- The **root system** anchors the plant in place. **Roots** absorb water and dissolved minerals and store the products of photosynthesis. The extreme branching of roots and their high

surface area-to-volume ratios allow them to absorb water and mineral nutrients from the soil efficiently.

- The **shoot system** consists of the stems, leaves, and flowers. The **leaves** are the chief organs of photosynthesis. The **stems** hold and display the leaves to the sun and provide connections for the transport of materials between roots and leaves. The flowers are reproductive organs.

The leaves arise from *nodes* on the stem, and the repeating unit between the nodes is called a *phytomer*.

As noted in Chapter 21, most angiosperms belong to one of two major clades. *Monocots* are generally narrow-leaved plants such as grasses, lilies, orchids, and palms. *Eudicots* are generally broad-leaved plants such as soybeans, roses, sunflowers, and maples. These two clades, which account for 97 percent of angiosperm species, differ in several important structural characteristics, such as the organization of the root system and the structure of the leaves (see Figure 24.1).

Plants develop differently than animals

The four processes that govern the development of all organisms, whether plant or animal, are *determination* (the commitment of an embryonic cell to its ultimate fate in the organism); *differentiation* (the specialization of a cell); *morphogenesis* (the organization and spatial distribution of cells into tissues and organs); and *growth* (increase in body size). In plants, these processes are influenced by three unique properties: apical meristems, cell walls, and the totipotency of most cells.

LINK The processes of development are described in Concept 14.1

APICAL MERISTEMS Plants grow throughout their lifetimes. Whereas adult humans, for example, have stem cells to replace tissues lost through damage or apoptosis, plants have *apical meristems* that are “always embryonic,” producing new roots, stems, leaves, and flowers throughout the plant’s life. We will discuss apical meristems in more detail below and in Concept 24.2.

FIGURE 24.1 Vegetative Plant Organs and Systems The basic plant body plan, with root and shoot systems, and the principal vegetative organs are similar in eudicots and monocots, although there are also some structural differences between the two clades.

FIGURE 24.2 Cytokinesis and Morphogenesis The plane of cell division can determine the growth pattern of a plant organ, as in this section of a shoot.

CELL WALLS Plant cells are surrounded by a cell wall. This rigid extracellular matrix makes it impossible for cells to move from place to place as they do in animal development. Instead, plant morphogenesis occurs through alterations in the plane of cell division at cytokinesis, which in turn change the direction in which a piece of tissue grows (**FIGURE 24.2**). In addition, unequal cell division can occur when the cytoplasm contains differentiation signals (cytoplasmic determinants) that are localized in one part of a cell (see Concept 14.2). Plant cytokinesis occurs along a *cell plate* laid down by Golgi vesicles (see Figure 7.7B). Unlike animal cells, in which the location of cytokinesis depends on the location of the middle of the mitotic spindle, the location of the plant cell plate is determined earlier—as early as mitotic prophase.

FRONTIERS Because the plane of cell division is so important in plant morphogenesis, the mechanism by which a cell determines where the cell plate will form is under investigation. By screening for mutations leading to abnormal cell plate orientation in the model organism *Arabidopsis thaliana*, biologists have isolated several genes that are involved in determining the plane of cell division. How these genes work remains to be discovered.

TOTIPOTENCY In animals, only early embryonic cells are totipotent, although some stem cell populations, such as those in bone marrow, are multipotent. In contrast, in plants even differentiated cells are pluripotent, and most are totipotent (see Figure 14.3). This means a plant can readily repair damage wrought by the environment or herbivores.

Apical–basal polarity and radial symmetry are characteristic of the plant body

Two basic patterns are established early in plant embryogenesis (embryo formation) (**FIGURE 24.3**):

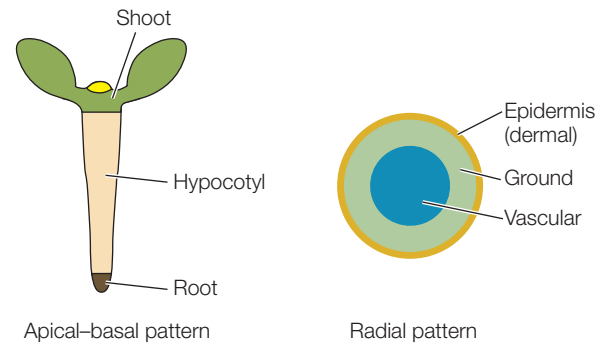

FIGURE 24.3 Two Patterns for Plant Morphogenesis (A) The apical–basal pattern is the arrangement of cells and tissues along the main axis from root to shoot. (B) The radial pattern determines the concentric arrangement of tissues when organs grow in thickness.

- The *apical–basal* axis: the arrangement of cells and tissues along the main axis from root to shoot
- The *radial* axis: the concentric arrangement of the *tissue systems* (which we will discuss in the next section)

Both axes are best understood in developmental terms. We focus here on embryogenesis in the model eudicot *Arabidopsis thaliana*, in which the process has been most intensively studied.

The first step in the formation of a plant embryo is a mitotic division of the zygote that gives rise to two daughter cells (**FIGURE 24.4, STEP 1**). An asymmetrical plane of cell division results in an uneven distribution of cytoplasm between these two cells, which face different fates. Signals in the smaller, apical (upper) daughter cell induce it to produce the embryo proper, while the other, larger daughter cell produces a supporting structure, the **suspensor** (**FIGURE 24.4, STEP 2**). This division not only establishes the apical–basal axis of the new plant but also determines its polarity (which end is the tip, or apex, and which is the base). A long, thin suspensor and a more spherical or globular embryo are distinguishable after just four mitotic divisions (see Figure 14.1). The suspensor soon ceases to elongate.

In eudicots, the initially globular embryo develops into the characteristic *heart stage* as the **cotyledons** (“seed leaves”) start to grow (**FIGURE 24.4, STEP 3**). Further elongation of the cotyledons and of the main axis of the embryo gives rise to the *torpedo stage*, during which some of the internal tissues begin to differentiate (**FIGURE 24.4, STEP 4**). Between the cotyledons is the **shoot apical meristem**; at the other end of the axis is the **root apical meristem**. Each of these meristems contains undifferentiated cells that will continue to divide to give rise to the organs that will develop over the life of the plant.

As shown in Figure 24.4, step 2, the plant embryo is first a sphere and later a cylinder. The root and stem retain the cylindrical shape throughout the plant’s life. You can see this most easily in the trunk of a tree. By the end of embryogenesis, the radial symmetry of the plant has been established. The embryonic plant contains three tissue systems, arranged concentrically, that will give rise to the tissues of the adult plant body.

FIGURE 24.4 Plant Embryogenesis The basic body plan of the model eudicot *Arabidopsis thaliana* is established in several steps. By the heart stage, the three tissue systems are established: the dermal (gold), ground (light green), and vascular (blue) tissue systems.

