen in the body plan of the **annelids** (FIGURE 23.16; see also Figure 23.4A).

In most large annelids, the coelom in each segment is isolated from those in other segments. A separate nerve center called a *ganglion* controls each segment; nerve cords that connect the ganglia coordinate their functioning. Most annelids lack a rigid external protective covering; instead, they have a thin, permeable body wall that serves as a general surface for gas

FIGURE 23.16 Annelids Have Many Body Segments The segmented structure of the annelids is apparent both externally and internally. Many organs of this earthworm, a common annelid, are repeated serially.

exchange. These animals are thus restricted to moist environments because they lose body water rapidly in dry air. The approximately 16,500 described annelid species live in marine, freshwater, and moist terrestrial environments.

Many annelids have one or more pairs of eyes and one or more pairs of tentacles (with which they capture prey or filter food from the surrounding water) at the anterior end of the body (**FIGURE 23.17A**). In some species, the body wall of most segments extends laterally as a series of thin outgrowths called *parapodia*. The parapodia function in gas exchange, and some species use them to move. Stiff bristles called *setae* protrude from each parapodium, forming temporary contact with the substrate and preventing the animal from slipping backward when its muscles contract.

Members of one annelid group, the *pogonophorans*, secrete tubes made of chitin and other substances, in which they live (**FIGURE 23.17B**). Pogonophorans have lost their digestive tract (they have no mouth or gut). So how do they obtain nutrition? Part of the answer is that pogonophorans can take up dissolved organic matter directly from the sediments in which they live or from the surrounding water. Much of their nutrition, however, is provided by endosymbiotic bacteria that live in a specialized organ known as the *trophosome*. These bacteria oxidize hydrogen sulfide and other sulfur-containing compounds, fixing carbon from methane in the process. The uptake of the hydrogen sulfide, methane, and oxygen used by the bacteria is facilitated by hemoglobin in the pogonophorans' tentacles. It is this hemoglobin that gives the tentacles their red color (see Figure 23.17B).

Oligochaetes have no parapodia, eyes, or anterior tentacles, and they have only four pairs of setae bundles per segment. Earthworms—the most familiar oligochaetes—burrow in and

ingest soil, from which they extract food particles. All oligochaetes are *hermaphroditic*; that is, each individual is both male and female. Sperm are exchanged simultaneously between two copulating individuals. Eggs and sperm are deposited outside the adult's body, in a cocoon secreted by the *clitellum* (see Figure 23.16). Fertilization occurs within the cocoon after it is shed, and when development is complete, miniature worms emerge and immediately begin independent life.

Leeches, like oligochaetes, lack parapodia and tentacles. They live in freshwater or terrestrial habitats. The leech coelom is not divided into compartments, and the coelomic space is largely filled with undifferentiated tissue. Groups of segments at each end of the body are modified to form suckers, which serve as temporary anchors that help the leech move. With its posterior sucker attached to a substrate, the leech extends its body by contracting its circular muscles. The anterior sucker is then attached, the posterior one detached, and the leech shortens itself by contracting its longitudinal muscles.

A leech feeds by making an incision in its vertebrate host, from which blood flows; it then secretes an anticoagulant into the wound to keep the blood flowing. For centuries, medical practitioners used leeches to treat diseases they believed were caused by an excess of blood or by “bad blood.” Although most leeching practices (such as inserting a leech in a person's throat to alleviate swollen tonsils) have been abandoned, *Hirudo medicinalis* (the medicinal leech; **FIGURE 23.17C**) is used medically even today to reduce fluid pressure and prevent blood clotting in damaged tissues, to eliminate pools of coagulated blood, and to prevent scarring. The anticoagulants of certain other leech species contain anesthetics and blood vessel dilators and are being studied for possible medical uses.

(A) *Spirographis spallanzanii*(B) *Riftia* sp.(C) *Hirudo medicinalis***FIGURE 23.17 Diversity among the Annelids**

(A) “Fan worms,” or “feather duster worms,” are sessile marine annelids that grow in chitinous tubes, from which their tentacles extend and filter food from the water. (B) Pogonophorans live around hydrothermal vents deep in the ocean. Like fan worms, their tentacles protrude from chitinous tubes. They do not possess a digestive tract, however, and obtain most of their nutrition from endosymbiotic bacteria. (C) The medicinal leech has been a tool of physicians and healers for centuries.

MOLLUSKS The most diverse group of lophotrochozoans are the **mollusks**, with about 100,000 species that inhabit a wide array of aquatic and terrestrial environments. There are four major clades of mollusks: chitons, gastropods, bivalves, and cephalopods. Although these groups differ dramatically in morphology, they all share the same three major body components: a foot, a visceral mass, and a mantle (**FIGURE 23.18A**).

- The molluscan *foot* is a muscular structure that originally was both an organ of locomotion and a support for internal organs. In cephalopods such as squids and octopuses, the foot has been modified to form arms and tentacles borne on a head with complex sensory organs. In other groups, such as clams, the foot is a burrowing organ. In some groups the foot is greatly reduced.
- The heart and the digestive, excretory, and reproductive organs are concentrated in a centralized, internal *visceral mass*.
- The *mantle* is a fold of tissue that covers the organs of the visceral mass. The mantle secretes the hard, calcareous shell that is typical of many mollusks.

In most mollusks, the mantle extends beyond the visceral mass to form a *mantle cavity*. Within this cavity lie *gills* that are used for gas exchange. When cilia on the gills beat, they create a current of water. The gill tissue, which is highly vascularized (contains many blood vessels), takes up oxygen from the water and releases carbon dioxide. Many mollusks use their gills as filter-feeding devices; others feed using a rasping structure known as the *radula* to scrape algae from rocks. In some mollusks, such as the marine cone snails, the radula has been modified into a drill or poison dart.

Molluscan blood vessels do not form a closed circulatory system. Blood and other fluids empty into a large, fluid-filled hemocoel, through which fluids move around the animal and deliver oxygen to the internal organs. Eventually, the fluids reenter the blood vessels and are moved by a heart.

The approximately 1,000 living species of **chitons** (**FIGURE 23.18B**) are characterized by eight overlapping calcareous plates, surrounded by a structure known as the girdle. These plates and girdle protect the chiton's internal organs and muscular foot. The chiton body is bilaterally symmetrical, and the internal organs, particularly the digestive and nervous systems, are relatively simple. Most chitons are marine omnivores that scrape algae, bryozoans, and other organisms from rocks with their sharp radula. An adult chiton spends most of its life clinging to rock surfaces with its large, muscular, mucus-covered foot. It moves slowly by means of rippling waves of muscular contraction in the foot. Fertilization in most chitons takes place in the water, but in a few species fertilization is internal and embryos are brooded within the body.

Gastropods are the most species-rich and widely distributed mollusks, with nearly 70,000 living species. Snails, whelks, limpets, slugs, nudibranchs (sea slugs), and abalones are all gastropods. Most species move by gliding on their muscular foot, but in a few species—the sea butterflies and heteropods—the foot is a swimming organ with which the animal moves through open ocean waters. The only mollusks that live in terrestrial environments—land snails and slugs—are gastropods

(**FIGURE 23.18C**). In these terrestrial species, the mantle tissue is modified into a highly vascularized lung.

Clams, oysters, scallops, and mussels are all familiar **bivalves**. The 30,000 living species are found in both marine and freshwater environments. Bivalves have a very small head and a hinged, two-part shell that extends over the sides of the body as well as the top (**FIGURE 23.18D**). Many clams use their foot to burrow into mud and sand. Bivalves feed by taking in water through an opening called an *incurrent siphon* and filtering food from the water with their large gills, which are also the main sites of gas exchange. Water and gametes exit through the *excurrent siphon*. Fertilization takes place in open water in most species.

There are about 800 living species of **cephalopods**—squids, octopuses, and nautilus. Their excurrent siphon is modified to allow the animal to control the water content of the mantle cavity. The modification of the mantle into a device for forcibly ejecting water from the cavity through the siphon enables these animals to move rapidly by “jet propulsion” through the water. With their greatly enhanced mobility, cephalopods (which first appeared early in the Cambrian) became the major predators in the open waters of the Devonian oceans. They remain important marine predators today.

Cephalopods capture and subdue prey with their tentacles (see Figure 23.19B). As is typical of active, rapidly moving predators, cephalopods have a head with complex sensory organs, most notably eyes that are comparable to those of vertebrates in their ability to resolve images. The head is closely associated with a large, branched foot that bears the tentacles and a siphon (**FIGURE 23.18E**). The large, muscular mantle provides an external supporting structure. The gills hang in the mantle cavity. Many cephalopods have elaborate courtship behavior, which can involve striking color changes.

Many early cephalopods had a chambered external shell divided by partitions penetrated by tubes through which gases and liquids could be moved to control the animal's buoyancy. Nautilus are the only surviving cephalopods that have such external chambered shells, although squids and cuttlefish retain internal shells.

Shells have been lost several times among the mollusks, as in several groups of gastropods, including the slugs and nudibranchs (**FIGURE 23.19A**). These shell-less gastropods gain some protection from predation by being distasteful or toxic to many species. The often brilliant coloration of nudibranchs is *aposematic*, meaning it serves to warn potential predators of toxicity. Among the cephalopods, the octopuses have lost both external and internal shells (**FIGURE 12.19B**). Their lack of shells allows octopuses to escape predators by squeezing into small crevices.

Ecdysozoans must shed their cuticles

The distinguishing characteristic of **ecdysozoans** is their stiff external covering, or **cuticle**, which is secreted by the underlying *epidermis* (the outermost cell layer). The cuticle provides these animals with both protection and support. Once formed, however, the cuticle cannot grow. How, then, can ecdysozoans increase in size? They do so by shedding, or **molting**, the cuticle

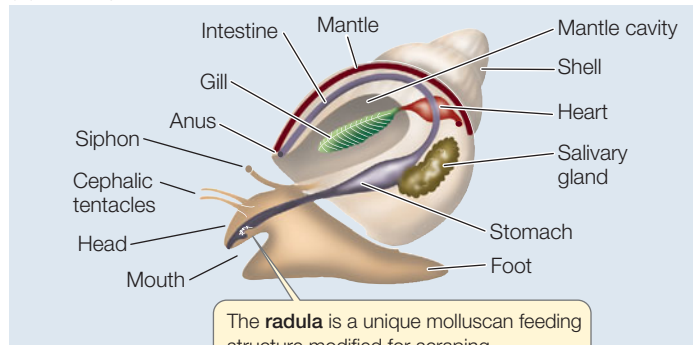

(A) Generalized molluscan body plan

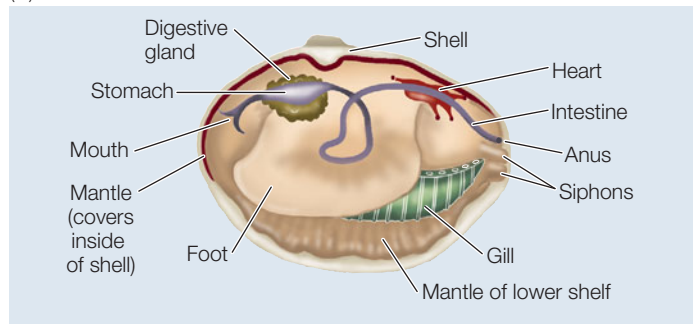

(B) Chitons

(C) Gastropods

FIGURE 23.19 Mollusks in Some Groups Have Lost Their Shells (A) Nudibranchs (“naked gills”), also called sea slugs, are shell-less gastropods. This species is brightly colored, alerting potential predators of its toxicity. (B) Octopuses have lost both the external and internal shell, which allows these cephalopods to squeeze through tight spaces.

and replacing it with a new, larger one. This molting process gives the clade its name (Greek *ecdysis*, “to get out of”).

A soft-bodied arthropod from the Cambrian, fossilized in the process of molting, shows that molting evolved more than 500 million years ago (FIGURE 23.20A). An increasingly rich array of molecular and genetic evidence, including a set of Hox genes shared by all ecdysozoans, suggests they have a single common ancestor. Thus molting of a cuticle is a trait that may have evolved only once during animal evolution.

Before an ecdysozoan molts, a new cuticle is already forming underneath the old one. Once the old cuticle is shed, the new one expands and hardens. Until it has hardened, though, the animal is vulnerable to its enemies, both because its outer surface is easy to penetrate and because an animal with a soft cuticle moves slowly or not at all (FIGURE 23.20B).

In many ecdysozoans that have wormlike bodies, the cuticle is relatively thin and flexible; it offers the animal some protection but provides only modest body support. A thin cuticle

allows the exchange of gases, minerals, and water across the body surface, but it restricts the animal to moist habitats. Many species of ecdysozoans with thin cuticles live in marine sediments from which they obtain prey. Some freshwater species absorb nutrients directly through their thin cuticles, as do parasitic species that live within their hosts.

The cuticles of other ecdysozoans, notably the arthropods, function as external skeletons, or **exoskeletons**. These exoskeletons are thickened by layers of protein and a strong,

(A)

(B) *Heterophrynus batesi*

FIGURE 23.20 Molting, Past and Present (A) A 500-million-year-old fossil from the Cambrian captured an individual of a long-extinct arthropod species in the process of molting, demonstrating that molting is an evolutionarily ancient trait. (B) This tailless whip scorpion has just emerged from its discarded exoskeleton and will be highly vulnerable until its new cuticle has hardened.

waterproof polysaccharide called **chitin**. An animal with a rigid, chitin-reinforced exoskeleton can neither move in a wormlike manner nor use cilia for locomotion. A hard exoskeleton also impedes the passage of oxygen and nutrients into the animal, presenting new challenges in other areas besides growth. New mechanisms of locomotion and gas exchange evolved in those ecdysozoans with hard exoskeletons.

To move rapidly, an animal with a rigid exoskeleton must have body extensions that can be manipulated by muscles. Such *appendages* evolved in the late Precambrian and led to the **arthropod** (Greek, “jointed foot”) clade. Arthropod appendages exist in an amazing variety of forms. They serve many functions, including walking and swimming, gas exchange, food capture and manipulation, copulation, and sensory perception. Arthropods grasp food with their mouths and associated appendages and digest it internally. Their muscles are attached to the inside of the exoskeleton.

The arthropod exoskeleton has had a profound influence on the evolution of these animals. Encasement within a rigid body covering provides support for walking on dry land, and the waterproofing provided by chitin keeps the animal from dehydrating in dry air. These features have allowed arthropods to invade terrestrial environments several times.

The evolution of the diverse arthropods and their relatives will be described in greater detail in Concept 23.4. Here we describe the other major groups of ecdysozoans.

NEMATODES **Nematodes**, or *roundworms*, have a thick, multi-layered cuticle that gives their unsegmented body its shape. As a nematode grows, it sheds its cuticle four times. Nematodes exchange oxygen and nutrients with their environment through both the cuticle and the gut, which is only one cell

layer thick. Materials are moved through the gut by rhythmic contraction of a highly muscular organ, the *pharynx*, at the worm’s anterior end. Nematodes move by contracting their longitudinal muscles.

Nematodes are probably the most abundant and universally distributed of all major animal groups. About 25,000 species have been described, but the actual number of living species may be in the millions. Many are microscopic; the largest known nematode, which reaches a length of 9 meters, is a parasite in the placentas of sperm whales. Countless nematodes live as scavengers in the upper layers of the soil, on the bottoms of lakes and streams, and in marine sediments. The topsoil of rich farmland may contain 3–9 billion nematodes per acre. A single rotting apple may contain as many as 90,000 individuals.

One soil-inhabiting nematode, *Caenorhabditis elegans*, serves as a model organism in the laboratories of geneticists and developmental biologists. It is ideal for such research because it is easy to cultivate, matures in 3 days, and has a fixed number of body cells. Its genome has been completely sequenced.

Many nematodes are predators, feeding on protists and small animals (including other roundworms). Most significant to humans, however, are the many species that parasitize plants and animals (**FIGURE 23.21A**). The nematodes that parasitize humans (causing serious diseases such as trichinosis, filariasis, and elephantiasis), domesticated animals, and economically important plants have been studied intensively in an effort to find ways of controlling them.