The plant body is constructed from three tissue systems

A *tissue* is an organized group of cells that have features in common and that work together as a structural and functional unit. In plants, tissues, in turn, are grouped into **tissue systems**. Despite their structural diversity, all vascular plants are constructed from three tissue systems: *dermal*, *vascular*, and *ground*. These three tissue systems are established during embryogenesis and ultimately extend throughout the plant body in a concentric arrangement (FIGURE 24.5). Each tissue system has distinct functions and is composed of different mixtures of cell types.

DERMAL TISSUE SYSTEM The **dermal tissue system** forms the *epidermis*, or outer covering, of a plant, which usually consists of a single cell layer. Epidermal cells are typically small. Some of them differentiate to form one of three specialized structures:

- *Stomata*, which are pores for gas exchange in leaves
- *Trichomes*, or leaf hairs, which provide protection against insects and damaging solar radiation

- *Root hairs*, which greatly increase root surface area, thus providing more surface for the uptake of water and mineral nutrients

Aboveground epidermal cells secrete a protective extracellular **cuticle** made of *cutin* (a polymer composed of long chains of fatty acids), a complex mixture of waxes, and cell wall polysaccharides. The cuticle limits water loss, reflects potentially damaging solar radiation, and serves as a barrier against pathogens.

The stems and roots of woody plants develop a dermal tissue called *periderm*. As we will see in Concept 24.2, this tissue ultimately forms *cork*, an external layer that is impermeable to water and gases.

GROUND TISSUE SYSTEM Virtually all the tissue lying between dermal tissue and vascular tissue in both shoots and roots is part of the **ground tissue system**, which therefore makes up most of the plant body. Ground tissue contains three cell types.

FIGURE 24.5 Three Tissue Systems Extend throughout the Plant Body The arrangement shown here is typical of eudicots, but the three tissue systems are continuous in the bodies of all vascular plants.

Parenchyma cells are the most abundant ground tissue cells. They have large vacuoles and relatively thin cell walls. They perform photosynthesis (in the shoot) and store protein (in fruits) and starch (in roots).

Collenchyma cells are elongated and have thick cell walls. They provide support for growing tissues such as stems. The familiar “strings” in celery consist primarily of collenchyma cells.

Sclerenchyma cells have very thick walls reinforced with the polyphenol polymer *lignin*. Most sclerenchyma cells undergo programmed cell death (apoptosis), but their strong cell walls remain to provide support for the plant. There are two types of sclerenchyma cells: fibers and sclereids. Elongated **fibers** provide relatively rigid support to wood and other parts of the plant, within which they are often organized into bundles.

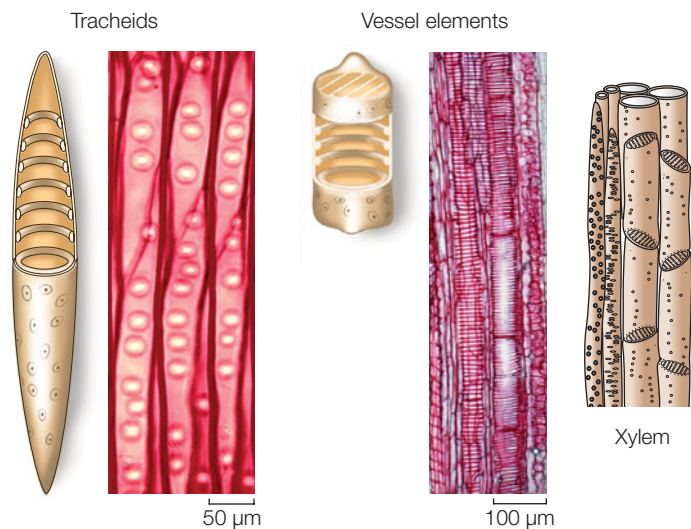

The bark of trees owes much of its mechanical strength to long fibers. **Sclereids** occur in various shapes and may pack together densely, as in a nut’s shell or in some seed coats.

Isolated clumps of sclereids, called *stone cells*, in pears and some other fruits give them their characteristic gritty texture.

VASCULAR TISSUE SYSTEM The **vascular tissue system** is the plant’s plumbing or transport system—the distinguishing feature of vascular plants. Its two constituent tissues, the *xylem* and *phloem*, distribute materials throughout the plant.

Xylem distributes water and mineral ions taken up by the roots to all the cells of the roots, stems, and leaves. Like most sclerenchyma, xylem is made up of dead cells. It contains two types of conducting cells. **Tracheids** are spindle-shaped cells, with thinner regions in the cell wall called *pits* through which water can move with little resistance from one tracheid to its neighbors. **Vessel elements** are larger in diameter than tracheids. They meet end-to-end and partially break down their end walls, forming an open pipeline for water conduction.

Phloem generally consists of living cells. It transports carbohydrates (primarily sugars) from sites where they are produced by photosynthesis (called *sources*; primarily leaves) to sites where they are used or stored (called *sinks*, such as growing tissues, roots, and developing flowers). The characteristic cells of the phloem are **sieve tube elements**, which, like vessel elements, meet end-to-end, forming *sieve tubes*. Instead of the

ends of the cells breaking down, however, the sieve tube elements are connected by plasmodesmata (see Figure 4.7), which form a set of pores called a *sieve plate*. Adjacent to the sieve tubes are metabolically more active *companion cells*.

Sieve tube elements

Xylem and phloem tissues may also contain fibers, which provide structural support.

Do You Understand Concept 24.1?

- Make a table listing the three tissue systems of plants and their functions.
- What are the similarities and differences between plant and animal development?
- What are the similarities and differences between a root and a shoot?
- A mutant strain of *Arabidopsis thaliana* lacks apical-basal polarity in the embryo. What would you expect the phenotype of the plant to be?

By the end of embryogenesis, the plant embryo is encased in a seed and is ready to germinate. We will return to seeds and their germination in subsequent chapters. For now, let's see how the cells and tissues we have just described allow the embryo to build an adult plant body.

concept 24.2 Meristems Build Roots, Stems, and Leaves

All plants experience **primary growth**, which is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. Primary growth occurs throughout the life of the plant. In addition, many gymnosperms (e.g., pine trees) and eudicots, especially trees, experience **secondary growth**, by which they increase in thickness. Tissues produced by primary growth are referred to as *primary tissues* and comprise what is called the primary plant body. Tissues produced by secondary growth are referred to as *secondary tissues* and comprise the secondary plant body. A plant that

results entirely from primary growth consists of nonwoody tissues and is referred to as *herbaceous*. *Woody* plants, such as trees and shrubs, have, in addition to the primary plant body, a secondary plant body consisting of wood and bark.

As we discuss how vegetative plant organs develop and grow, you will find examples of organs whose functions deviate from the norm, such as roots and stems that are used to store water and nutrients, and leaves that are used for protection or support. The evolution of these novel roles for established organs is an example of natural selection working with what is already present, as well as an example of the interaction between evolution and development—the topic of evolutionary developmental biology (evo-devo).

LINK See Concepts 14.4 and 14.5 for a discussion of evolutionary developmental biology

A hierarchy of meristems generates the plant body

Even before seed germination, the plant embryo has two meristems: a shoot apical meristem at the end of the embryonic shoot and a root apical meristem near the end of the embryonic root (see Figure 24.4). The dividing cells of the meristems are comparable to animal stem cells: after their division, one daughter cell is capable of differentiating, and the other retains its undifferentiated phenotype.

In the adult plant, two types of meristems contribute to growth and development (**FIGURE 24.6**):

- **Apical meristems** orchestrate primary growth, giving rise to the primary plant body. This growth is characterized by cell division followed by cell expansion (elongation).
- **Lateral meristems** orchestrate secondary growth. Two lateral meristems, *vascular cambium* and *cork cambium*, contribute to the secondary plant body.

Because apical meristems can perpetuate themselves indefinitely, a shoot or root can continue to lengthen and grow indefinitely; in other words, the growth of a shoot or root is **indeterminate**. Primary growth leads to the elongation of shoots and roots and the formation of organs. All plant organs arise ultimately from cell divisions in apical meristems, followed by cell expansion and cell differentiation. You will see this pattern of

division → expansion → differentiation

in several types of meristems.

As they do in the embryo, apical meristems in the adult plant form root and shoot organs. They do so by producing three **primary meristems**. From the outside to the inside of the root or shoot, which are both cylindrical, the primary meristems are the **protoderm**, the **ground meristem**, and the **procambium**. These meristems, in turn, give rise to the three tissue systems:

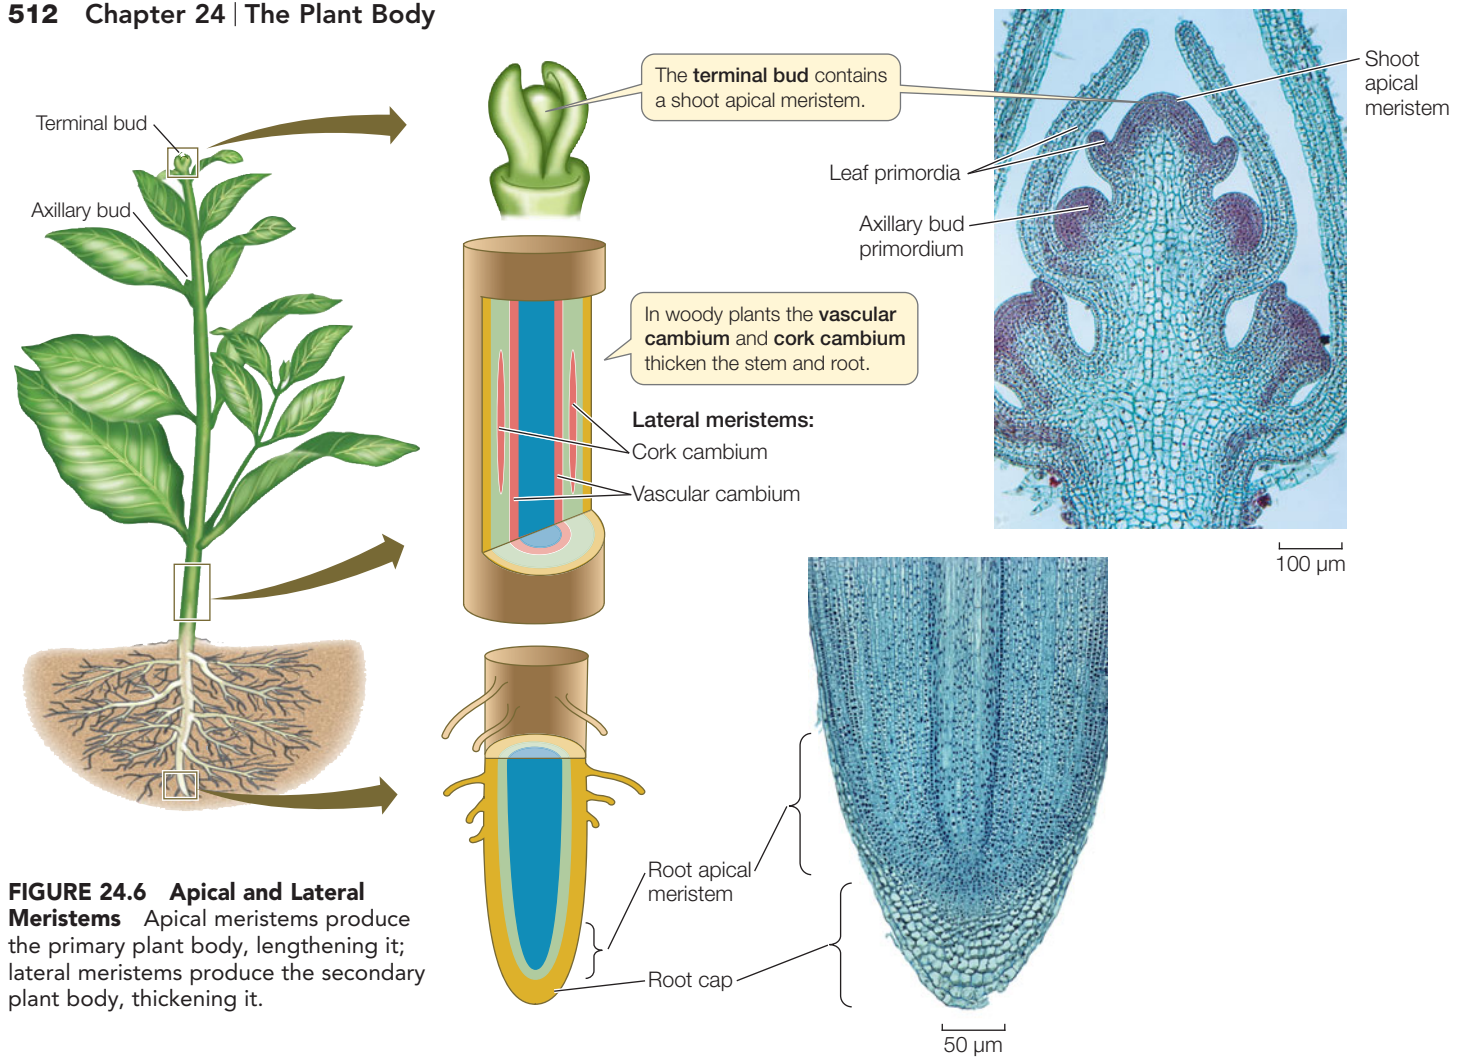

FIGURE 24.6 Apical and Lateral Meristems Apical meristems produce the primary plant body, lengthening it; lateral meristems produce the secondary plant body, thickening it.

Let's look now at how these meristems function in the root and shoot.

FRONTIERS The relative activities of meristems that produce vegetative growth and those that produce reproductive growth are important measures for plant breeders. Plant breeders are interested in knowing what genes regulate the ratio between these two types of growth. For example, such knowledge might allow them to increase the amount of seeds that a crop plant makes by increasing (within limits) the ratio of reproductive to vegetative growth. Analyses of mutants and of the genomes of crops and model organisms may reveal which genes control meristem activity.