The structure of parasitic nematodes is similar to that of free-living species, but the life cycles of many parasitic species have special stages that facilitate the transfer of individuals among hosts. *Trichinella spiralis*, the species that causes the human disease trichinosis, has a relatively simple life cycle. A person may become infected by eating the flesh of an animal (usually a pig) that has *Trichinella* larvae encysted in its muscles (**FIGURE 23.21B**). The larvae are activated in the person’s digestive tract,

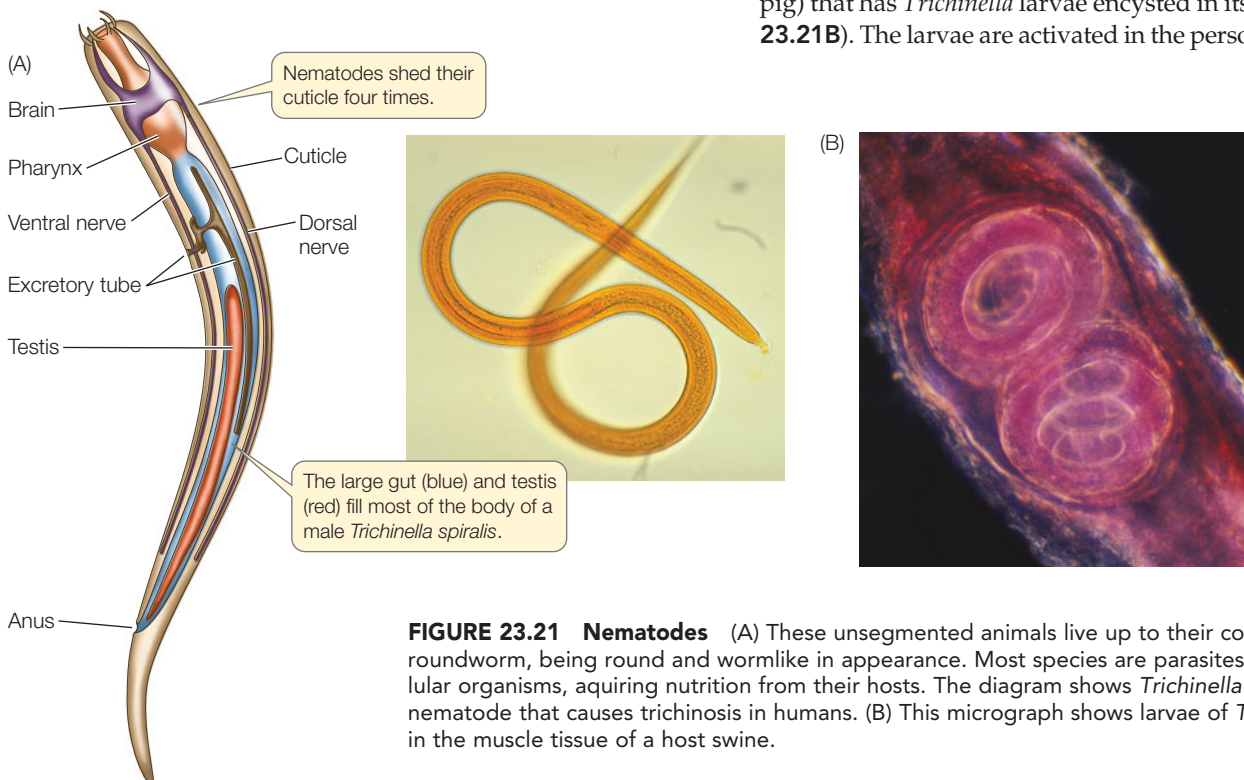

FIGURE 23.21 Nematodes (A) These unsegmented animals live up to their common name of roundworm, being round and wormlike in appearance. Most species are parasites of other multicellular organisms, acquiring nutrition from their hosts. The diagram shows *Trichinella spiralis*, a parasitic nematode that causes trichinosis in humans. (B) This micrograph shows larvae of *T. spiralis* encysted in the muscle tissue of a host swine.

emerge from their cysts, and attach to the intestinal wall, where they feed. Later, they bore through the intestinal wall and are carried in the bloodstream to muscles, where they form new cysts. If present in great numbers, these cysts can cause severe pain or death.

FRONTIERS Although nematodes that infect plants are pests of many crop species, parasitic and predatory nematodes of insects are now being selected for use in controlling crop pests. The larva of the beetle *Diabrotica virgifera*, known as western corn rootworm, devastates untreated corn fields in large areas of North America and Europe, causing over \$1 billion a year in losses in the United States alone. Pesticides that kill the beetle larvae also harm many beneficial insects. New strains of a nematode that kills the corn rootworm have been selected by researchers for attraction to the “alarm molecules” produced by infected corn plants. These modified strains of nematodes show great promise for effectively controlling corn rootworms without using nonspecific pesticides.

HORSEHAIR WORMS About 320 species of the unsegmented **horsehair worms** have been described. As their name implies, these animals are extremely thin in diameter; they range from a few millimeters up to a meter in length. Most adult horsehair worms live in fresh water among the leaf litter and algal mats that accumulate near the shores of streams and ponds. A few species live in damp soil.

Horsehair larvae are internal parasites of freshwater crayfish and of terrestrial and aquatic insects (FIGURE 23.22). An adult horsehair worm has no mouth, and its gut is greatly reduced and probably nonfunctional. Some species feed only as larvae, absorbing nutrients from their hosts across the body wall. But other species continue to grow and shed their cuticles even after they have left their hosts, suggesting that some adult worms may be able to absorb nutrients from their environment.

FIGURE 23.22 Horsehair Worm Larvae Are Parasitic The larvae of this horsehair worm (*Paragordius tricuspidatus*) can manipulate its host’s behavior. The hatching worm causes the cricket to jump into water, where the worm will continue its life cycle as a free-living adult. The insect, having delivered its parasitic burden, drowns.

SMALL MARINE CLADES There are several small, relatively poorly known groups of benthic marine ecdysozoans. The 16 species of **priapulids** are cylindrical, unsegmented, wormlike animals with a three-part body plan consisting of a proboscis, trunk, and caudal appendage (“tail”). It should be clear from their appearance why they were named after the Greek fertility god Priapus (FIGURE 23.23A). The 150 species of **kinorhynchs** live in marine sands and muds and are virtually microscopic; no kinorhynchs are longer than 1 millimeter. Their bodies are divided into 13 segments, each with a separate cuticular plate (FIGURE 23.23B). The minute (less than 1 mm long) **loriciferans** were not discovered until 1983. About 100 living species are known to exist, although many of these are still being

APPLY THE CONCEPT

There are two major groups of protostomes

The table shows a small sample of amino residues that have been used to reconstruct the relationships of some major animal groups. (The full dataset includes data on 11,234 amino acid positions across 77 species of animals.)

1. Construct a phylogenetic tree of these seven animals using the parsimony method (see Chapter 16). Use the sponge as your outgroup to root the tree. Assume that all changes among amino acids are equally likely.
2. How many changes (from one amino acid residue to another) occur along each branch on your tree?
3. Which branch on your tree represents the eumetazoans? The protostomes? The lophotrochozoans? The ecdysozoans? The deuterostomes?

ANIMAL	AMINO ACID POSITION											
	1	2	3	4	5	6	7	8	9	10	11	12
Sponge	P	P	M	S	V	R	Q	N	L	V	I	L
Clam	E	A	M	R	I	K	L	S	I	V	I	L
Earthworm	E	P	M	R	I	K	L	S	I	V	M	L
Tardigrade	E	K	M	R	I	R	L	N	L	V	L	L
Fruit fly	E	K	M	R	I	S	L	D	L	V	L	L
Sea urchin	E	P	M	R	V	R	Q	N	L	T	V	K
Human	E	P	I	R	V	R	Q	N	L	T	V	K

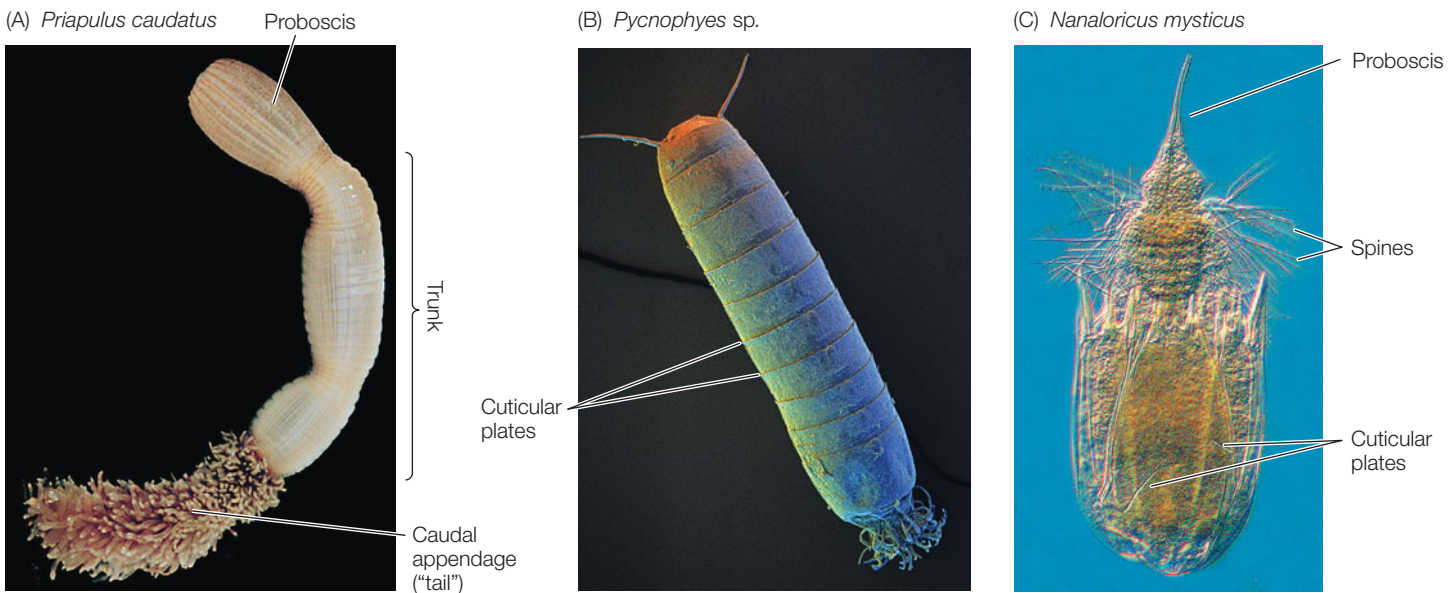

FIGURE 23.23 Benthic Marine Ecdysozoans Members of these groups are marine bottom-dwellers. (A) Most priapulid species live in burrows on the ocean floor, extending the proboscis for feeding. (B) Kinorhynchs are virtually microscopic. The cuticular plates that cover their bodies are molted periodically. (C) Six cuticular plates form a “corset” around the minute loriciferan body.

described. The body is divided into a head, neck, thorax, and abdomen and is covered by six plates, from which the loriciferans get their name (Latin *lorica*, “corset”; FIGURE 23.23C).

Do You Understand Concept 23.3?

- How does an animal’s body covering influence the way it breathes, feeds, and moves?
- Why are most annelids restricted to moist environments?
- Briefly describe how the basic body organization of mollusks has been modified to yield a wide diversity of animals.
- What are three ways in which nematodes have a significant impact on humans?

We turn now to the arthropods. Members of the four arthropod subgroups not only dominate the ecdysozoan clade but are also among the most diverse animals on Earth.

concept 23.4 Arthropods Are Diverse and Abundant Animals

Arthropods and their relatives are ecdysozoans with paired appendages. Arthropods are an extremely diverse group of animals in numbers of species. Furthermore, the number of individual arthropods alive at any one time is estimated to be about 10^{18} , or a billion billion. Among the animals, only the nematodes are thought to exist in greater numbers.

Several key features have contributed to the success of the arthropods. Their bodies are segmented, and their muscles are attached to the inside of their rigid exoskeletons. Each segment has muscles that operate that segment and the jointed appendages attached to it. Jointed appendages permit complex movements, and different appendages are specialized for different functions. Encasement of the body within a rigid exoskeleton provides the animal with support for walking in the water or on dry land and provides some protection against predators. The waterproofing provided by chitin keeps the animal from dehydrating in dry air.

Representatives of the four major arthropod groups living today are all species-rich: the *chelicerates* (including the arachnids—spiders, scorpions, mites, and their relatives), *myriapods* (millipedes and centipedes), *crustaceans* (including shrimps, crabs, and barnacles), and *hexapods* (insects and their relatives). Phylogenetic relationships among arthropod groups are currently being reexamined in light of a wealth of new information, much of it based on gene sequences. These studies suggest that the chelicerates are the sister group to the remaining arthropods, and that the crustaceans may be paraphyletic with respect to the hexapods. There is strong support for the monophyly of arthropods as a whole.

The jointed appendages of arthropods gave the clade its name, from the Greek words *arthron*, “joint,” and *podos*, “foot” or “limb.” Arthropods evolved from ancestors with simple, unjointed appendages. The exact forms of those ancestors are unknown, but some arthropod relatives with segmented bodies and unjointed appendages survive today. Before we describe the modern arthropods, we will discuss those arthropod relatives.

Arthropod relatives have fleshy, unjointed appendages

Until fairly recently, biologists debated whether the **onychophorans** (velvet worms) were more closely related to annelids or arthropods, but molecular evidence clearly links them to the

(A) *Peripatus* sp.(B) *Echiniscus* sp.

arthropods. Indeed, with their soft, fleshy, unjointed, claw-bearing legs, onychophorans may be similar in appearance to the arthropod ancestor (FIGURE 23.24A). The 150 species of onychophorans live in leaf litter in humid tropical environments. Their soft, segmented bodies are covered by a thin, flexible cuticle that contains chitin. They use their fluid-filled body cavities as hydrostatic skeletons. Fertilization is internal, and large, yolky eggs are brooded within the female's body.

Tardigrades (water bears) also have fleshy, unjointed legs and use their fluid-filled body cavities as hydrostatic skeletons (FIGURE 23.24B). Tardigrades are tiny (0.5–1.5 mm long) and

FIGURE 23.24 Arthropod Relatives with Unjointed Appendages

(A) Onychophorans have unjointed legs and use the body cavity as a hydrostatic skeleton. (B) Tardigrades can be abundant on the wet surfaces of mosses and plants and in temporary pools of water.

lack both a circulatory system and gas-exchange organs. The 800 known species live in marine sands and on temporary water films on plants. When these films dry out, the animals also lose water and shrink to small, barrel-shaped objects that can survive for at least a decade in a dormant state. Tardigrades have been found in densities as high as 2 million per square meter of moss.

Chelicerates are characterized by pointed, nonchewing mouthparts

In the **chelicerates**, the head bears two pairs of pointed appendages modified to form mouthparts, called *chelicerae*, which are used to grasp (rather than chew) prey. In addition, many chelicerates have four pairs of walking legs. The 98,000 described species are placed in three major clades: pycnogonids, horseshoe crabs, and arachnids.

The *pycnogonids*, or sea spiders, are a poorly known group of about 1,000 marine species (FIGURE 23.25A). Most are small, with leg spans less than 1 cm, but some deep-sea species have leg spans up to 60 cm. A few pycnogonids eat algae, but most are carnivorous, eating a variety of small invertebrates.

There are four living species of *horseshoe crabs*, but many close relatives are known from fossils. Horseshoe crabs, which have changed very little morphologically during their long fossil history, have a large horseshoe-shaped covering over most of the body. They are common in shallow waters along the eastern coast of North America and the southern and eastern coasts of Asia, where they scavenge and prey on bottom-dwelling animals. Periodically they crawl into the intertidal zone in large numbers to mate and lay eggs (FIGURE 23.25B).

Arachnids are abundant in terrestrial environments. Most arachnids have a simple life cycle in which miniature adults hatch from internally fertilized eggs and begin independent lives almost immediately. Some arachnids retain their eggs during development and give birth to live young.

(A) *Anoplodactylus* sp.(B) *Limulus polyphemus*

FIGURE 23.25 Two Small Chelicerate Groups

(A) Although they are not spiders, it is easy to see why sea spiders were given their common name. (B) Horseshoe crabs are an ancient group that has changed very little in morphology over time; such species are sometimes referred to as "living fossils."

FIGURE 23.26 Arachnid Diversity

(A) Known for their web-spinning abilities, spiders are expert predators. This green lynx spider has captured a fly. (B) A desert scorpion assumes the animal's aggressive attack position. These arachnids are fearsome predators, and their sting can be dangerous to humans. (C) Harvestmen, also called daddy longlegs, are scavengers. (D) Mites include many free-living species as well as blood-sucking, external parasites.

(A) *Peucetia* sp.(B) *Opisthophthalmus carinatus*

The most species-rich and abundant arachnids are the spiders, scorpions, harvestmen, mites, and ticks (FIGURE 23.26). More than 50,000 described species of mites and ticks live in soil, leaf litter, mosses, and lichens, under bark, and as parasites of plants and animals. Mites are vectors for wheat and rye mosaic viruses; they cause mange in domestic animals and skin irritation in humans.