The root apical meristem gives rise to the root cap and the root primary meristems

The root apical meristem produces all the cells that contribute to growth in the length of a root (FIGURE 24.7A). Some of the daughter cells from the apical (tip) end of the root apical meristem contribute to a **root cap**, which protects the delicate growing region of the root as it pushes through the soil. The root cap secretes a mucopolysaccharide (slime) that acts as a lubricant. Even so, the cells of the root cap are often damaged or scraped away and must therefore be replaced constantly. The root cap is also the structure that detects the pull of gravity and thus controls the downward growth of roots.

Above the root cap, the cells in the root tip are arranged in several zones. The apical and primary meristems constitute the **zone of cell division**, the source of all the cells of the root's primary tissues. The daughter cells of the divisions that occur in this zone become the three cylindrical primary meristems: the protoderm, the ground meristem, and the procambium. Just above this zone is the **zone of cell elongation**, where the newly formed cells are elongating and thus pushing the root farther into the soil. Above that zone is the **zone of cell maturation**, where the cells are differentiating. These three zones grade imperceptibly into one another; there is no abrupt line of demarcation.

The products of the root's primary meristems become root tissues

The products of the three primary meristems (the protoderm, ground meristem, and procambium) are the tissue systems of the mature root: the *epidermis* (dermal tissue), *cortex* (ground tissue), and *stele* (vascular tissue).

The protoderm gives rise to the **epidermis**, an outer layer of cells that protect the root and absorb mineral ions and water. Many of the epidermal cells produce long, delicate root hairs (FIGURE 24.7B).

Internal to the protoderm, the ground meristem gives rise to a region of ground tissue that is many cells thick, called the

APPLY THE CONCEPT

Meristems build roots

A research team investigated how long root cells continued to divide after being produced by the root apical meristem. They incubated germinating bean seeds for 2 hours with their roots suspended in water containing radioactive thymidine, which is taken up by dividing cells and incorporated into their DNA as it replicates (making the DNA radioactive).

After this incubation period, they removed some of the seeds (time 0 in the table) and took longitudinal slices from the roots (see Figure 24.7A). They transferred the rest of the seeds to water containing nonradioactive thymidine and left them there for various times (12, 36, and 72 hours) before taking root slices. They tallied the number of radioactive cells found in each of the four regions of each root and compared those numbers with the total number of cells in each region. The table shows the results.

TIME AFTER TRANSFER (HR)	RADIOACTIVE CELLS/TOTAL CELLS			
	ROOT CAP	ROOT APICAL MERISTEM	ZONE OF CELL ELONGATION	ZONE OF CELL MATURATION
0	0/63	90/115	0/32	0/22
12	2/58	95/110	16/29	0/27
36	36/60	45/119	14/30	12/31
72	12/24	0/116	2/31	30/32

- At 0 hours, why did only root apical meristem cells contain radioactive thymidine?
- For each region, calculate the percentages of radioactive cells and plot those percentages over time.
- Explain the rise and fall in the percentage of radioactive cells in each region.

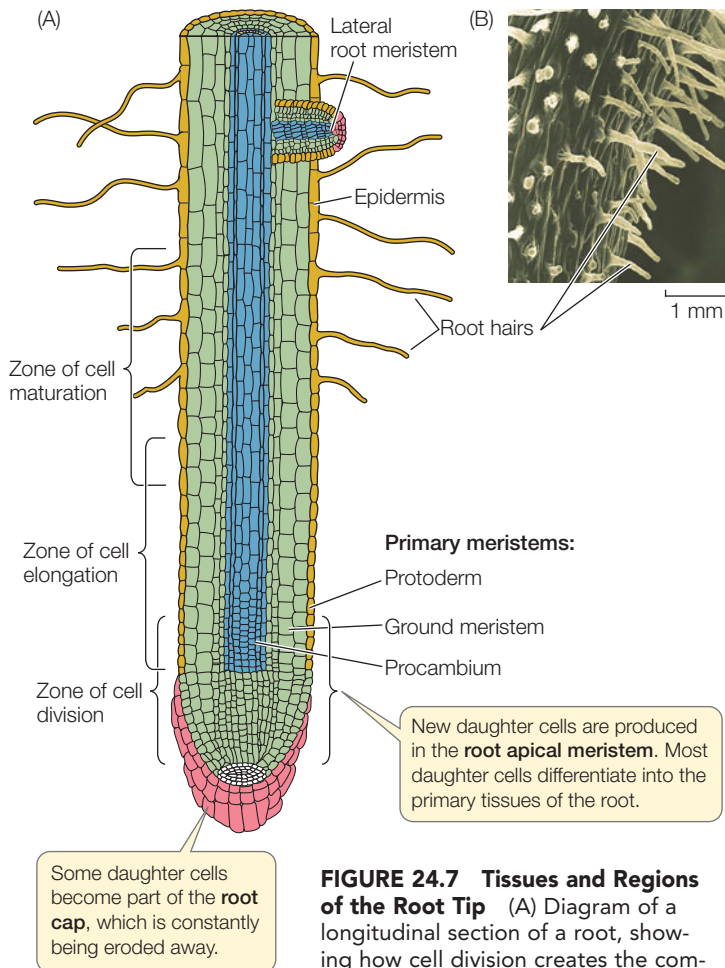

FIGURE 24.7 Tissues and Regions of the Root Tip (A) Diagram of a longitudinal section of a root, showing how cell division creates the complex structure of the root. (B) Root hairs, seen with a scanning electron microscope.

cortex. The parenchyma cells of the cortex are relatively unspecialized and often serve as storage depots. The innermost layer of the cortex is the **endodermis**. Unlike those of other cortical cells, the cell walls of the endodermal cells contain *suberin*, a waterproof substance. Strategic placement of suberin in only certain parts of the cell wall enables the cylindrical ring of endodermal cells to control the movement of water and dissolved mineral ions into the vascular tissue system.

LINK The role of the endodermis is described in more detail in Concept 25.3

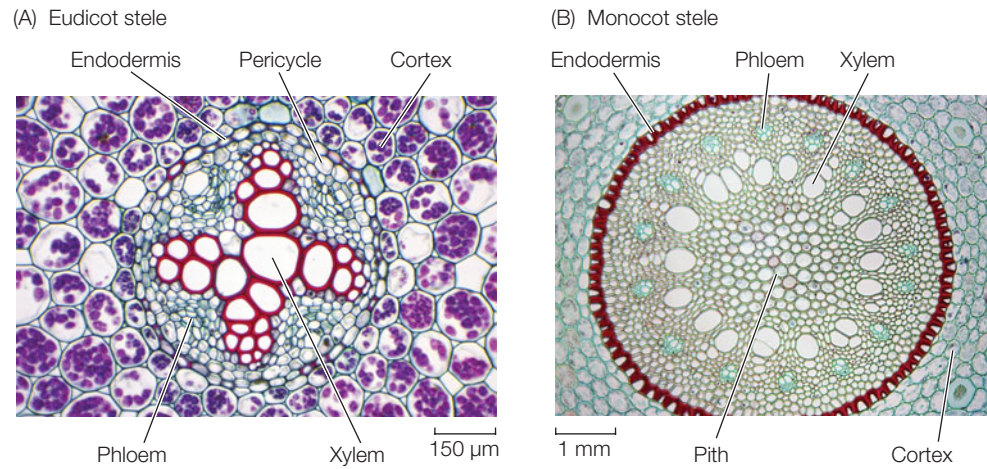

Interior to the endodermis is the **vascular cylinder**, or **stele**, produced by the procambium. The stele consists of three types of cells: pericycle, xylem, and phloem. The **pericycle** consists of one or more layers of parenchyma cells. It has three important functions:

- It is the tissue within which *lateral roots* arise.
- It can contribute to secondary growth by giving rise to lateral meristems that thicken the root.
- The plasma membranes of its cells contain membrane transport proteins that export nutrient ions into the cells of the xylem.

At the very center of the root of a eudicot lies the xylem. Seen in cross section, it typically has the shape of a star with a variable number of points (**FIGURE 24.8A**). Between the points are bundles of phloem. In monocots, a region of parenchyma cells, called the **pith**, typically lies in the center of the root, surrounded by xylem and phloem (**FIGURE 24.8B**). Pith, which often stores carbohydrate reserves, is also found in the stems of eudicots.

FIGURE 24.8 Products of the Root's Primary Meristems

The protoderm gives rise to the epidermis, the outermost layer of cells. The ground meristem produces the cortex, the innermost layer of which is the endodermis. The vascular tissues of the root are found in the stele, which is the product of the procambium. The arrangement of tissues in the stele differs in the roots of (A) eudicots and (B) monocots.

Eudicot Root • Monocot Root

The root system anchors the plant and takes up water and dissolved minerals

Water and mineral nutrients enter most plants through the root system, which is located in the soil. Although hidden from view, the root system is often larger than the visible shoot system. For example, the root system of a 4-month-old winter rye plant (*Secale cereale*) was found to be 130 times larger than the shoot system, with almost 13 million branches that had a cumulative length of over 500 kilometers!

The root system of angiosperms originates in an embryonic root called the *radicle*. In most eudicots the radicle develops as a primary root (called the **taproot**) that extends downward by tip growth and outward by initiating **lateral roots** (see Figure 24.7A). The taproot itself often functions as a nutrient storage organ, as in carrots, sugar beets, and sweet potato (FIGURE 24.9A).

In monocots, the radicle-derived initial root is short-lived. Monocots form a **fibrous root system** composed of numerous thin roots that are all roughly equal in diameter (FIGURE 24.9B). Because they originate from the stem at ground level or below, the roots of a typical monocot are called **adventitious** (“arriving from outside”) **roots**. Many fibrous root systems have a large surface area for the absorption of water and minerals, and they cling to soil very well. The fibrous root systems of

(A) Taproots

(C) Prop roots

**FIGURE 24.9 Root Systems of Eudicots and Monocots**

(A) The taproot systems of some eudicots, such as carrots (*Daucus carota*) and sugar beets (*Beta vulgaris*), are nutrient storage organs. (B) These leeks (*Allium ampeloprasum*), which are monocots, have fibrous root systems. (C) The stems of this hala tree (*Pandanus tectorius*), another monocot, are supported by prop roots.

grasses, for example, may protect steep hillsides where runoff from rain would otherwise cause erosion.

In some monocots—corn, banyan trees, and some palms, for example—adventitious roots function as props to help support the shoot (FIGURE 24.9C). **Prop roots** are critical to these plants, which, unlike most eudicot tree species, are unable to support aboveground growth through the thickening of their stems.

The products of the stem's primary meristems become stem tissues

The shoot is composed of repeating modules called *phytomers*. Each phytomer consists of a *node* with its attached leaf or leaves; an *internode*, or section of stem between nodes; and one or more *axillary buds* in the angle between each leaf and the stem (see Figure 24.1). The shoot grows by adding new phytomers. Those new phytomers originate from shoot apical meristems, which are formed at the tips of stems and in axillary buds.

The shoot apical meristem, like the root apical meristem, forms three primary meristems: protoderm, ground meristem, and procambium. These primary meristems, in turn, give rise to the three shoot tissue systems. The shoot apical meristem repetitively lays down the beginnings of leaves and axillary buds. Leaves arise from bulges called *leaf primordia*, which form

as cells divide on the sides of the shoot apical meristem (see Figure 24.6). *Bud primordia* form above the bases of the leaf primordia, where they may become new apical meristems and initiate new shoots. The growing stem has no protective structure analogous to the root cap, but the leaf primordia can act as a protective covering for the shoot apical meristem.

The vascular tissue of young stems is divided into discrete **vascular bundles** (FIGURE 24.10). Each vascular bundle contains both xylem and phloem. In eudicots, the vascular bundles are arranged along the periphery and appear in a circle in cross section, but in monocots they are seemingly scattered throughout the stem.

The stem supports leaves and flowers

The central function of stems is to elevate and support the photosynthetic organs (leaves) as well as the reproductive organs (flowers).

Various modifications of stems are seen in nature. The *tuber* of a potato, for example—the part of the plant eaten by