Spiders, of which 38,000 species have been described, are important terrestrial predators with hollow chelicerae, which they use to inject venom into their prey. Some have excellent vision that enables them to chase and seize their prey. Others spin elaborate webs made of protein threads in which they snare prey. The threads are produced by modified abdominal appendages connected to internal glands that secrete the proteins, which solidify on contact with air. The webs of different groups of spiders are strikingly varied, and this variation enables the spiders to position their snares in many different environments for many different types of prey.

(C) *Leiobunum rotundum*(D) *Lorryia formosa***Mandibles and antennae characterize the remaining arthropod groups**

The remaining arthropods have *mandibles*, rather than chelicerae, as mouthparts, so they are together called **mandibulates**. Mandibles are often used for chewing as well as for biting and holding food. Another distinctive characteristic of the mandibulates is the presence of sensory antennae on the head.

The **myriapods** comprise the centipedes, millipedes, and their close relatives. Centipedes and millipedes have a well-formed head with the mandibles and antennae characteristic of mandibulates. Their distinguishing feature is a long, flexible, segmented trunk that bears many pairs of legs (FIGURE 23.27). Centipedes, which have one pair of legs per segment, prey on insects and other small animals. In millipedes, two adjacent segments are fused so that each fused segment has two pairs of legs. Millipedes scavenge and eat plants. More than 3,000 species of centipedes and 11,000 species of millipedes have been

(A) *Scolopendra angulata*(B) *Sigmoria trimaculata*

FIGURE 23.27 Myriapods (A) Centipedes have modified appendages that function as poisonous fangs for capturing active prey. They have one pair of legs per segment. (B) Millipedes, which are scavengers and plant eaters, have smaller jaws and legs than centipedes do. They have two pairs of legs per segment.

(A) *Grapsus grapsus*

(B) *Armadillium vulgare*

FIGURE 23.28 Crustacean Diversity (A) This decapod crustacean, is a “Sally Lightfoot” crab from the Galápagos. (B) Isopods, also known as “pillbugs,” are terrestrial. The darker, unpatterned individual is male, the other is female. (C) Minute copepods such as this one are an important link in aquatic food chains. (D) Tadpole shrimp are branchiopods, not to be confused with the decapod crustaceans commonly called shrimp, or with the branchiopods seen in Figure 23.15. (E) Barnacles are sessile, attaching to a substrate by their muscular stalks and feeding with retractable feeding appendages (the delicate, tentacle-like structures seen here).

(C) *Eudiaptomus gracilis*

(D) *Lepidurus* sp.

(E) *Lepas anatifera*

described; many more species probably remain unknown. Although most myriapods are less than a few centimeters long, some tropical species are ten times that size.

Crustaceans are the dominant marine arthropods today, and they are also common in freshwater and some terrestrial environments. The most familiar crustaceans are the shrimps, lobsters, crayfishes, and crabs (all *decapods*; **FIGURE 23.28A**) and the sow bugs (*isopods*; **FIGURE 23.28B**). Additional species-rich groups include the *amphipods*, *ostracods*, *copepods* (**FIGURE 23.28C**), and *branchiopods* (**FIGURE 23.28D**), all of which are found in freshwater and marine environments.

Barnacles are unusual crustaceans that are sessile as adults (**FIGURE 23.28E**). Adult barnacles look more like mollusks than like other crustaceans, but as the zoologist Louis Agassiz remarked more than a century ago, a barnacle is “nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth.”

Most of the 52,000 described species of crustaceans have a body that is divided into three regions: head, thorax, and abdomen (**FIGURE 23.29A**). The segments of the head are fused together, and the head bears five pairs of appendages. Each of the multiple thoracic and abdominal segments usually bears one pair of appendages. The appendages on different parts of the body are specialized for different functions, such as gas exchange, chewing, capturing food, sensing, walking, and swimming. In many species, a fold of the exoskeleton, the *carapace*, extends dorsally and laterally back from the head to cover and protect some of the other segments.

The fertilized eggs of most crustacean species are attached to the outside of the female’s body, where they remain during their early development. At hatching, the young of some species are released as larvae; those of other species are released

as juveniles that are similar in form to the adults. Still other species release eggs into the water or attach them to an object in the environment.

Over half of all described species are insects

During the Devonian period, more than 400 million years ago, some mandibulates colonized terrestrial environments. Of the several groups (including some crustacean isopods and decapods) that successfully colonized the land, none is more prominent today than the six-legged **hexapods**: the insects and their relatives. Insects are abundant and diverse in terrestrial and freshwater environments; only a few live in salt water.

The wingless relatives of the insects—the springtails, two-pronged bristletails, and proturans—are probably the most similar of living forms to insect ancestors. These insect relatives have a simple life cycle; they hatch from eggs as miniature adults. They differ from insects in having internal mouthparts. Springtails can be extremely abundant (up to 200,000 per square meter) in soil, leaf litter, and on vegetation and are the most abundant hexapods in the world in terms of number of individuals (rather than number of species).

About 1 million of the 1.8 million described living species of life are insects. As we discussed at the beginning of this chapter, biologists have estimated that many millions of insect species remain to be discovered. Like crustaceans, insects have a body with three regions—head, thorax, and abdomen. They have a single pair of antennae on the head and three pairs of legs attached to the thorax. In most groups of insects, the thorax also bears two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments (**FIGURE 23.29B**).

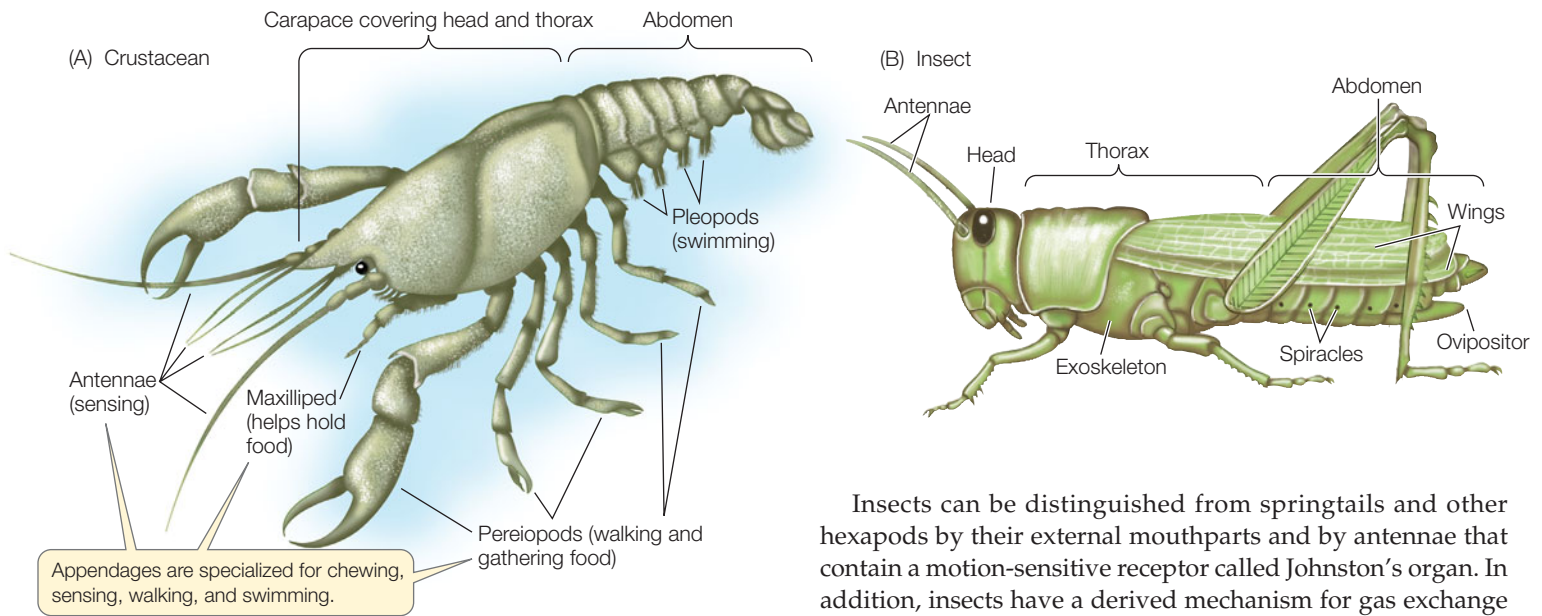

FIGURE 23.29 Two Segmented Body Plans The bodies of crustaceans and insects are divided into three regions, the head, thorax, and abdomen. (A) In crustaceans, each body region bears specialized appendages, and a shell-like carapace covers the head and thorax. (B) The thorax of insects bears three pairs of legs, and in most groups, two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments (see Figure 14.19).

Insects can be distinguished from springtails and other hexapods by their external mouthparts and by antennae that contain a motion-sensitive receptor called Johnston's organ. In addition, insects have a derived mechanism for gas exchange in air: a system of air sacs and tubular channels called *tracheae* (singular *trachea*) that extend from external openings called *spiracles* inward to tissues throughout the body (see Figure 37.2). Insects use nearly all species of plants and many species of animals as food.

TABLE 23.2 lists the major insect groups. Two groups—the jumping bristletails and silverfish—are wingless and have simple life cycles, like the springtails and other close insect

APPLY THE CONCEPT

Over half of all described species are insects

The following data were used by entomologist Terry Erwin to estimate the undescribed diversity of insects. Review the design of Erwin's experiment in the opening story of this chapter. Then use Erwin's data to answer the questions and consider how changes in the assumptions may affect the estimates.

Approximate number of beetle species collected from <i>Luehea seemanii</i> trees:	1,200
Estimated number of host-specific beetles in this sample:	163
Number of species of canopy trees per hectare of forest:	70
Percentage of beetle species living in canopy (as opposed to ground-dwelling species):	75%
Percentage of beetles among all insect species:	40%

1. From the data above, estimate the number of insect species in an average hectare of Panamanian forest. Assume that the data for beetles on *L. seemanii* are representative of the other tree species, and that all the species of beetles that are *not* host-specific were collected in the original sample. Remember to sum your estimates of the number of (a) host-specific

beetle species in the forest canopy; (b) non-host-specific beetle species in the forest canopy; (c) beetle species on the forest floor; and (d) species of all insects other than beetles.

2. Use the following information to estimate the number of insect species on Earth. There are about 50,000 species of tropical forest trees. Assume that the data for beetles on *L. seemanii* are representative for other species of tropical trees, and calculate the number of host-specific beetles found on these trees. Add an estimated 1 million species of beetles that are expected across different species of trees (including temperate regions). Estimate the number of ground-dwelling beetle species based on the percentage used in question 1. Now estimate the number of species of insects found worldwide, based on the percentage of beetles among all insect species.
3. The estimates in questions 1 and 2 are based on many assumptions. Do you think these assumptions are reasonable? Why or why not? Would you argue for a different set of assumptions? How do you think these changes in assumptions would affect your calculations? Can you think of ways to test your assumptions?

TABLE 23.2 The Major Insect Groups^a

GROUP	APPROXIMATE NUMBER OF DESCRIBED LIVING SPECIES
Jumping bristletails (Archaeognatha)	300
Silverfish (Thysanura)	370
PTERYGOTE (WINGED) INSECTS (PTERYGOTA)	
Mayflies (Ephemeroptera)	2,000
Dragonflies and damselflies (Odonata)	5,000
Neopterans (Neoptera)^b	
Ice-crawlers (Grylloblattodea)	25
Gladiators (Mantophasmatodea)	15
Stoneflies (Plecoptera)	1,700
Webspinners (Embioptera)	300
Angel insects (Zoraptera)	30
Earwigs (Dermaptera)	1,800
Grasshoppers and crickets (Orthoptera)	20,000
Stick insects (Phasmida)	3,000
Cockroaches (Blattodea)	3,500
Termites (Isoptera)	2,750
Mantids (Mantodea)	2,300
Booklice and barklice (Psocoptera)	3,000
Thrips (Thysanoptera)	5,000
Lice (Phthiraptera)	3,100
True bugs, cicadas, aphids, leafhoppers (Hemiptera)	80,000
Holometabolous neopterans (Holometabola)^c	
Ants, bees, wasps (Hymenoptera)	125,000
Beetles (Coleoptera)	375,000
Twisted-wing parasites (Strepsiptera)	600
Lacewings, ant lions, dobsonflies (Neuropterida)	4,700
Scorpionflies (Mecoptera)	600
Fleas (Siphonaptera)	2,400
True flies (Diptera)	120,000
Caddisflies (Trichoptera)	5,000
Butterflies and moths (Lepidoptera)	250,000

^a The hexapod relatives of insects include the springtails (Collembola; 3,000 spp.), two-pronged bristletails (Diplura; 600 spp.), and proturans (Protura; 10 spp.). All are wingless and have internal mouthparts.

^b Neopteran insects can tuck their wings close to their bodies.

^c Holometabolous insects are neopterans that undergo complete metamorphosis.

relatives. The remaining groups are all *pterygote insects*. Pterygotes have two pairs of wings, except in some groups where one or both pairs of wings have been secondarily lost. Secondarily wingless groups include the parasitic lice and fleas, some beetles, and the worker individuals in many ants.

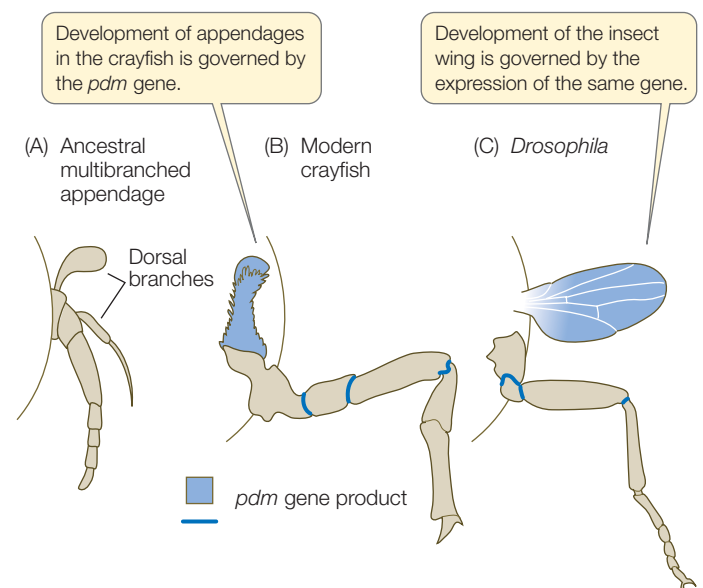

Hatchling pterygotes do not look like adults, and they undergo substantial changes at each molt. The immature stages of

insects between molts are called **instars**. A substantial change that occurs between one developmental stage and another is called **metamorphosis**. If the changes between its instars are gradual, an insect is said to have **incomplete metamorphosis**. If the change between at least some instars is dramatic, an insect is said to have **complete metamorphosis** (see Figure 30.3). In many insects with complete metamorphosis, the different life stages are specialized for different environments and use different food sources. In many species, the larvae are adapted for feeding and growing, whereas the adults are specialized for reproduction and dispersal.

LINK Insect metamorphosis is under the control of hormones, as described in Concept 30.1

Pterygote insects were the first animals in evolutionary history to achieve the ability to fly. Flight opened up many new lifestyles and feeding opportunities that only the insects could exploit, and it is almost certainly one of the reasons for the remarkable numbers of insect species and individuals, and for their unparalleled evolutionary success.

Molecular data suggest that insects began to diversify about 450 million years ago, about the time of the appearance of the first land plants. These early hexapods evolved in a terrestrial environment that lacked any similar organisms, which in part accounts for their remarkable success. But the success of the insects is also due to their wings. Homologous genes control the development of insect wings and crustacean appendages, suggesting that the insect wing evolved from a dorsal branch of a crustacean-like limb:

The dorsal limb branch of crustaceans is used for gas exchange. Thus the insect wing probably evolved from a gill-like structure that had a gas exchange function.

The adults of most flying insects have two pairs of stiff, membranous wings attached to the thorax. True flies, however, have one pair of wings and a pair of stabilizers called *halteres*. In winged beetles, one pair of wings—the forewings—forms

(A) *Libellula saturata*, Odonata(B) *Melanoplus differentialis*, Orthoptera(C) *Anisocelis flavolineata*, Hemiptera(D) *Limnephilus* (larva), Trichoptera(E) *Trachelophorus giraffa*, Coleoptera(F) *Junonia coenia*, Lepidoptera(G) *Scathophaga stercoraria*, Diptera(H) *Polistes gallicus*, Hymenoptera

FIGURE 23.30 Diverse Winged Insects (A) Unlike most flying insects, a dragonfly cannot fold its wings over its back. (B) Orthopteran insects such as grasshoppers undergo several larval molts (instars), but the juveniles resemble small adults (incomplete metamorphosis). (C) Hemipterans are “true” bugs. The leaflike extensions on this Costa Rican bug are cryptic (camouflaging) in the leaf litter the bug normally inhabits. (D–H) Holometabolous insects undergo complete metamorphosis. (D) A larval caddisfly (right) emerges from its dark pupal case. (E) Coleoptera is the largest insect group; beetles such as this Madagascan giraffe weevil account for more than half of all holometabolous species. (F) The buckeye butterfly is found in most parts of North America. (G) Many fly species feed on carrion and excrement, as does this golden dung fly. (H) This European paper wasp is a hymenopteran, a group in which most members display social behaviors.

heavy, hardened wing covers. Flying insects are important pollinators of flowering plants.

Two groups of pterygotes, the mayflies and dragonflies (FIGURE 23.30A), cannot fold their wings against their bodies.

This is the ancestral condition for pterygote insects, and the mayflies and dragonflies are not closely related to one another. Members of these groups have predatory or herbivorous aquatic larvae that transform into flying adults after they crawl out of the water. Dragonflies (and their relatives the damselflies) are active predators as adults. In contrast, adult mayflies lack functional digestive tracts. Mayflies live only about a day, just long enough to mate and lay eggs.

All other pterygote insects—the *neopterans*—can tuck their wings out of the way upon landing and crawl into crevices and other tight places. Some neopteran groups undergo incomplete metamorphosis, so hatchlings of these insects are sufficiently similar in form to adults to be recognizable. Examples include the grasshoppers (FIGURE 23.30B), roaches, mantids, stick insects, termites, stoneflies, earwigs, thrips, true bugs (FIGURE 23.30C), aphids, cicadas, and leafhoppers. They acquire adult organ systems, such as wings and compound eyes, gradually through several juvenile instars.

More than 80 percent of all insects belong to a subgroup of the neopterans called the *holometabolous* insects (see Table 23.2), which undergo complete metamorphosis (FIGURE 23.30D). The many species of beetles account for almost half of this group (FIGURE 23.30E). Also included are lacewings and their relatives; caddisflies; butterflies and moths (FIGURE 23.30F); sawflies; true flies (FIGURE 23.30G); and bees, wasps, and ants, some species of which display unique and highly specialized social behaviors (FIGURE 23.30H).

Do You Understand Concept 23.4?

- What features have contributed to making arthropods among the most abundant animals on Earth, both in number of species and number of individuals?
- Describe the difference between incomplete and complete metamorphosis.
- Can you think of some possible reasons why there are so many species of insects?

The majority of Earth's animal species are protostomes, so it is not surprising that the protostome groups display a huge variety of different body plans and other characteristics. We will now consider the diversity of the deuterostomes, a group that contains far fewer species than the protostomes but which is even more intensively studied and, not incidentally, is the group to which humans belong.

concept 23.5 Deuterostomes Include Echinoderms, Hemichordates, and Chordates

It may surprise you to learn that you and a sea urchin are both deuterostomes. Adult sea stars, sea urchins, and sea cucumbers—the most familiar echinoderms—look so different from adult vertebrates (fishes, frogs, lizards, birds, and mammals) that it is difficult to believe all these animals are closely related. Two major pieces of evidence indicate that the deuterostomes share a common ancestor not shared with the protostomes:

- Deuterostomes share a pattern of early development in which the mouth forms at the opposite end of the embryo from the blastopore, and the blastopore develops into the anus (this is opposed to the protostomes, in which the blastopore becomes the mouth).
- Recent phylogenetic analyses of the DNA sequences of many different genes offer strong support for the shared evolutionary relationships of deuterostomes.

Note that neither of the above factors is apparent in the morphology of the adult animals.

Although there are far fewer species of deuterostomes than of protostomes (see Table 23.1), the deuterostomes are of special interest because they include many large animals—including humans—that strongly influence the characteristics of ecosystems. Many deuterostome species have been intensively studied in all fields of biology. Complex behaviors are especially well developed among some deuterostomes and are a vast and fascinating field of study in themselves (see Chapter 41).

There are three major clades of living deuterostomes:

- **Echinoderms:** sea stars, sea urchins, and their relatives
- **Hemichordates:** acorn worms and pterobranchs
- **Chordates:** sea squirts, lancelets, and vertebrates

All deuterostomes are triploblastic and coelomate (see Figure 23.3C). Skeletal support features, where present, are internal rather than external. Some species have segmented bodies, but the segments are less obvious than those of annelids and arthropods.

yourBioPortal.com

Go to WEB ACTIVITY 23.5
Deuterostome Classification

The earliest deuterostomes were bilaterally symmetrical, segmented animals with a pharynx that had slits through which water flowed. Echinoderms evolved their adult forms with unique symmetry (in which the body parts are arranged along five radial axes) much later, whereas other deuterostomes retained the ancestral bilateral symmetry.

The echinoderms and hemichordates (together known as *ambulacrarians*) have a bilaterally symmetrical, ciliated larva (FIGURE 23.31A). Adult hemichordates also are bilaterally symmetrical. Echinoderms, however, undergo a radical change in form as they develop into adults (FIGURE 23.31B), changing from a bilaterally symmetrical larva to an adult with **pentaradial symmetry** (symmetry in five or multiples of five). As is typical of animals with radial symmetry, echinoderms have no head, and they move equally well (but usually slowly) in many directions. Rather than having an anterior–posterior (head–tail) and dorsal–ventral (back–belly) body organization, echinoderms have an *oral* side (containing the mouth) and an opposite *aboral* side (containing the anus).

Echinoderms have unique structural features

About 13,000 species of echinoderms in 23 major groups have been described from fossil remains. They are probably only a small fraction of those that actually lived. Only 6 of the 23 major groups known from fossils are represented by species that survive today; many clades became extinct during the periodic mass extinctions that have occurred throughout Earth's history (see Table 18.1). Nearly all of the 7,000 extant species of echinoderms live only in marine environments.

In addition to having pentaradial symmetry, adult echinoderms have two unique structural features. One is a system of calcified internal plates covered by thin layers of skin and some muscles. The calcified plates of most echinoderms are thick, and they fuse inside the entire body, forming an *internal skeleton*. The other unique feature is a **water vascular system**, a network of water-filled canals leading to extensions called **tube feet**. This system functions in gas exchange, locomotion, and feeding (see Figure 23.31B).

Members of one major extant clade, the *crinoids* (sea lilies and feather stars), were more abundant and species-rich 300 to 500 million years ago than they are today. There are some 80 described living sea lily species, most of which are sessile organisms attached to a substrate by a stalk. Feather stars (FIGURE 23.32A) grasp the substrate with flexible appendages that allow for limited movement. About 600 living species of feather stars have been described.

FIGURE 23.31 Bilaterally Symmetrical Echinoderm Larvae become Radially Symmetrical Adults (A) The ciliated larva of a sea star has bilateral symmetry. Hemichordates have a similar larval form. (B) The radially symmetrical adult sea star displays the canals and tube feet of the echinoderm water vascular system, as well as the calcified internal skeleton. The body's orientation is oral–aboral rather than anterior–posterior.

Unlike the crinoids, most of the other surviving echinoderms are motile. The two main groups of motile echinoderms are the *echinozoans* (sea urchins and sea cucumbers; **FIGURES 23.32B,C**) and *asterozoans* (sea stars and brittle stars; **FIGURE 23.32D,E**).

The tube feet of the different echinoderm groups have been modified in a great variety of ways to capture prey. Sea lilies, for example, feed by orienting

FIGURE 23.32 Echinoderm Diversity (A) The flexible arms of this feather star are clearly visible. (B) Sea urchins are important grazers on algae in the intertidal zones of the world's oceans. (C) Sea cucumbers are unique among echinoderms in having an anterior–posterior rather than an oral–aboral orientation of the mouth and anus. This individual is in the spawning position; normally it would travel across the seafloor on its tube feet. (D) Sea stars are important predators on bivalve mollusks such as mussels and clams. Suction tips on its tube feet allow a sea star to grasp both shells of the bivalve and pull them open. (E) The arms of the brittle star are composed of hard but jointed plates.

(A) *Comanthina schlegelii*

(B) *Sphaerechinus granularis*

(C) *Thelenota* sp.

(D) *Marthasterias glacialis*

(E) *Ophiopholis aculeata*

their arms in passing water currents. Food particles strike and stick to their tube feet, which are covered with mucus-secreting glands. The tube feet transfer food particles to grooves in the arms, where ciliary action carries the particles to the mouth. Sea cucumbers capture food with their anterior tube feet, which are modified into large, feathery, sticky tentacles that can be protruded from the mouth. Periodically, a sea cucumber withdraws the tentacles, wipes off the material that has adhered to them, and digests it.

Many sea stars use their tube feet to capture large prey such as annelids, gastropod and bivalve mollusks, small crustaceans such as crabs, and fishes. With hundreds of tube feet acting simultaneously, a sea star can grasp a bivalve in its arms, anchor the arms with its tube feet, and by steady contraction of the muscles in its arms, gradually exhaust the muscles the bivalve uses to keep its shell closed (see Figure 23.32D). To feed on a bivalve, a sea star can push its stomach out through its mouth and then through the narrow space between the two halves of the bivalve's shell. The sea star's stomach then secretes enzymes that digest the prey.

Most sea urchins eat algae, which they catch with their tube feet from the plankton or scrape from rocks with a complex rasping structure. Most of the 2,000 species of brittle stars ingest particles from the upper layers of sediments and assimilate the organic material from them, although some species filter suspended food particles from the water, and others capture small animals.

Hemichordates are wormlike marine deuterostomes

The roughly 100 species of hemichordates—acorn worms and pterobranchs—have a body organized in three major parts, consisting of a *proboscis*, a *collar* (which bears the mouth), and a *trunk* (which contains the other body parts). The 70 known species of acorn worms range up to 2 meters in length (FIGURE 23.33A). They live in burrows in muddy and sandy marine sediments. The digestive tract of an acorn worm consists of a mouth behind which are a muscular *pharynx* and an *intestine*. The pharynx opens to the outside through a number of *pharyngeal slits* through which water can exit. Highly vascularized tissue surrounding the pharyngeal slits serves as a gas-exchange apparatus. Acorn worms breathe by pumping water into the mouth and out through the pharyngeal slits. They capture prey with the large proboscis, which is coated with sticky mucus to which small organisms in the sediment stick. The mucus and its attached prey are conveyed by cilia to the mouth. In the esophagus, the food-laden mucus is compacted into a ropelike mass that is moved through the digestive tract by ciliary action.

The 30 living species of pterobranchs are sedentary marine animals up to 12 millimeters long that live in a tube secreted by

the proboscis. Some species are solitary; others form colonies of individuals joined together (FIGURE 23.33B). Behind the proboscis is a collar with anywhere from one to nine pairs of arms. The arms bear long tentacles that capture prey and function in gas exchange.

Chordate characteristics are most evident in larvae

As mentioned earlier, it is not obvious from examining the morphology of adult animals that echinoderms and chordates share a common ancestor. The evolutionary relationships among some chordate groups are not immediately apparent either. The features that reveal these evolutionary relationships are seen primarily in the larvae—in other words, it is during the early developmental stages that their evolutionary relationships are evident.

There are three principal chordate clades: the **cephalochordates**, **urochordates**, and **vertebrates**. There are about 3,000 living species of urochordates and 62,000 living species of vertebrates, but only about 30 living species of cephalochordates.

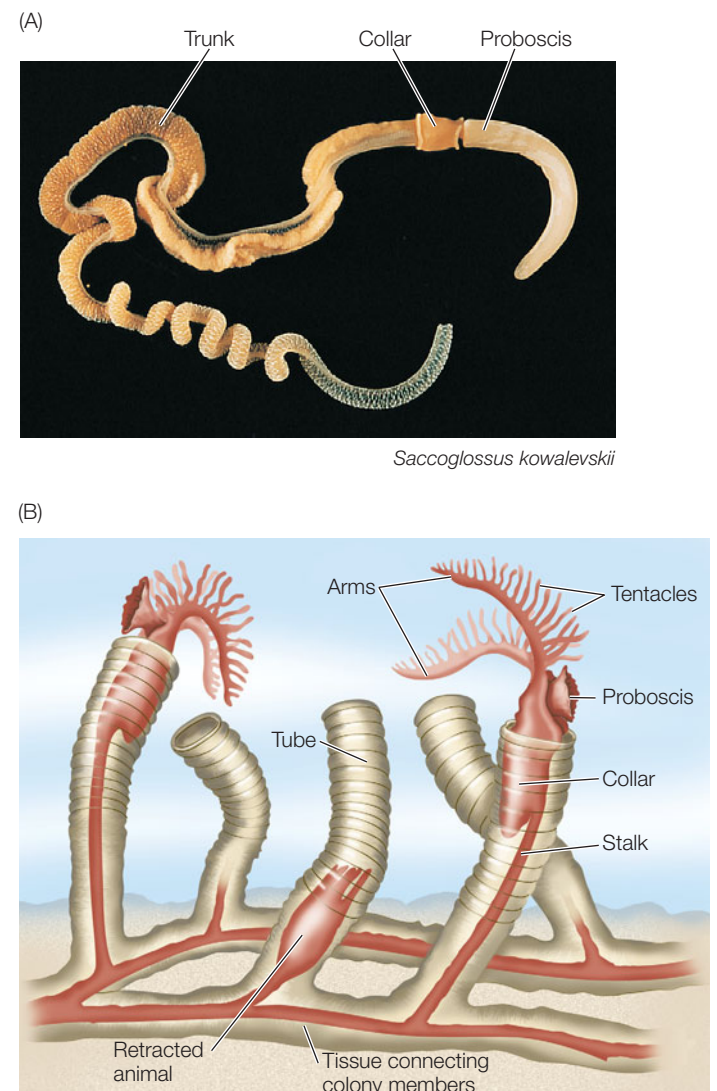

FIGURE 23.33 Hemichordates (A) The proboscis of an acorn worm is modified for burrowing. (B) The structure of a colonial pterobranch.

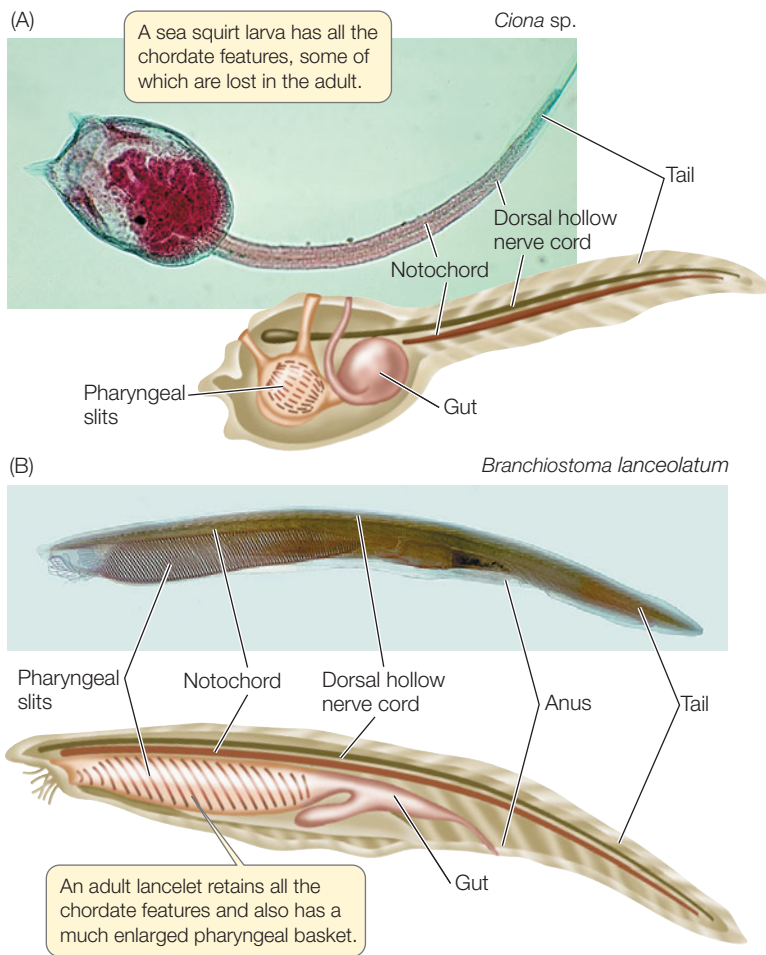

FIGURE 23.34 The Key Features of Chordates Are Most Apparent in Early Developmental Stages The pharyngeal slits of both the urochordate ascidian and the cephalochordate lancelet develop into a pharyngeal basket. (A) The ascidian larva (but not the adult) has all three chordate features: a dorsal hollow nerve cord, postanal tail, and notochord. (B) All three chordate synapomorphies are retained in the adult lancelet.