Eudicot Stem • Monocot Stem

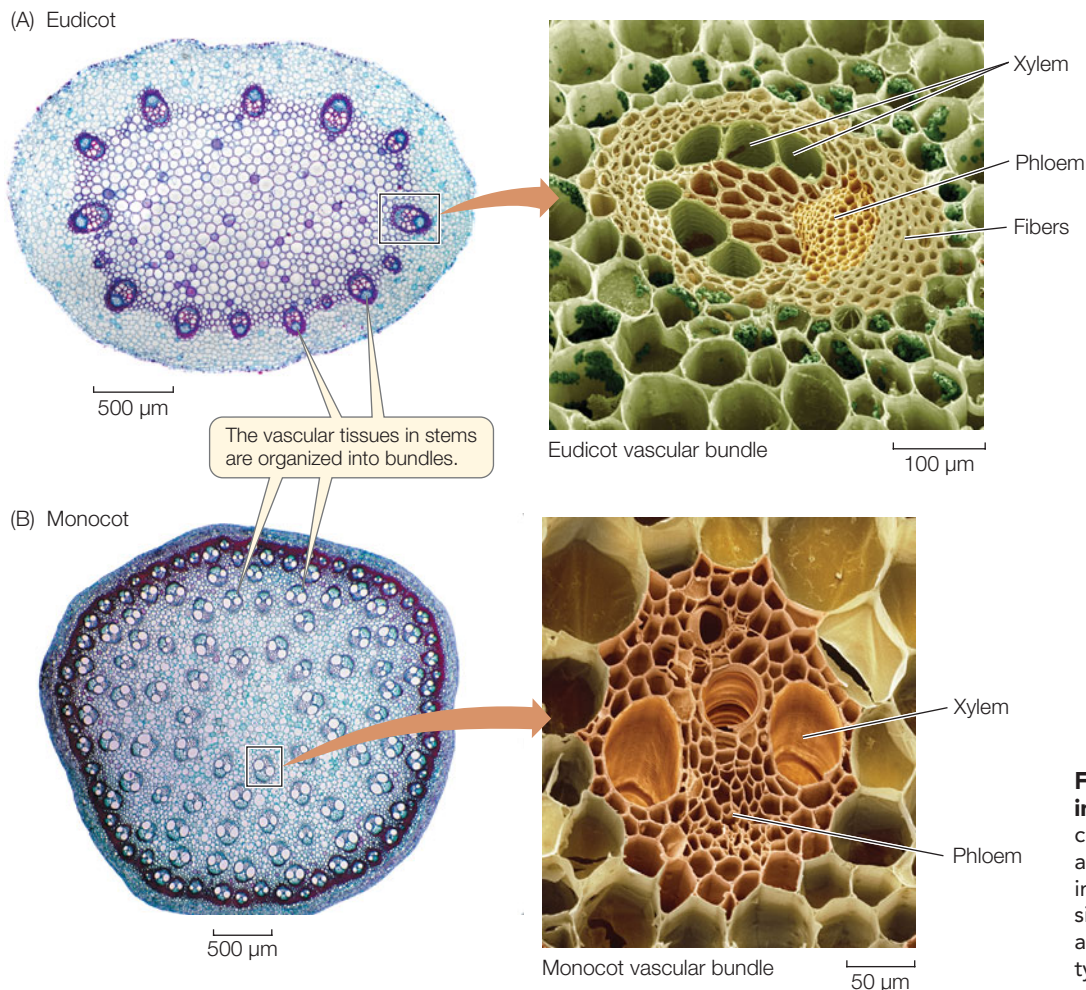

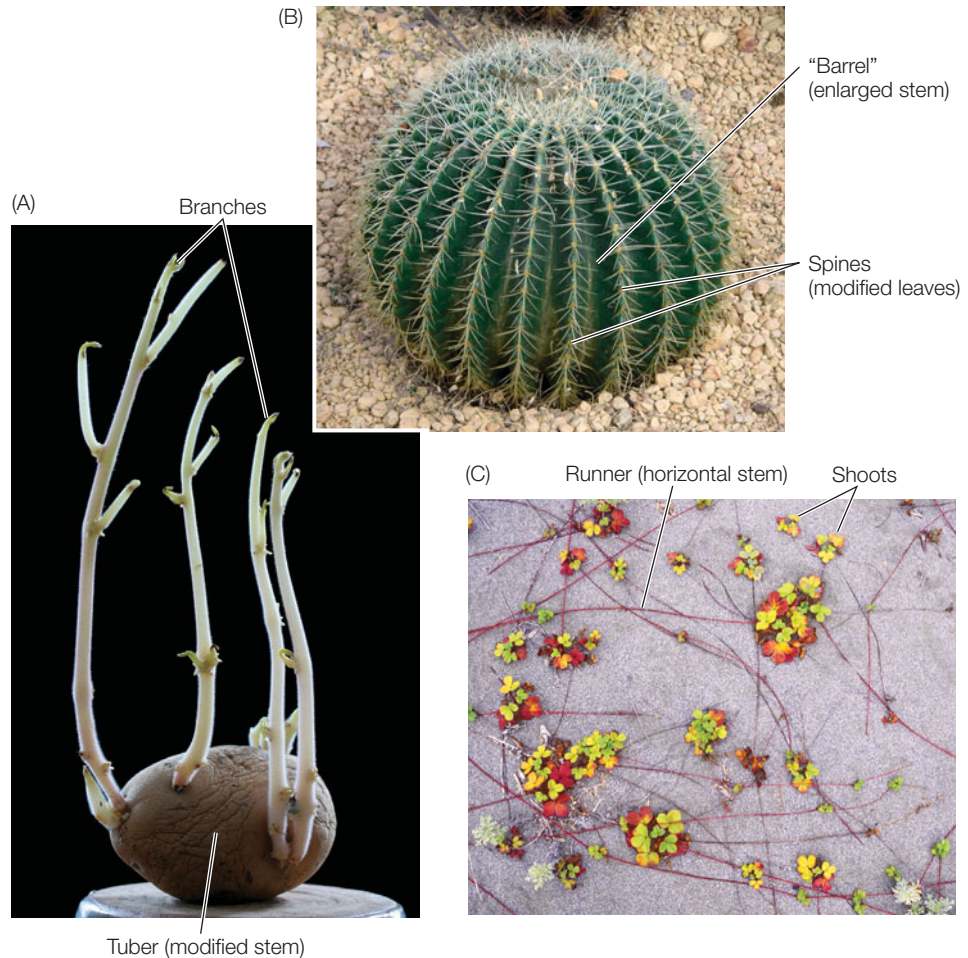

FIGURE 24.10 Vascular Bundles in Stems (A) In herbaceous eudicot stems, the vascular bundles are arranged in a cylinder, with pith in the center and the cortex outside the cylinder. (B) A scattered arrangement of vascular bundles is typical of monocot stems.

FIGURE 24.11 Modified Stems

(A) A potato (*Solanum tuberosum*) is a modified stem called a tuber; the sprouts that grow from its eyes are shoots, not roots. (B) The stem of this barrel cactus (*Echinocactus grusoni*) is enlarged to store water. Its highly modified leaves serve as thorny spines. Most of this plant's photosynthesis occurs in the stem. (C) The runners of beach strawberry (*Fragaria chiloensis*) are horizontal stems that produce roots and shoots at intervals. Rooted portions of the plant can live independently if the runner is cut.

humans—is not a root but rather an underground stem. The “eyes” of a potato are depressions containing axillary buds—in other words, a sprouting potato is just a branching stem (FIGURE 24.11A). Many desert plants have enlarged, water-retaining stems (FIGURE 24.11B). The *runners* of strawberry plants are horizontal stems from which roots grow at frequent intervals (FIGURE 24.11C). If the links between the rooted portions are broken, independent plants can develop on each side of the break—a form of vegetative (asexual) reproduction (see Concept 7.1).

Leaves are the primary site of photosynthesis

For most of its life, a plant produces leaves from shoot apical meristems. As shown in Figure 24.6, leaves originate from leaf primordia at the sides of the shoot apical meristem. Unlike the growth of roots and stems, the growth of leaves is finite, or **determinate**: leaves generally stop growing once they reach a predetermined mature size.

Typically, the **blade** of a leaf is a thin, flat structure attached to the stem by a stalk called a **petiole** (see Figure 24.1). In many plants, the leaf blade is held by its petiole at an angle almost perpendicular to the rays of the sun. This orientation, with the leaf surface facing the sun, maximizes the amount of light available for photosynthesis. Some leaves track the sun over the course of the day, moving so that they constantly face it.