Adult chordates vary greatly in form, but all chordates display the following derived structures at some stage in their development (**FIGURE 23.34**):

- A dorsal hollow nerve cord
- A tail that extends beyond the anus
- A dorsal supporting rod called the notochord

The **notochord** is the most distinctive derived chordate trait. It is composed of a core of large cells with turgid fluid-filled vacuoles, which make it rigid but flexible. In most urochordates the notochord is lost during metamorphosis to the adult stage. In most vertebrate species, it is replaced during development by vertebrae that provide support for the body.

The ancestral pharyngeal slits (not a derived feature of this group) are present at some developmental stage of chordates but are often lost in adults. The pharynx, which develops around the pharyngeal slits, functioned in chordate ancestors as the site for oxygen uptake and the elimination of carbon

dioxide and water (as in acorn worms). The pharynx is much enlarged in some chordate species (as in the *pharyngeal basket* of the lancelet in **Figure 23.34B**).

Adults of most cephalochordates and urochordates are sessile

The 30 species of cephalochordates, or *lancelets*, are small animals that rarely exceed 5 centimeters in length. The notochord, which provides body support, extends the entire length of the body throughout their lives (see **Figure 23.34B**). Lancelets are found in shallow marine and brackish waters worldwide. Most of the time they lie covered in sand with their head protruding above the sediment, but they can swim. They filter prey from the water with their pharyngeal basket.

All urochordates live in marine environments. More than 90 percent of the known species are *ascidians* (sea squirts). Individual ascidians range in length from less than 1 millimeter to 60 centimeters. Some ascidians form colonies by asexual budding from a single founder. Colonies may measure several meters across. The baglike body of an adult ascidian is enclosed in a tough tunic, leading to its alternate name of “tunicate” (**FIGURE 23.35**). The tunic is composed of proteins and a complex polysaccharide secreted by epidermal cells. The ascidian pharynx is enlarged into a pharyngeal basket that filters prey from the water passing through it.

In addition to its pharyngeal slits, an ascidian larva has a dorsal hollow nerve cord and a notochord that is restricted mostly to the tail region (see **Figure 23.34A**). Bands of muscle that surround the notochord provide support for the body. After a short time swimming in the plankton, the larvae of most species settle on the seafloor and transform into sessile adults. The swimming,

Polycarpa aurata

FIGURE 23.35 An Adult Urochordate The colorful tunic of this adult ascidian (also known as a tunicate) has led to the species' two common names, “golden sea squirt” and “ink spot sea squirt.”

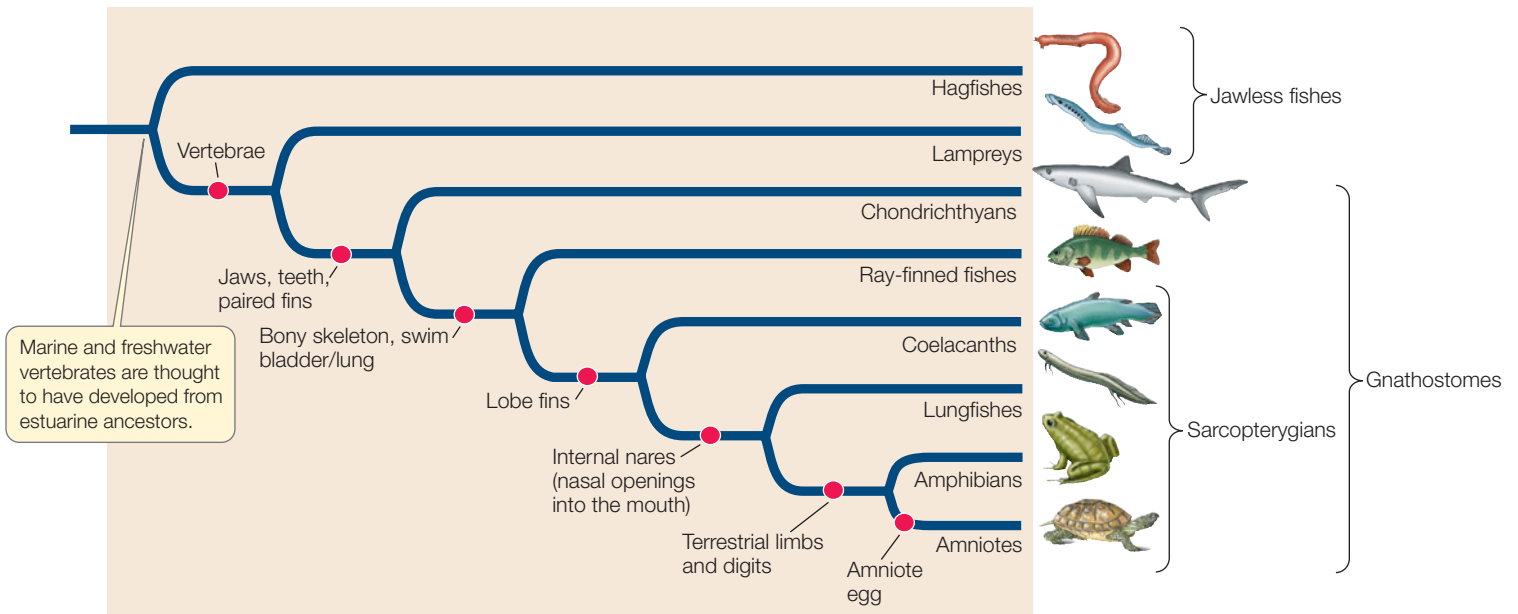

FIGURE 23.36 Phylogeny of the Living Vertebrates This phylogenetic tree shows the evolution of some of the key innovations among the major groups of vertebrates.

tadpolelike larvae suggest a close evolutionary relationship between ascidians and vertebrates (see Figure 16.4).

A dorsal supporting structure replaces the notochord in vertebrates

The vertebrates take their name from the unique, jointed, dorsal **vertebral column** that replaces the notochord during early development as their primary supporting structure (FIGURE 23.36).

As we have discussed, the hemichordates, echinoderms, cephalochordates, and urochordates are marine animals. The lineage that led to the vertebrates is also thought to have evolved in the oceans, although probably in an estuarine environment (where fresh water meets salt water). Vertebrates have since radiated into marine, freshwater, terrestrial, and aerial environments worldwide.

The *hagfishes* are thought by many biologists to be the sister group to the remaining vertebrates (as shown in Figure 23.36). Hagfishes (FIGURE 23.37A) have a weak circulatory system, with three small accessory hearts (rather than a single, large heart), a partial *cranium* or skull (containing no *cerebrum* or *cerebellum*, two main regions of the brain of other vertebrates), and no jaws or stomach. They also lack separate, jointed vertebrae and have a skeleton composed of cartilage. Thus, some biologists do not consider hagfishes vertebrates, and use instead the term *craniates* to refer collectively to the hagfishes and the vertebrates. Some analyses of gene sequences suggest, however, that hagfishes may be more closely related to the vertebrate lampreys (FIGURE 23.37B); in this phylogenetic arrangement, the two groups are collectively called the *cyclostomes* (“circle mouths”). If in fact the hagfishes and lampreys do form a monophyletic group, then hagfishes must have secondarily

FIGURE 23.37 Modern Jawless Fishes (A) Hagfishes burrow in the ocean mud, from which they extract small prey. They also scavenge on dead or dying fish. Their degenerate eyes led to their being mislabeled “blind eels.” (B) Sea lampreys are ectoparasites that attach to the bodies of living fish and use their large, jawless mouths to suck blood and flesh. They can survive in both fresh and salt water, as this individual attached to a salmon returning to its spawning ground will do.

lost many of the major vertebrate morphological features during their evolution.

The 58 known species of hagfishes are unusual marine animals that produce copious quantities of slime as a defense. They are virtually blind and rely largely on the four pairs of sensory tentacles around their mouth to detect food. Although they have no jaws, hagfishes have a tonguelike structure equipped with toothlike rasps that they can use to tear apart dead organisms and to capture their principal prey, annelid worms. Hagfishes have direct development (no larvae), and individuals may actually change sex from year to year (from male to female and vice versa).

The nearly 50 species of lampreys either live in fresh water, or they live in coastal salt water and move into fresh water to breed. Although the lampreys and hagfishes may look superficially similar (with elongate eel-like bodies and no paired fins), they differ greatly in their biology.

Lampreys have a complete braincase and distinct and separate (although rudimentary) vertebrae, all cartilaginous rather than bony. Lampreys undergo a complete metamorphosis from filter-feeding larvae known as *ammocoetes*, which are morphologically quite similar in general structure to adult lancelets. The adults of many species of lampreys are parasitic, although several lineages of lampreys evolved to become nonfeeding as adults. These nonfeeding adult lampreys survive only a few weeks after metamorphosis—just long enough to breed. In the species that are parasitic as adults, the round mouth is a rasping and sucking organ that is used to attach to their prey and rasp at the flesh (see Figure 23.37B). Some species of lampreys are critically endangered because of recent habitat changes and losses.

The vertebrate body plan can support large, active animals

Four key features characterize the vertebrates:

- An anterior *skull* with a large brain

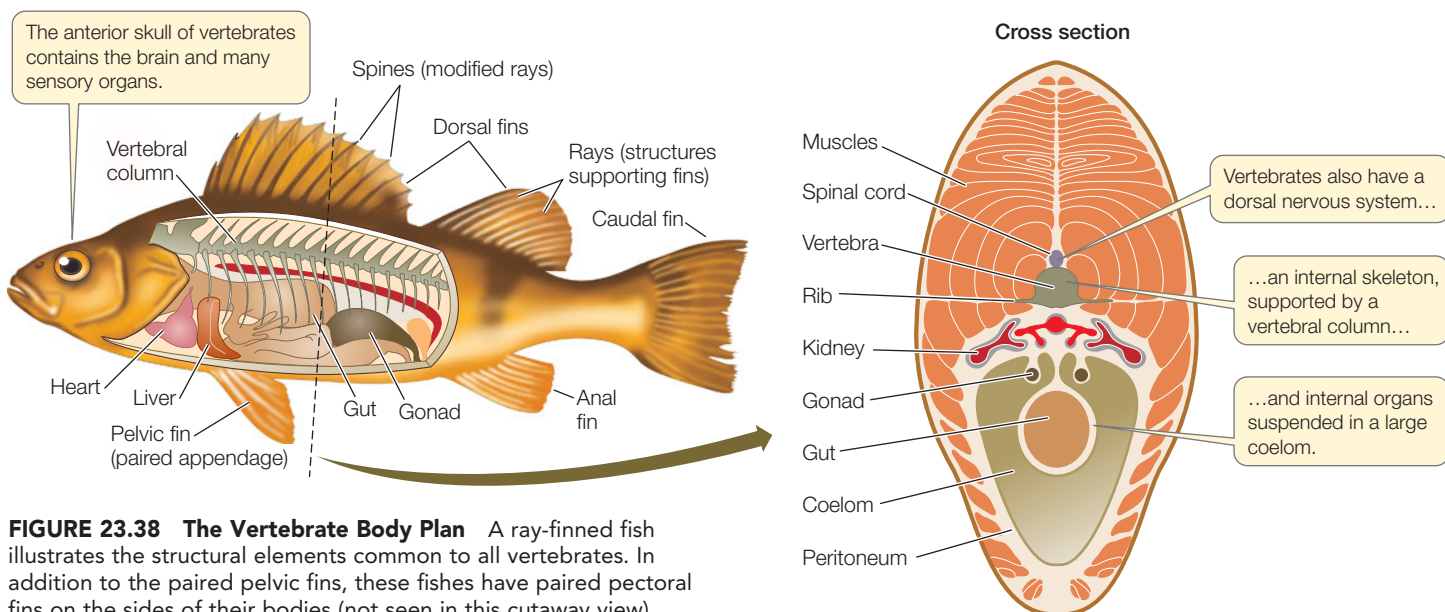

FIGURE 23.38 The Vertebrate Body Plan A ray-finned fish illustrates the structural elements common to all vertebrates. In addition to the paired pelvic fins, these fishes have paired pectoral fins on the sides of their bodies (not seen in this cutaway view).

- A rigid internal *skeleton* supported by the vertebral column
- Internal organs *suspended in a coelom*
- A well-developed *circulatory system*, driven by contractions of a ventral *heart*

This organization of the vertebrate body is exemplified by the bony fish diagrammed in **FIGURE 23.38**. Many kinds of jawless fishes were found in the seas, estuaries, and fresh waters of the Devonian period, but hagfishes and lampreys are the only jawless fishes that survived beyond the Devonian. During that period, the *gnathostomes* (Greek, “jaw mouths”) evolved jaws via modifications of the skeletal arches that supported the gills (**FIGURE 23.39**). Jaws greatly improved feeding efficiency, as an animal with jaws can grasp, subdue, and swallow large prey.

The earliest jaws were simple, but the evolution of *teeth* made predators more effective. In predators, teeth function crucially both in grasping and in breaking up prey. In both predators and herbivores, teeth enable an animal to chew both soft and hard body parts of their food. Chewing also aids chemical digestion and improves an animal’s ability to extract nutrients from its food.

Fins and swim bladders improved stability and control over locomotion

Paired fins stabilize the position of jawed fishes in water (and in some cases, help propel them). Most aquatic gnathostomes have a pair of pectoral fins just behind the gill slits, and a pair of pelvic fins anterior to the anal region (see Figures 23.38 and 23.40). Median dorsal and anal fins stabilize the fish, or may be used for propulsion in some species. In many fishes, the caudal (tail) fin helps propel the animal and enables it to turn rapidly.

Several groups of gnathostomes became abundant during the Devonian. Among them were the **chondrichthyans**—sharks, skates, and rays (940 living species) and chimaeras (40 living

FIGURE 23.39 Vertebrate Jaw Evolution Jaws of vertebrates are derived from modifications of the anterior gill arches of jawless fishes.

species). Like hagfishes and lampreys, these fishes have a skeleton composed entirely of firm but pliable cartilage. Their skin is flexible and leathery, sometimes bearing scales that give it the consistency of sandpaper. Sharks move forward by means of lateral undulations of their body and caudal fin (**FIGURE 23.40A**). Skates and rays propel themselves by means of vertical undulating movements of their greatly enlarged pectoral fins (**FIGURE 23.40B**).

Most sharks are predators, but some feed by straining plankton from the water. Most skates and rays live on the ocean floor, where they feed on mollusks and other animals buried in the sediments. Nearly all cartilaginous fishes live in the oceans, but a few are estuarine or migrate into lakes and rivers. One group of stingrays is found in river systems of South America. The less familiar chimaeras (**FIGURE 23.40C**) live in deep-sea or cold waters.

In the ancestor of the bony vertebrates, gas-filled sacs that extended from the digestive tract supplemented the gas-exchange function of the gills by giving the animals access to atmospheric oxygen. These features enabled those fishes to live where oxygen was periodically in short supply, as it often is in freshwater environments. These lunglike sacs evolved into *swim bladders* (organs of buoyancy), as well as into the lungs of tetrapods. By adjusting the amount of gas in its swim bladder, a fish can control the depth at which it remains suspended in the water while expending very little energy to maintain its position.

Ray-finned fishes, and most remaining groups of vertebrates, have internal skeletons of calcified, rigid *bone* rather than flexible cartilage. The outer body surface of most species of ray-finned fishes is covered with flat, thin, lightweight scales that provide some protection or enhance movement through the water. The gills of ray-finned fishes open into a single chamber covered by a hard flap, called an *operculum*. Movement of the operculum improves the flow of water over the gills, where gas exchange takes place.

FIGURE 23.40 Chondrichthyans The fins of chondrichthyans lack supportive rays. (A) Most sharks, such as this sandbar shark, are active marine predators. (B) The fins of skates and rays, represented here by a ribbontail stingray, are modified for feeding on the ocean bottom. (C) A chimaera, or ratfish.

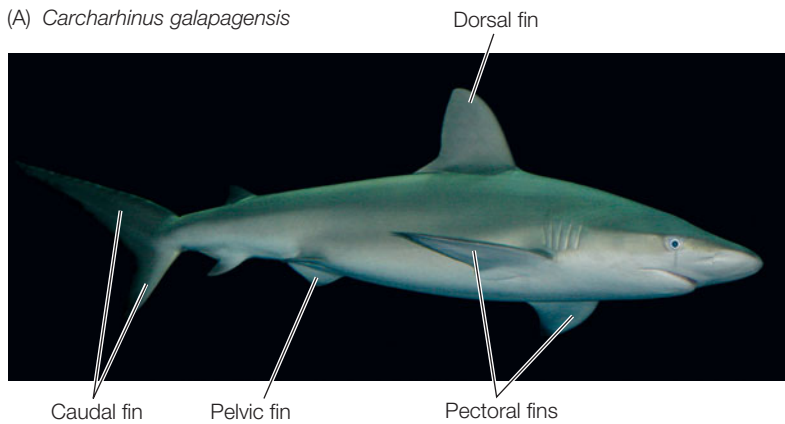

FIGURE 23.41 Ray-Finned Fishes (A) The two ray-finned species shown here are mutualists in their coral reef ecosystem. The larger sweetlips illustrates the body plan most commonly associated with this highly diverse clade. (B) Eels such as this moray have the large teeth and powerful jaws typical of predatory fishes. Their elongated, virtually finless bodies are adapted to hunting and hiding in narrow crevices.

Ray-finned fishes radiated extensively in the Tertiary. Today there are about 30,000 known living species, encompassing a remarkable variety of sizes, shapes, and lifestyles (FIGURE 23.41). The smallest are less than 1 centimeter long as adults; the largest weigh as much as 900 kilograms. Ray-finned fishes exploit nearly all types of aquatic food sources. In the oceans they filter plankton from the water, rasp algae from rocks, eat corals and other soft-bodied colonial animals, dig animals from soft sediments, and prey on virtually all kinds of other fishes. In fresh water they eat plankton, devour insects, eat fruits that fall into the water in flooded forests, and prey on other aquatic vertebrates and, occasionally, terrestrial vertebrates.

Do You Understand Concept 23.5?

- What are three developmental patterns the earliest deuterostomes had in common?
- What are some of the ways that echinoderms use their tube feet to obtain food?
- What synapomorphies respectively characterize the chordates and the vertebrates?
- How do the hagfishes differ from the lampreys in morphology and life history? Why do some biologists not consider the hagfishes to be vertebrates?

In some fishes, the lunglike sacs that gave rise to swim bladders became specialized for another purpose: breathing air. That adaptation set the stage for the vertebrates to move onto the land.

concept 23.6 Life on Land Contributed to Vertebrate Diversification

The evolution of lunglike sacs in fishes set the stage for the invasion of the land. Some early ray-finned fishes probably used those sacs to supplement their gills when oxygen levels in the water were low, as lungfishes and many groups of ray-finned fishes do today. But with their unjointed fins, those fishes could only flop around on land. Changes in the structure of the fins first allowed some fishes to support themselves better in shallow water and, later, to move better on land.

Jointed fins enhanced support for fishes

Two pairs of muscular, jointed fins evolved in the ancestor of the **sarcopterygians**, which include coelacanths, lungfishes, and tetrapods. Each of the jointed appendages of sarcopterygians is

(B) *Gymnothorax meleagris*

joined to the body by a single enlarged bone. The coelacanths flourished from the Devonian until about 65 million years ago, when they were thought to have become extinct. However, in 1938 a commercial fisherman caught a living coelacanth off South Africa. Since that time, hundreds of individuals of this extraordinary fish, *Latimeria chalumnae* (FIGURE 23.42A), have been collected. A second species, *L. menadoensis*, was discovered in 1998 off the Indonesian island of Sulawesi.

Lungfishes, which also have jointed fins that are connected to the body by a single enlarged bone, were important predators in shallow-water habitats in the Devonian, but most lineages died out. The six surviving species live in stagnant swamps and muddy waters in South America, Africa, and Australia (FIGURE 23.42B). Lungfishes have lungs derived from the lunglike sacs of their ancestors as well as gills. When ponds dry up, individuals of most species can burrow deep into the mud and survive for many months in an inactive state while breathing air.

Some early aquatic sarcopterygians began to use terrestrial food sources, became more fully adapted to life on land, and eventually evolved to become ancestral **tetrapods** (four-legged vertebrates). The earliest tetrapod limbs appear to have functioned in holding the animals upright in shallow water, allowing them to hold their head above the water's surface. These same structures were then co-opted for movement on land, at first probably for foraging on brief trips out of water.

(A) *Latimeria chalumnae*(B) *Protopterus annectens*

FIGURE 23.42 The Closest Relatives of Tetrapods (A) The African coelacanth, discovered in deep waters of the Indian Ocean, represents one of two surviving species of a group that was once thought to be extinct. (B) All surviving lungfish species, such as this African lungfish, live in the Southern Hemisphere.

Amphibians adapted to life on land

Most modern **amphibians** are confined to moist environments because they lose water rapidly through the skin when exposed to dry air. In addition, their eggs are enclosed within delicate membranous envelopes that cannot prevent water loss in dry

conditions. In some amphibian species, adults live mostly on land but return to fresh water to lay their eggs, which are usually fertilized outside the body (**FIGURE 23.43**). The fertilized eggs give rise to larvae that live in water until they undergo metamorphosis to become terrestrial adults. However, many amphibians (especially those in tropical and subtropical areas) have evolved a wide diversity of additional reproductive modes and types of parental care. Internal fertilization evolved many times among the amphibians. Many species develop directly into adultlike forms from fertilized eggs laid on land or carried by the parents. Other species of amphibians are entirely aquatic, never leaving the water at any stage of their lives, and many of these species retain a larval-like morphology.

The more than 6,500 known species of amphibians living on Earth today belong to three major groups: the wormlike, limbless, tropical, burrowing or aquatic *caecilians* (**FIGURE 23.44A**), the tail-less frogs and toads (collectively called *anurans*; **FIGURE 23.44B**), and the tailed *salamanders* (**FIGURE 23.44C,D**).

Most early stages in the life cycle of many amphibians take place in water. The aquatic tadpole transforms into a terrestrial adult through metamorphosis. Some species of amphibians, however, have direct development (with no aquatic larval stage), and others are aquatic throughout life.

FIGURE 23.43 In and Out of the Water Most early stages in the life cycle of many amphibians take place in water. The aquatic tadpole transforms into a terrestrial adult through metamorphosis. (A) *Gymnophis multiplicata*(B) *Bufo periglenes*(C) *Tylototriton verrucosus*(D) *Eurycea waterlooensis*

Anurans are most diverse in wet tropical and warm temperate regions, although a few are found at very high latitudes. There are far more anurans—about 5,800 described species, with more being discovered every year—than any other amphibians. Some anurans have tough skins and other adaptations that enable them to live for long periods in very dry deserts, whereas others live in moist terrestrial and arboreal environments. Some species are completely aquatic as adults. All anurans have a very short vertebral column, with a strongly modified pelvic region that is adapted for leaping, hopping, or propelling the body through water by kicking the hind legs.

The approximately 600 described species of salamanders are most diverse in temperate regions of the Northern Hemisphere, but many species are also found in cool, moist environments in the mountains of Central America, and a few species penetrate into the South American tropics. Many salamanders live in rotting logs or moist soil. One major group has lost lungs, and these species exchange gases entirely through the skin and mouth lining—body parts that all amphibians use in addition to their lungs. Through *paedomorphosis* (retention of the juvenile state), a completely aquatic lifestyle has evolved several times among the salamanders (see Figure 23.44D). Most species of salamanders have internal fertilization, which is usually achieved through the transfer of a small jellylike, sperm-embedded capsule called a *spermatophore*.

Many amphibians have complex social behaviors. Most male anurans utter loud, species-specific calls to attract females of their own species (and sometimes to defend breeding territories), and they compete for access to females that arrive at the breeding sites. Many amphibians lay large numbers of

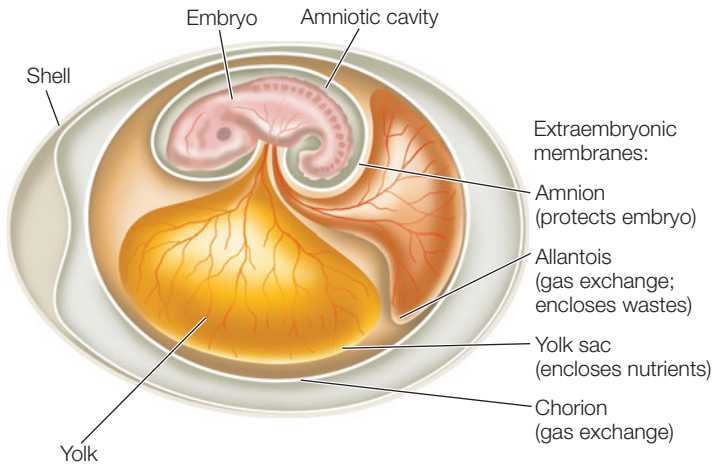

eggs, which they abandon once they are deposited and fertilized. Some amphibians lay only a few eggs, which are fertilized and then guarded in a nest or carried on the backs, in the vocal pouches, or even in the stomachs of one of the parents. A few species of frogs, salamanders, and caecilians are *viviparous*, meaning they give birth to well-developed young that have received nutrition from the female during gestation.

Amphibians are the focus of much attention today because populations of many species are declining rapidly, especially in mountainous regions of western North America, Central and South America, and northeastern Australia. Worldwide, about one-third of amphibian species are now threatened with extinction or have disappeared completely in the last few decades. Scientists are investigating several hypotheses to account for these population declines, including the adverse effects of habitat alteration by humans, increased solar radiation caused by destruction of Earth's ozone layer, pollution from urban and industrial areas and airborne agricultural pesticides and herbicides, and the spread of a pathogenic chytrid fungus that attacks amphibians. Scientists have documented the spread of the chytrid fungus through Central America, where many species of amphibians have become extinct (including Costa Rica's golden toad; see Figure 23.44B).

Amniotes colonized dry environments

Several key innovations contributed to the ability of members of one clade of tetrapods to exploit a wide range of terrestrial habitats. The animals that evolved these water-conserving traits are called **amniotes**.

The **amniote egg** (which gives the group its name) is relatively impermeable to water and allows the embryo to develop in a contained aqueous environment:

The leathery or brittle, calcium-impregnated shell of the amniote egg retards evaporation of the fluids inside but permits passage of oxygen and carbon dioxide. The egg also stores large quantities of food in the form of *yolk*, allowing the embryo to attain a relatively advanced state of development before it hatches. Within the shell are *extraembryonic membranes* that protect the embryo from desiccation and assist its gas exchange and excretion of waste nitrogen.

yourBioPortal.com

Go to WEB ACTIVITY 23.6
The Amniote Egg

In several different groups of amniotes, the amniote egg became modified, allowing the embryo to grow inside (and

receive nutrition from) the mother. For instance, the mammalian egg lost its shell while the functions of the extraembryonic membranes were retained and expanded.

LINK The roles of the extraembryonic membranes of the amniote egg are discussed in Concept 33.5

Other innovations evolved in the organs of terrestrial adults. A tough, impermeable skin, covered with scales or modifications of scales such as hair and feathers, greatly reduced water loss. Adaptations of the vertebrate excretory organs, the kidneys, allowed amniotes to excrete concentrated urine, ridding the body of waste nitrogen without losing a large amount of water in the process.

During the Carboniferous, amniotes split into two major groups, the mammals and reptiles (**FIGURE 23.45**). More than 18,700 species of **reptiles** exist today, over half of which are *birds*. Birds are the only living members of the otherwise extinct *dinosaurs*, the dominant terrestrial predators of the Mesozoic.

Reptiles adapted to life in many habitats

The lineage leading to modern reptiles began to diverge from other amniotes about 250 million years ago. One reptilian group that has changed very little over the intervening millennia is the *turtles*. The dorsal and ventral bony plates of turtles form a shell into which the head and limbs can be withdrawn in many species (**FIGURE 23.46A**). The dorsal shell is an expansion of

FIGURE 23.45 Phylogeny of Amniotes This tree of amniote relationships shows the primary split between mammals and reptiles. The reptile portion of the tree shows a lineage leading to the turtles, another to the lepidosaurs (snakes, lizards, and tuataras), and a third branch that includes all the archosaurs (crocodiles, several extinct groups, and the birds). There is some uncertainty in the placement of the turtle lineage; some data support a relationship between turtles and archosaurs.

FIGURE 23.46 Reptilian Diversity (A) Turtles are unique shelled vertebrates. The dorsal shell, or carapace, is an adaptation of the rib bones. (B) The tuatara represents one of only two surviving species in a lineage that diverged long ago. (C,D) Lizards and snakes are the major squamate groups. (C) The leopard gecko is a desert lizard native to Afghanistan, Pakistan, and northwestern India. (D) The nonvenomous Mexican milk snake has a color pattern similar to that of the deadly coral snake. Such evolutionary adaptation, in which the harmless species gains protection from its resemblance to a deadly animal, is known as Batesian mimicry.

(A) *Emydoidea blandingii*(B) *Sphenodon punctatus*(C) *Eublepharis macularius*(D) *Lampropeltis triangulum*

the ribs, and it is a mystery how the pectoral girdles evolved to be inside the ribs of turtles, making them unlike any other vertebrates. Most turtles live in aquatic environments, but several groups, such as tortoises and box turtles, are terrestrial. Sea turtles spend their entire lives at sea except when they come ashore to lay eggs. Human exploitation of sea turtles and their eggs has resulted in worldwide declines of these species, all of which are now endangered. A few species of turtles are strict herbivores or carnivores, but most species are omnivores that eat a variety of aquatic and terrestrial plants and animals.

The *lepidosaurs* constitute the second-most species-rich clade of living reptiles. This group is composed of the *squamates* (lizards, snakes, and amphisbaenians—the last a group of mostly legless, wormlike, burrowing reptiles with greatly reduced eyes) and the *tuataras*, which superficially resemble lizards but differ from them in tooth attachment and several internal anatomical features. Many species related to the tuataras lived during the Mesozoic era, but today only two species, restricted to a few islands off New Zealand, survive (FIGURE 23.46B).

The skin of a lepidosaur is covered with horny scales that greatly reduce loss of water from the body surface. These scales, however, make the skin unavailable as an organ of gas exchange. Gases are exchanged almost entirely via the lungs, which are proportionally much larger in surface area than those of amphibians. A lepidosaur forces air into and out of its lungs by bellowslike movements of its ribs. The three-chambered lepidosaur heart partially separates oxygenated blood from the lungs from deoxygenated blood returning from the body. With this type of heart, lepidosaurs can generate high blood pressure and can sustain a relatively high metabolism.

Most lizards are insectivores, but some are herbivores; a few prey on other vertebrates. The largest lizard, which grows as long as 3 meters and can weigh more than 150 kilograms, is the predaceous Komodo dragon of the East Indies. Most lizards walk on four limbs (FIGURE 23.46C), although limblessness has evolved repeatedly in the group, especially in burrowing and grassland species. One major group of limbless squamates is the snakes (FIGURE 23.46D). All snakes are carnivores, and many can swallow objects much larger than themselves. Several snake groups evolved venom glands and the ability to inject venom rapidly into their prey.

FRONTIERS One group of lizards, the geckoes, are well known for their ability to climb smooth vertical surfaces. Biologists recently discovered that they accomplish this task using microscopically branched elastic fibers on their toe pads, which grip surfaces using atomic-scale attractive forces. These microscopic structures of gecko feet are now the basis for the development of new dry adhesives based on similar carbon “nanotubes.” These new adhesives are expected to have many applications, from connecting materials in the vacuum of space to the assembly of electronic microdevices.

Crocodylians and birds share their ancestry with the dinosaurs

Another reptilian group, the *archosaurs*, includes the crocodylians, dinosaurs, and birds. *Dinosaurs* rose to prominence about 215 million years ago and dominated terrestrial environments

(A) *Crocodylus niloticus*(B) *Rhea americana*

for about 150 million years; only one group of dinosaurs, the *birds*, survived the mass extinction event at the Cretaceous–Tertiary boundary. During the Mesozoic, most terrestrial animals more than a meter long were dinosaurs. Many were agile and could run rapidly; they had special muscles that enabled the lungs to be filled and emptied while the limbs moved. We can infer the existence of such muscles in extinct dinosaurs from the structure of the vertebral column in fossils. Some of the largest dinosaurs weighed as much as 70,000 kilograms.

Modern *crocodilians*—crocodiles, caimans, gharials, and alligators—are confined to tropical and warm temperate environments (FIGURE 23.47A). Crocodilians spend much of their time in water, but they build nests on land or on floating piles of vegetation. The eggs are warmed by heat generated by decaying organic matter that the female places in the nest. Typically, the female guards the eggs until hatching, and she often facilitates hatching. In some species, the female continues to guard and communicate with her offspring after they hatch. All crocodilians are carnivorous. They eat vertebrates of all kinds, including large mammals.