Leaf anatomy is beautifully adapted to carry out photosynthesis and to support that process by exchanging the gases O_2 and CO_2 with the environment, limiting evaporative water loss, and exporting the products of photosynthesis to the rest of the plant. FIGURE 24.12 shows a section of a typical eudicot leaf in three dimensions.

Most eudicot leaves have two zones of photosynthetic parenchyma tissue called **mesophyll** (which means “middle of the leaf”). The upper layer or layers of mesophyll, which consist of elongated cells, constitute a zone called *palisade mesophyll*. The lower layer or layers, which consist of irregularly shaped cells, constitute a zone called *spongy mesophyll*. Within the mesophyll is a network of air spaces through which CO_2 can diffuse to

Eudicot Leaf

FIGURE 24.13 A Woody Twig Has Both Primary and Secondary Tissues The shoot apical meristems inside the buds of this dormant twig will produce primary growth in spring. Lateral meristems in the wood will produce secondary growth.

yourBioPortal.com

Go to ANIMATED TUTORIAL 24.1
Secondary Growth: The Vascular Cambium

CO₂—the other raw material of photosynthesis. Therefore, water and gases are exchanged through pores in the leaf called *stomata* (see Concept 25.3).

In some plant species, leaves are highly modified for special functions. For example, some modified leaves serve as storage depots for energy-rich molecules, as in the bulbs of onions. In other species, such as succulents, the leaves store water. The protective spines of cacti are modified leaves. Other plants, such as peas, have modified portions of leaves called *tendrils* that support the plant by wrapping around other structures or plants.

Many eudicot stems and roots undergo secondary growth

As we have seen, the roots and stems of some eudicots develop a secondary plant body, the tissues of which we commonly refer to as *wood* and *bark*. These tissues are derived by secondary growth from the two lateral meristems:

- The **vascular cambium** produces cells that make up *secondary xylem* (wood) and *secondary phloem* (inner bark).
- The **cork cambium** produces mainly waxy-walled protective cells. It supplies some of the cells that become outer bark.

Each year, deciduous trees lose their leaves, leaving bare branches and twigs in winter. These twigs illustrate both primary and secondary growth (**FIGURE 24.13**). The apical meristems of the twigs are enclosed in buds protected by *bud scales*. When the buds begin to grow in spring, the scales fall away, leaving scars, which show us where the bud was and allow us to identify each year's growth. The woody portions of the twig are the product of primary and secondary growth. Only the buds and the newest growth from the apical meristem consist entirely of primary tissues.

In the stem, the vascular cambium is initially a single layer of cells lying between the primary xylem and the primary phloem within the vascular bundles. A stem or root increases in diameter when the cells of the vascular cambium divide, producing secondary xylem cells toward the inside of the stem or root and secondary phloem cells toward the outside (see Figure 24.13).

Secondary xylem conducts water and minerals and continues to do so for many years. Secondary phloem, however, is active in transport of sugars for only a year. As secondary growth of a stem or root continues, the expanding vascular

photosynthesizing cells. Vascular tissue branches extensively throughout the leaf, forming a network of *veins* that extend to within a few cell diameters of all its cells, ensuring that the mesophyll cells are well supplied with water and mineral nutrients. The products of photosynthesis are loaded into the veins for export to the rest of the plant.

LINK Photosynthesis is described in Concepts 6.5 and 6.6

FRONTIERS What directs a cell in a leaf primordium to differentiate appropriately for its eventual position on the upper or lower side of the mature leaf, so that the cell becomes, for example, a palisade mesophyll cell or a spongy mesophyll cell? Some sort of positional information is presumably involved. The nature of this information is being investigated in *Arabidopsis thaliana*. Mutational analyses indicate that both transcription factors and microRNAs are involved in the differentiation process. Further studies may reveal exactly how positional information is transmitted during leaf development.

Covering virtually the entire leaf on both its upper and lower surfaces is a layer of nonphotosynthetic epidermal cells. These cells secrete a cuticle that is impermeable to water. Although the epidermis keeps water in the leaf, it also keeps out

tissue stretches and breaks the epidermis and the outer layers of the cortex, which ultimately flake away. Tissue derived from the secondary phloem then becomes the outermost part of the stem. Before the dermal tissues are broken away, however, cells lying near the surface of the secondary phloem begin to divide, forming a cork cambium. This meristematic tissue produces layers of **cork**, a protective tissue composed of cells with thick walls waterproofed with suberin. The cork soon becomes the outermost tissue of the stem or root. Without the activity of the cork cambium, the sloughing off of the outer primary tissues would expose the plant to potential damage, such as excessive water loss or invasion by microorganisms. Sometimes the cork cambium produces cells to the inside as well as to the outside; these inside cells constitute a tissue known as the *phelloderm*.

The cork cambium, cork, and phelloderm constitute a secondary dermal tissue called **periderm**. As the vascular cambium continues to produce secondary vascular tissue, these corky layers are lost, but the continuous formation of new cork cambia in the underlying secondary phloem gives rise to new corky layers. The periderm and the secondary phloem—that is, all the tissues external to the vascular cambium—constitute the **bark**.

Cross sections of most tree trunks (which are mature stems) in temperate-zone forests reveal annual rings in the wood (**FIGURE 24.14**), which result from seasonal changes in environmental conditions. In spring, when water is relatively plentiful, the tracheids or vessel elements produced by the vascular cambium tend to be large in diameter and thin-walled. Such wood is well adapted for transporting large quantities of water and mineral nutrients. As water becomes less available in summer, narrower cells with thicker walls are produced, which make this summer wood darker and sometimes more dense than the wood formed in spring. Thus each growing season is recorded by a clearly visible annual ring. Trees in the moist tropics do not experience these seasonal changes, so they do not lay down

such obvious regular rings. In temperate-zone trees, variations in temperature or water supply can lead to the formation of more than one “annual” ring in a single year, but most years bring a new annual ring and a new batch of leaves.

Only eudicots and other non-monocot angiosperms, along with many gymnosperms, have a vascular cambium and a cork cambium and thus undergo secondary growth. The few monocots that form thickened stems—palms, for example—do so without secondary growth. Palms have a very wide apical meristem that produces a wide stem, and dead leaf bases add to the diameter of the stem. All monocots grow in essentially this way, as do other angiosperms that lack secondary growth.

Do You Understand Concept 24.2?

- Compare primary and secondary growth, creating a table with the following headings: the plant groups that undergo them; the organs that are involved during the plant life cycle; the meristems that are involved; and the products of the meristems.
- Why are annual rings used to determine the age of a tree trunk?
- What is the difference between determinate and indeterminate growth? What plant organs undergo each type of growth?
- What are the selective advantages of indeterminate growth?

Natural selection has acted on the plant body plan to produce a remarkable diversity of plant forms. Artificial selection by humans on the plants that provide us with food and fiber has greatly altered plant form as well.