Biologists have long accepted the phylogenetic position of birds among the reptiles, although birds clearly have many unique, derived morphological features. In addition to the strong morphological evidence for the placement of birds among the reptiles, fossil and molecular data emerging over the last few decades have provided definitive supporting evidence. Birds are thought to have emerged among the *theropods*, a group of predatory dinosaurs that share such traits as bipedal stance, hollow bones, a *furcula* (“wishbone”), elongated

FIGURE 23.47 Archosaurs (A) Crocodiles, alligators, and their relatives live in tropical and warm temperate climates. The Nile crocodile is commonly found over much of the African continent. (B) Birds are the other living archosaur group. This South American rhea is a palaeognath, a group that includes several flightless and weakly flying birds of the Southern Hemisphere. Flightless members of this early-diverging group lack the sternum keel structure that anchors the flight muscles of other bird groups.

metatarsals with three-fingered feet, elongated forelimbs with three-fingered hands, and a pelvis that points backward.

The living bird species fall into two major groups that diverged during the late Cretaceous, about 80 to 90 million years ago, from a flying ancestor. The few modern descendants of one lineage include a group of secondarily flightless and weakly flying birds, some of which are very large. This group, called the *palaeognaths*, includes the South and Central American tinamous and several large, flightless birds of the southern continents; these include the rheas (FIGURE 23.47B), emu, kiwis, cassowaries, and the world’s largest bird, the ostrich. The second lineage, the *neognaths*, has left a much larger number of descendants, most of which have retained the ability to fly.

The evolution of feathers allowed birds to fly

During the Mesozoic era, about 175 million years ago, a lineage of theropods gave rise to the birds. Recent fossil discoveries show that the scales of some theropod dinosaurs were modified to form *feathers*. The feathers of many of these dinosaurs were structurally similar to those of modern birds (FIGURE 23.48).

The oldest known avian fossil, *Archaeopteryx*, which lived about 150 million years ago, had teeth, but it was covered with feathers that are virtually identical to those of modern birds (see Figure 23.48B). It also had well-developed wings, a long tail, and a furcula to which some of the flight muscles were probably attached. *Archaeopteryx* had clawed fingers on its forelimbs, but it also had typical perching bird claws on its hindlimbs. It probably lived in trees and shrubs and used the fingers to assist it in clambering over branches.

The evolution of feathers was a major force for diversification. Feathers are lightweight but are strong and structurally complex. The large quills of the flight feathers on the wings arise from the skin of the forelimbs to create the flying surfaces. Other strong feathers sprout like a fan from the shortened tail and serve as stabilizers during flight. The feathers that cover the body, along with an underlying layer of down feathers, provide birds with insulation that helps them survive in virtually all of Earth’s climates.

The bones of theropod dinosaurs, including birds, are hollow with internal struts that increase their strength. Hollow bones would have made early theropods lighter and more mobile; later they facilitated the evolution of flight. The sternum (breastbone) of flying birds forms a large, vertical keel to which the flight muscles are attached.

Flight is metabolically expensive. A flying bird consumes energy at a rate 15 to 20 times faster than a running lizard of

FIGURE 23.48 Mesozoic Bird Relatives The fossil record supports the evolution of birds from other dinosaurs. (A) *Microraptor gui* was a feathered dinosaur from the early Cretaceous (about 140 mya). (B) Dating from roughly the same time frame, *Archaeopteryx* is the oldest known birdlike fossil.

and other vertebrates. By eating the fruits and seeds of plants, birds serve as major agents of seed dispersal. **FIGURE 23.49** shows representatives of a few of the major groups of birds.

Mammals radiated as nonavian dinosaurs declined in diversity

Small and medium-sized **mammals** coexisted with the dinosaurs for millions of years. After the nonavian dinosaurs disappeared during the mass extinction at the close of the Mesozoic era, mammals increased dramatically in numbers, diversity, and size. Today mammals range in size from tiny shrews and bats weighing only about 2 grams to the blue whale, the largest animal on Earth, which measures up to 33 meters long and can weigh as much as 160,000 kilograms. Mammals have far fewer, but more highly differentiated, teeth than do fishes, amphibians, or reptiles. Differences among mammals in the number, type, and arrangement of teeth reflect their varied diets.

the same weight. Because birds have such high metabolic rates, they generate large amounts of heat. They control the rate of heat loss using their feathers, which may be held close to the body or elevated to alter the amount of insulation they provide (see Concept 29.4). The lungs of birds allow air to flow through unidirectionally rather than by pumping air in and out (see Figure 37.5). This flow-through structure of the lungs increases the efficiency of gas exchange and thereby supports an increased metabolic rate.

There are about 10,000 species of birds alive today. They range in size from the 150-kilogram ostrich to a hummingbird weighing only 2 grams. The teeth—so prominent among other dinosaurs—were secondarily lost in the ancestral birds, but birds nonetheless eat almost all types of animal and plant material. Insects and fruits are the most important dietary items for terrestrial species. Birds also eat seeds, nectar and pollen, leaves and buds, carrion, and fish

(A) *Balearica regulorum gibbericeps*

(B) *Megascops asio*

(C) *Carduelis carduelis*

FIGURE 23.49 Some Diverse Birds (A) The East African crowned crane feeds on insects, small reptiles, and even small mammals. Like other crane species, its mating and courtship behavior includes an elaborate dance display. (B) Owls such as this screech owl are nighttime predators that can locate prey using their sensitive auditory systems. (C) Perching, or passeriform, birds such as this European goldfinch comprise the most species-rich of all bird groups.

(A) *Ornithorhynchus anatinus*(B) *Didelphis virginiana*(C) *Spermophilus mexicanus*(D) *Macroderma gigas*

(E)

(F) *Megaptera novaeangliae*

Four key features distinguish the mammals:

- *Sweat glands*, which secrete sweat that evaporates and thereby cools an animal (see Concept 29.4).
- *Mammary glands*, which in females secrete a nutritive fluid (milk) on which newborn individuals feed.
- *Hair*, which provides a protective and insulating covering.
- A *four-chambered heart* that completely separates the oxygenated blood coming from the lungs from the deoxygenated blood returning from the body (this last characteristic is convergent with the archosaurs, including modern birds and crocodiles; see Concept 38.2).

Mammalian eggs are fertilized within the female's body, and the embryos undergo a period of development in the female's body in an organ called the *uterus* prior to being born. Most mammals have a covering of hair (fur), which is luxuriant in some species but has been greatly reduced in others, including the cetaceans (whales and dolphins) and humans. Thick layers of insulating fat (blubber) replace hair as a heat-retention mechanism in the cetaceans; humans learned to use clothing for this purpose when they dispersed from warm tropical areas.

FIGURE 23.50 Mammalian Diversity (A) The duck-billed platypus is one of the five surviving species of prototherians—mammals that lay eggs. (B) Female marsupial mammals have a ventral pouch in which they nurture their offspring, which are extremely small at birth. The young of this opossum have grown large enough to leave her pouch. (C–F) Eutherian mammals. (C) Almost half of all eutherians are rodents, such as this Mexican ground squirrel. (D) Flight evolved in the common ancestor of bats. Virtually all bat species are nocturnal. (E) Many large mammals are important herbivores in terrestrial environments. Nowhere are these assemblages more spectacular than on the grass and brushlands of the African continent. (F) Humpback whales are cetaceans, a cetartiodactyl group that returned to the marine environment. A mother and calf are seen here.

The approximately 5,000 species of living mammals are divided into two primary groups: the *prototherians* and the *therians*. Only five species of prototherians are known, and they are found only in Australia and New Guinea. These mammals, the duck-billed platypus and four species of echidnas, differ from other mammals in lacking a placenta, laying eggs, and having sprawling legs (FIGURE 23.50A). Prototherians supply milk for their young, but they have no nipples on their mammary glands; the milk simply oozes out and is lapped off the fur by the offspring.

TABLE 23.3 Major Groups of Living Eutherian Mammals

GROUP	APPROXIMATE NUMBER OF LIVING SPECIES	EXAMPLES
Gnawing mammals (Rodentia)	2,300	Rats, mice, squirrels, woodchucks, ground squirrels, beaver, capybara
Flying mammals (Chiroptera)	1,100	Bats
Soricomorph insectivores (Soricomorpha)	430	Shrews, moles
Even-toed hoofed mammals and cetaceans (Cetartiodactyla)	320	Deer, sheep, goats, cattle, antelopes, giraffes, camels, swine, hippopotamus, whales, dolphins
Carnivores (Carnivora)	290	Wolves, dogs, bears, cats, weasels, pinnipeds (seals, sea lions, walruses)
Primates (Primates)	235	Lemurs, monkeys, apes, humans
Lagomorphs (Lagomorpha)	80	Rabbits, hares, pikas
African insectivores (Afrosoricida)	50	Tenrecs, golden moles
Spiny insectivores (Erinaceomorpha)	24	Hedgehogs
Armored mammals (Cingulata)	21	Armadillos
Tree shrews (Scandentia)	20	Tree shrews
Odd-toed hoofed mammals (Perissodactyla)	20	Horses, zebras, tapirs, rhinoceroses
Long-nosed insectivores (Macroscelidea)	16	Elephant shrews
Pilosans (Pilosa)	10	Anteaters, sloths
Pholidotans (Pholidota)	8	Pangolins
Sirenians (Sirenia)	5	Manatees, dugongs
Hyracoids (Hyracoidea)	4	Hyraxes, dassies
Elephants (Proboscidea)	3	African and Indian elephants
Dermopterans (Dermoptera)	2	Flying lemurs
Aardvark (Tubulidentata)	1	Aardvark

Most mammals are viviparous

Members of the viviparous *therian* clade are further divided into the *marsupials* and the *eutherians*. Females of most marsupial species have a ventral pouch in which they carry and feed their offspring (FIGURE 23.50B). Gestation (pregnancy) in marsupials is brief; the young are born tiny but with well-developed forelimbs, with which they climb to the pouch. They attach to a nipple but cannot suck. The mother ejects milk into the tiny offspring until they grow large enough to suckle. Once her offspring have left the uterus, a female marsupial may become sexually receptive again. She can then carry fertilized eggs that are capable of initiating development and can replace the offspring in her pouch should something happen to them.

Eutherians include the majority of mammals. Eutherians are sometimes called *placental mammals*, but this name is inappropriate because some marsupials also have placentas. Eutherians are more developed at birth than are marsupials; no external pouch houses them after they are born.

The approximately 5,000 living species of morphologically diverse eutherians are divided into 20 major groups (TABLE 23.3). The largest group is the rodents (FIGURE 23.50C), with about 2,300 species. Rodents are traditionally defined by the unique morphology of their teeth, which are adapted for gnawing through substances such as wood. The next largest group comprises the approximately 1,100 bat species (FIGURE 23.50D)—the flying mammals. The bats are followed by the

moles and shrews, with about 430 species. The relationships of the major groups of eutherians to one another have been difficult to determine because most of the major groups diverged in a short period of time during an explosive adaptive radiation.

Grazing and *browsing* by members of several eutherian groups helped transform the terrestrial landscape. Herds of grazing herbivores feed on open grasslands, whereas browsers feed on shrubs and trees. The effects of herbivores on plant life favored the evolution of the spines, tough leaves, and difficult-to-eat growth forms found in many plants. In turn, adaptations to the teeth and digestive systems of many herbivore lineages allowed these species to consume many plants despite such defenses—a striking example of coevolution. A large animal can survive on food of lower quality than a small animal can, and large size evolved in several groups of grazing and browsing mammals (FIGURE 23.50E). The evolution of large herbivores, in turn, favored the evolution of large carnivores able to attack and overpower them.

Several lineages of terrestrial eutherians subsequently returned to the aquatic environments their ancestors had left behind (FIGURE 23.50F). The completely aquatic cetaceans—whales and dolphins—evolved from artiodactyl ancestors (whales are closely related to the hippopotamuses). The seals, sea lions, and walruses also returned to the marine environment, and their limbs became modified into flippers. Weasel-like otters retain their limbs but have also returned to aquatic

environments, colonizing both fresh and salt water. The manatees and dugongs colonized estuaries and shallow seas.

Do You Understand Concept 23.6?

- Many amphibians have a biphasic life cycle that includes an aquatic larva and a terrestrial adult. What are some exceptions to this common pattern?
- In the not-too-distant past, the idea that birds were reptiles met with skepticism. Explain how fossils, morphology, and molecular evidence now support the position of birds among the reptiles.
- Contrast the reproductive modes of prototherians, marsupials, and eutherians.

The evolutionary history of one eutherian group—the primates—is of special interest to us because it includes the human lineage. The primates have been the subject of extensive research in most aspects of their biology, including behavior, ecology, physiology, and molecular biology.

concept 23.7 Humans Evolved among the Primates

The **primates** underwent extensive evolutionary radiation from an ancestral small, arboreal, insectivorous mammal. Grasping limbs with opposable digits are one of the major adaptations to arboreal life that distinguish primates from other mammals.

Early in their evolutionary history, the primates split into two main clades, the prosimians and the anthropoids (**FIGURE 23.51**). *Prosimians*—lemurs, lorises, and their close relatives—once lived on all continents, but today they are restricted to Africa, Madagascar, and tropical Asia. A second primate lineage, the *anthropoids*—tarsiers, New World monkeys, Old World monkeys, and apes—evolved about 65 million years ago in Africa or Asia. New World monkeys diverged from Old World monkeys and apes at a slightly later date, but at an early enough date that they might have reached South America from Africa when those two continents were still close to each other. All New World monkeys are arboreal, and many have long, prehensile tails with which they can grasp branches. Many Old World monkeys are arboreal as well, but a number of species are terrestrial. No Old World primate has a prehensile (grasping) tail.

About 35 million years ago, a lineage that led to the apes separated from the Old World

monkeys. Between 22 and 5.5 million years ago, dozens of species of apes lived in Europe, Asia, and Africa. The Asian apes (gibbons and orangutans), African apes (gorillas and chimpanzees), and humans are their modern descendants.

Human ancestors evolved bipedal locomotion

About 6 million years ago in Africa, a lineage split occurred that would lead to the chimpanzees on the one hand and to the *hominid* clade on the other. It is the latter that includes modern humans and their extinct close relatives.

The earliest known protohominids, the *ardipithecines*, had distinct morphological adaptations for *bipedal locomotion* (walking on two legs). Bipedal locomotion frees the forelimbs to manipulate objects and to carry them while walking. It also elevates the eyes, enabling the animal to see over tall vegetation to spot predators and prey. Bipedal locomotion is also energetically more economical than quadrupedal locomotion. All three advantages were probably important for the *ardipithecines* and their descendants, the *australopithecines*.

FIGURE 23.51 Phylogeny of the Primates The phylogeny of primates is among the best studied of any major group of mammals. This tree is based on evidence from many genes, morphology, and fossils.

The first *australopithecine* skull was found in South Africa in 1924. Since then australopithecine fossils have been found at many African sites. The most complete fossil skeleton of an australopithecine yet found was discovered in Ethiopia in 1974. The skeleton was approximately 3.5 million years old and was that of a young female who has since become known to the world as “Lucy.” Lucy was assigned to the species *Australopithecus afarensis*, and her discovery captured worldwide interest. Fossil remains of more than a hundred *A. afarensis* individuals have since been discovered, and recent discoveries have unearthed fossils of other australopithecines that lived in Africa 4–5 million years ago.

Experts disagree over how many species are represented by australopithecine fossils, but it is clear that multiple species of hominids lived together over much of eastern Africa several million years ago (FIGURE 23.52). A lineage of larger species (weighing about 40 kilograms) is represented by *Paranthropus robustus* and *P. boisei*, both of which died out between 1 and 1.5 million years ago. Members of a smaller lineage of australopithecines gave rise to the genus *Homo*.

Early members of the genus *Homo* lived contemporaneously with *Paranthropus* in Africa for about a million years. Some 2-million-year-old fossils of an extinct species called *H. habilis* were discovered in the Olduvai Gorge, Tanzania. Other fossils of *H. habilis* have been found in Kenya and Ethiopia.

Associated with the fossils are tools that these early hominids used to obtain food.

Another extinct hominid species, *Homo erectus*, evolved in Africa about 1.6 million years ago. Soon thereafter it had spread as far as eastern Asia, becoming the first hominid to leave Africa. Members of *H. erectus* were nearly as large as modern people, but their brains were smaller and they had comparatively thick skulls. *Homo erectus* used fire for cooking and for hunting large animals, and made characteristic stone tools that have been found in many parts of the Old World. Populations of *H. erectus* survived until at least 250,000 years ago, although more recent fossils may also be attributable to this species. In 2004 some 18,000-year-old fossil remains of a small *Homo* were found on the island of Flores in Indonesia. Since then, numerous additional fossils of this diminutive hominid have been found on Flores, dating from 95,000 to 17,000 years ago. Many anthropologists think that this small species, named *H. floresiensis*, was most closely related to *H. erectus*.

FIGURE 23.52 A Phylogenetic Tree of Hominids At times in the past, more than one species of hominid lived on Earth at the same time. Originating in Africa, hominids spread to Europe and Asia multiple times. All but one of these closely related species are now extinct; modern *Homo sapiens* have colonized nearly every corner of the planet.

Human brains became larger as jaws became smaller

In the hominid lineage leading to *Homo sapiens* and *H. neanderthalensis*, the brain increased rapidly in size. At the same time, the powerful jaw muscles of our ancestors dramatically decreased in size. These two changes were simultaneous, suggesting they might have been functionally correlated. A mutation in a myosin gene that is expressed in jaw muscles may have removed a barrier that had previously prevented this remodeling of the human cranium.

The striking enlargement of the brain relative to body size in the hominid lineage was probably favored by an increasingly complex social life. Any features that allowed group members to communicate more effectively with one another would have been valuable in cooperative hunting and gathering and for improving one's status in the complex social interactions that must have characterized early human societies, just as they do in ours today.

Several *Homo* species coexisted during the mid-Pleistocene epoch, from about 1.5 million to about 250,000 years ago. All were skilled hunters of large mammals, but plants were important components of their diets. During this period another distinctly human trait emerged: rituals and a concept of life after death. Deceased individuals were buried with tools and clothing, supplies for their presumed existence in the next world.

One species, *Homo neanderthalensis*, was widespread in Europe and Asia between about 500,000 and 28,000 years ago. Neanderthals were short, stocky, and powerfully built. Their massive skull housed a brain somewhat larger than our own. They manufactured a variety of tools and hunted large mammals, which they probably ambushed and subdued in close combat. Early modern humans (*H. sapiens*) expanded out of Africa between 70,000 and 60,000 years ago. Then about 35,000 years ago, *H. sapiens* moved into the range of *H. neanderthalensis* in Europe and western Asia, so the two species must have interacted with one another. Neanderthals abruptly disappeared about 28,000 years ago. Many anthropologists believe it is likely that the Neanderthals were exterminated by these early modern humans. Scientists have been able to isolate large parts of the genome of *H. neanderthalensis* from recent fossils and to compare it with our own. These studies suggest that a small amount of interbreeding between the two species occurred shortly after *H. sapiens* expanded out of Africa.

Early modern humans made and used a variety of sophisticated tools. They created the remarkable paintings of large mammals, many of them showing scenes of hunting, found in European caves. The animals depicted were characteristic of the cold steppes and grasslands that occupied much of Europe during periods of glacial expansion. Early modern humans also spread across Asia, reaching North America perhaps as early as 20,000 years ago, although the date of their arrival in the New World is still uncertain. Within a few thousand years, they had spread southward through North America to the southern tip of South America.

Do You Understand Concept 23.7?

- Describe the differences between Old World and New World monkeys.
- What leads biologists to conclude that the evolution of brain size and jaw size may be functionally linked?
- If interbreeding between *Homo sapiens* and *H. neanderthalensis* took place after *H. sapiens* expanded out of Africa, what would you predict about the distribution of Neanderthal genes in modern human populations?

Besides the insects, which other groups of animals are thought to contain many more species than are known at present?

ANSWER It is perhaps easier to list the groups of animals for which a nearly complete inventory of living species has been completed than to list all the groups for which many new species remain to be described. Among the insects, the best-studied group in terms of species is the butterflies, which are widely collected and studied. There are still many species of other lepidopterans (such as moths), however, remaining to be discovered. Most other major insect groups contain many undescribed species. Among the vertebrates, most species of birds and mammals have been described, although several new species of mammals are still discovered and named each year. Species discovery and description remains high for almost all other major groups of animals.

After insects, and perhaps even rivaling the insects in undiscovered diversity, are the nematodes. Although known nematode diversity is only about 1/40th of the known insect diversity (in terms of number of described species), the taxonomy of nematodes is much more poorly studied than that of insects. Some biologists think there are likely to be species-specific parasitic nematodes of most other species of multicellular organisms. If so, then there may be as many species of nematodes as there are of plants, fungi, and other animals combined.

Most of the other diverse groups of animals contain many as yet undetected species, judging from the rate of new species descriptions. In particular, flatworms (especially the parasitic flukes and tapeworms), marine annelids, mollusks, crustaceans, myriapods, and chelicerates all contain large numbers of undescribed species. Among the vertebrates, the rate of discovery of new species remains particularly high for the fishes and amphibians.

23

SUMMARY

concept 23.1 Distinct Body Plans Evolved among the Animals

- Animals share a set of derived traits not found in other groups of organisms, including similarities in the sequences of many of their genes, the structure of their cell junctions, and the components of their extracellular matrix. **Review Figure 23.1 and WORKING WITH DATA 23.1**
- Patterns of embryonic development provide clues to the evolutionary relationships among animals. **Diploblastic** animals develop two embryonic cell layers; **triploblastic** animals develop three cell layers.
- Differences in their patterns of early development characterize two major clades of triploblastic animals, the **protostomes** and the **deuterostomes**.
- Animal **body plans** can be described in terms of **symmetry**, **body cavity** structure, **segmentation**, and type of appendages.
- Most animals have either **radial symmetry** or **bilateral symmetry**. Many bilaterally symmetrical animals exhibit **cephalization**, with sensory and nervous tissues in an anterior head.
- On the basis of their body cavity structure, animals can be described as **acoelomates**, **pseudocoelomates**, or **coelomates**. **Review Figure 23.3 and WEB ACTIVITY 23.1**
- Segmentation takes many forms and improves control of movement, especially if the animal also has appendages.

concept 23.2 Some Animal Groups Fall Outside the Bilateria

- All animals other than **sponges**, **placozoans**, **ctenophores**, and **cnidarians** belong to a large, monophyletic group called the **Bilateria**. **Eumetazoans**, which have tissues organized into distinct organs, include all animals other than sponges and placozoans. **See WEB ACTIVITY 23.2**
- Sponges and placozoans are simple, asymmetrical animals that lack differentiated cell layers and true organs. Sponges have skeletons made up of siliceous or calcareous **spicules**. They create water currents and capture food with flagellated feeding cells called choanocytes. Choanocytes are an evolutionary link between the animals and the choanoflagellate protists.
- The two cell layers of the radially symmetrical ctenophores are separated by an inert extracellular matrix called **mesoglea**. Ctenophores move by beating fused plates of cilia called **ctenes**. **Review Figure 23.7**
- The life cycle of most cnidarians has two distinct stages: a sessile **polyp** stage and a motile **medusa**. A fertilized egg develops into a free-swimming larval **planula**, which settles to the bottom and develops into a polyp. **Review Figure 23.8 and ANIMATED TUTORIAL 23.1**

concept 23.3 There Are Two Major Groups of Protostomes

- Protostomes (“mouth first”) are bilaterally symmetrical animals that have an anterior brain surrounding the entrance to the digestive tract and a ventral nervous system. Protostomes comprise two major clades, the lophotrochozoans and the ecdysozoans. **See WEB ACTIVITIES 23.3 and 23.4**
- **Lophotrochozoans** include a wide diversity of animals. Within this group evolved **lophophores** (a complex organ for food collection and gas exchange) and free-living **trochophore** larvae. These features were subsequently lost in some lineages. **Arrow worms** may be related to lophotrochozoans, or they may be the sister group to all other protostomes.
- Lophophores, wormlike body forms, and external shells are each found in many distantly related groups of lophotrochozoans. The most species-rich groups of lophotrochozoans are the **flatworms**, **annelids**, and **mollusks**.
- Annelids are a diverse group of segmented worms that live in moist terrestrial and aquatic environments. **Review Figure 23.16**
- Mollusks underwent a dramatic evolutionary radiation based on a body plan consisting of three major components: a foot, a mantle, and a visceral mass. The four major living molluscan clades—**chitons**, **bivalves**, **gastropods**, and **cephalopods**—demonstrate the diversity that evolved from this three-part body plan. **Review Figure 23.18**
- **Ecdysozoans** have a **cuticle** covering their body, which they must **molt** in order to grow. Some ecdysozoans, notably the **arthropods**, have a rigid cuticle reinforced with **chitin** that functions as an **exoskeleton**. New mechanisms of locomotion and gas exchange evolved among the arthropods.
- **Nematodes**, or roundworms, have a thick, multilayered cuticle. Nematodes are among the most abundant and universally distributed of all animal groups. **Review Figure 23.21**
- **Horsehair worms** are extremely thin; their larvae are internal parasites.
- Many ecdysozoan groups are wormlike in form. Members of several species-poor groups of wormlike marine ecdysozoans—**priapulids**, **kinorhynchs**, and **loriciferans**—have thin cuticles.
- One major ecdysozoan clade, the arthropods, has evolved jointed, paired appendages that have a wide diversity of functions.

concept 23.4 Arthropods Are Diverse and Abundant Animals

- Arthropods are the dominant animals on Earth in number of described species, and among the most abundant in number of individuals.

- Encasement within a rigid exoskeleton provides arthropods with support for walking as well as some protection from predators. The waterproofing provided by chitin keeps arthropods from dehydrating in dry air.
- Jointed appendages permit complex movements. Each arthropod segment has muscles attached to the inside of the exoskeleton that operate that segment and the appendages attached to it.
- Two groups of arthropod relatives, the **onychophorans** and the **tardigrades**, have simple, unjointed appendages.
- **Chelicerates** have a two-part body and pointed mouthparts than grasp prey; most chelicerates have four pairs of walking legs.
- Mandibles and antennae are synapomorphies of the **mandibulates**, which include **myriapods**, **crustaceans**, and **hexapods**.
- **Crustaceans** are the dominant marine arthropods and are also found in many freshwater and some terrestrial environments. Their segmented bodies are divided into three regions (head, thorax, and abdomen) with different, specialized appendages in each region.
- Hexapods—insects and their relatives—are the dominant terrestrial arthropods. They have the same three body regions as crustaceans, but no appendages form in their abdominal segments. Wings and the ability to fly first evolved among the insects, allowing them to exploit new lifestyles.

concept 23.5 Deuterostomes Include Echinoderms, Hemichordates, and Chordates

- Deuterostomes vary greatly in adult form, but based on the distinctive patterns of early development they share and on phylogenetic analyses of gene sequences, they represent a monophyletic group. There are far fewer species of deuterostomes than of protostomes, but many deuterostomes are large and ecologically important. **See WEB ACTIVITY 23.5**
- Echinoderms and hemichordates both have bilaterally symmetrical, ciliated larvae.
- Most adult echinoderms have **pentaradial symmetry**. Echinoderms have an internal skeleton of calcified plates and a unique **water vascular system** connected to extensions called **tube feet**. **Review Figure 23.31**
- Hemichordate adults are bilaterally symmetrical and have a three-part body that is divided into a proboscis, collar, and trunk. They include the acorn worms and the pterobranchs. **Review Figure 23.33**
- Chordates fall into three principal subgroups: **cephalochordates**, **urochordates**, and **vertebrates**.
- At some stage in their development, all chordates have a dorsal hollow nerve cord, a postanal tail, and a **notochord**. **Review Figure 23.34**

- Urochordates include the ascidians (sea squirts), which are sessile filter feeders as adults. Cephalochordates are the lancelets, which live buried in the sand of shallow marine and brackish waters.
- The vertebrate body is characterized by a rigid internal skeleton, which is supported by a **vertebral column** that replaces the notochord, internal organs suspended in a coelom, a ventral heart, and an anterior skull with a large brain. **Review Figure 23.38**
- The evolution of jaws from gill arches enabled individuals to grasp large prey and, together with teeth, cut them into small pieces.
- **Chondrichthyans** have skeletons of cartilage; almost all species are marine. The skeletons of **ray-finned fishes** are made of bone; these fishes have colonized most aquatic environments.

concept 23.6 Life on Land Contributed to Vertebrate Diversification

- Lungs and jointed appendages enabled vertebrates to colonize the land. The earliest split in the **tetrapod** tree is between the **amphibians** and the **amniotes** (reptiles and mammals).
- Most modern amphibians are confined to moist environments because they and their eggs lose water rapidly. **See ANIMATED TUTORIAL 23.2**
- An impermeable skin, efficient kidneys, and an egg that could resist desiccation evolved in the amniotes. **See WEB ACTIVITY 23.6**
- The major living **reptile** groups are the turtles, the lepidosaurs (tuataras, lizards, snakes, and amphisbaenas), and the archosaurs (crocodilians and birds). **Review Figure 23.45**
- **Mammals** are unique among animals in supplying their young with a nutritive fluid (milk) secreted by mammary glands. There are two primary mammalian clades: the prototherians (of which there are only five species) and the species-rich therians. The therian clade is subdivided into the marsupials and the eutherians. **Review Table 23.3**

concept 23.7 Humans Evolved among the Primates

- Grasping limbs with opposable digits distinguish **primates** from other mammals. The prosimian clade includes the lemurs and lorises; the anthropoid clade includes monkeys, apes, and humans. **Review Figure 23.51**
- Hominid ancestors developed efficient bipedal locomotion. In the lineage leading to *Homo*, brains became larger as jaws became smaller; the two events may have been developmentally linked. Several species of *Homo* coexisted in parts of the world until recently. **Review Figure 23.52**

PART

5

Plant Form and Function

The Plant Body

24

People use plants and substances made from them not only for food, but also for fiber, fuel, shelter, and medicines. The clothes you are wearing probably contain cotton, and the paper this book is printed on comes from wood pulp. About 5,000 years ago, Egyptians found that when stems of the papyrus plant (*Cyperus papyrus*) were peeled and dried, they could be formed into sheets that were easier to write on and store than parchment made from animal skins. About 3,000 years later, the Chinese invented a new method of papermaking that persists today: they mixed fibrous plant materials with water, mashed the mixture into a pulp, and pressed it into sheets, which they then dried.

With the advent of computers, economists predicted a lower demand for paper and therefore for the trees that provide the wood pulp used in papermaking. But this has not happened. Every year, U.S. residents use about 500 kilograms of paper per person, and paper constitutes about one-third of all solid waste. In both Europe and the United States, 90 percent of the forest cover that existed when papermaking was invented has disappeared because of the demand for fiber for paper as well as wood for energy production, heating, and construction. To regenerate these forests and to provide a sustainable resource for papermaking, there is considerable interest in growing fibrous crops that can substitute for trees.

Kenaf (*Hibiscus cannabinus*) is an angiosperm that grows readily and rapidly in Asia and parts of Africa. Although it does not produce wood, kenaf has stems rich in fiber. It has been cultivated for

three millennia in Asia, where its fiber is used to make bags, rope, dry bedding for animals, and even sails. There is now interest in using kenaf fiber for papermaking. Compared with southern pine trees, the current main source of pulp for paper, kenaf grows more rapidly (it matures in months rather than years), produces more fiber per hectare of land, and requires less water and fewer chemicals when used in paper production. Newspapers and greeting cards made from kenaf paper are stronger, yet thinner, than products made from typical wood pulp. The future of this plant as a resource for papermaking looks bright.

Kenaf is being grown as an alternative source of pulp for paper production

What are the properties of the kenaf plant that make it suitable for papermaking?*

*You will find the answer to this question on page 519.

KEY CONCEPTS

- 24.1** The Plant Body Is Organized and Constructed in a Distinctive Way
- 24.2** Meristems Build Roots, Stems, and Leaves
- 24.3** Domestication Has Altered Plant Form

concept 24.1 The Plant Body Is Organized and Constructed in a Distinctive Way

Plants must harvest energy from sunlight and mineral nutrients from the soil. Because they are stationary (*sessile*), they cannot move to find a more favorable environment or to avoid predators. Their body plan and physiology allow plants to respond to these challenges:

- Stems, leaves, and roots have structural adaptations that enable plants anchored to one spot to capture scarce resources effectively, both above and below the ground.
- Their ability to grow throughout their lifetimes enables plants to respond to environmental cues by redirecting their growth to exploit environmental opportunities, as when roots grow toward a water supply.

In Chapter 21 we see how modern plants arose from aquatic ancestors, giving rise to simple land plants and then vascular plants. Despite their obvious differences in size and form, all vascular plants have essentially the same simple structural organization. This chapter describes the basic architecture of the largest group of vascular plants, the angiosperms (flowering plants), and shows how so much diversity (there are more than 250,000 species of angiosperms) can literally grow out of such a simple basic form. In this chapter we focus on the angiosperms' three kinds of *vegetative* (nonsexual) organs: roots, stems, and leaves.

Plant organs are organized into two systems (FIGURE 24.1):