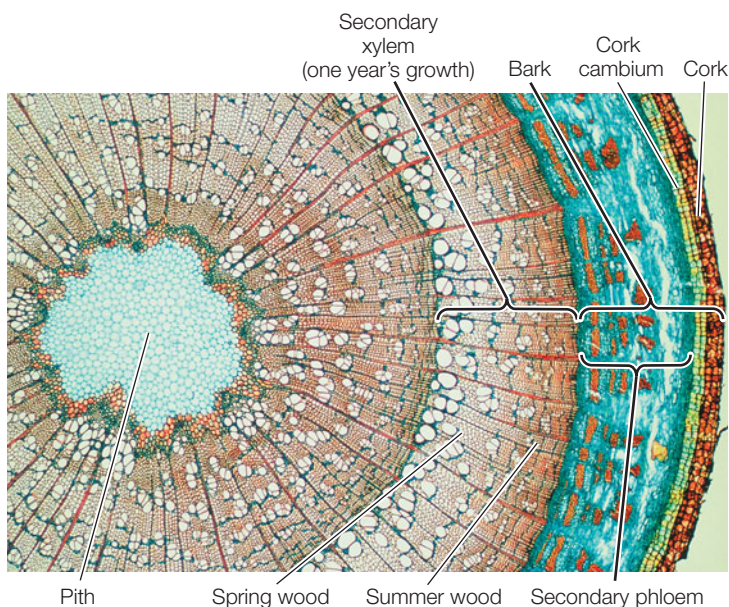

FIGURE 24.14 Annual Rings Rings of secondary xylem are a noticeable feature of this cross section from a tree trunk.

concept 24.3 Domestication Has Altered Plant Form

We have seen in this chapter that a very simple plant body plan—with roots, stems, leaves, meristems, and relatively few tissue and cell types—underlies the diversity of the flowering plants that cover our planet. Although differences in form among species are expected, members of the same plant species can be remarkably diverse in form as well. From a genetic perspective, this observation suggests that minor differences in genomes or gene regulation can underlie dramatic differences in plant form. (Nevertheless, some plant species do differ greatly in genome size, content, and organization.)

The form of the plant body is subject to natural selection. Phenotypes that can outcompete their peers for limiting resources have the highest fitness. Some plants have developed a viny, climbing phenotype that gives them access to light in crowded conditions. Others have a branched phenotype that puts neighboring plants in the shade. Still others have a deep and extensive root system that gives them access to water. Clearly, the vegetative body plan is as important in terms of

FIGURE 24.15 Corn Was Domesticated from the Wild Grass Teosinte Beginning more than 8,000 years ago in Mexico, farmers favored plants with minimal branching. Reducing the number of branches results in fewer ears per plant but allows each ear to grow larger and produce more seeds.

evolution as are phenotypes relating directly to reproduction, such as flower morphology.

When humans domesticated crops and chose from nature those phenotypes most suitable for cultivation, they set in motion a long experiment in artificial selection of the plant body. For example, in the case of corn (maize), farmers selected plants with tall, compact growth and few branches, minimizing competition among individual plants. Corn was domesticated from the wild grass teosinte, which still grows in the hills of Mexico (FIGURE 24.15). One of the most conspicuous differences between teosinte and domesticated corn is that teosinte, like other wild grasses, is highly branched, with many shoots, while domesticated corn has a single shoot. This morphological difference is due in large part to the activity of a single gene called *teosinte branched 1* (*tb1*). The protein product of *tb1* regulates the growth of axillary buds (see Figure 24.1). The allele of *tb1* in domesticated corn represses branching, while the allele in teosinte permits branching. Similarly, in the domestication of rice, farmers selected for a vertical orientation of the upper leaves so that sunlight could reach all the leaves and photosynthesis was maximized.

It may be hard to believe that a single species, *Brassica oleracea* (wild mustard), is the ancestor of so many familiar and morphologically diverse crops, including kale, broccoli, brussels sprouts, and cabbage (see Figure 15.4). An understanding of how the basic body plan of plants arises

makes it possible to appreciate how each of these crops was domesticated. Starting with morphologically diverse populations of wild mustard, humans selected and planted the seeds from variants with the trait they found desirable. Many generations of such artificial selection produced the crops that fill the produce section of the supermarket and the stands of the farmers' market.

What are the properties of the kenaf plant that make it suitable for papermaking?

ANSWER Kenaf is a biennial, herbaceous plant that grows rapidly from very active shoot apical meristems (Concept 24.1), reaching a height of 4–5 meters in 5 months. There are over 500 known genetic strains of kenaf. Over the centuries since its domestication, kenaf has been selected to grow taller and to branch less (Concept 24.3). In addition, the plant's adventitious roots have become longer, at about 2 meters (Concept 24.2), and more numerous, promoting the spread of the plant into dense stands in the field.

Kenaf stems are harvested for fiber (FIGURE 24.16). The phloem fibers are 3 millimeters long, somewhat longer than the fibers in wood; longer fibers are desirable for stronger products. In addition, the cell walls in kenaf stems are rich in cellulose but relatively poor in lignin. This makes kenaf easier to pulp than wood, which requires strong chemical treatments to hydrolyze the lignin in its cell walls. Furthermore, 1 hectare of kenaf produces 11–17 tons of fiber suitable for pulp and paper production; this is at least three times more than a hectare of southern pine trees produces. And bear in mind that it takes 5 months to grow the kenaf and 20 years to grow the pines!

The main uses of kenaf today are for the manufacture of rope, fiber-based bags, particleboard, and most recently, paper. The last use looks increasingly viable economically.

FIGURE 24.16 Kenaf Stems The stem of kenaf plants is rich in long phloem fibers. Their low lignin content makes the fibers attractive for making paper as well as other products. Paper derived from kenaf fibers has been used for printing newspapers.

24

SUMMARY

concept 24.1 The Plant Body Is Organized and Constructed in a Distinctive Way

- The vegetative organs of flowering plants are **roots**, which form a **root system**, and **stems** and **leaves**, which (together with flowers, which are sexual organs) form a **shoot system**. **Review Figure 24.1**
- Plant development is influenced by three unique properties of plants (compared to animals): apical meristems, the presence of cell walls, and the totipotency of most plant cells. **Review Figure 24.2**
- During embryogenesis, the apical–basal axis and the radial axis of the plant body are established, as are the **shoot apical meristem** and the **root apical meristem**. **Review Figures 24.3 and 24.4**
- Three **tissue systems**, arranged concentrically, extend throughout the plant body: the **dermal tissue system**, **ground tissue system**, and **vascular tissue system**. **Review Figure 24.5**
- The vascular tissue system includes **xylem**, which conducts water and mineral ions absorbed by the roots to the shoot, and **phloem**, which conducts the products of photosynthesis throughout the plant body.

concept 24.2 Meristems Build Roots, Stems, and Leaves

- **Primary growth** is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. Some plants also experience **secondary growth**, by which they increase in thickness.
- **Apical meristems** generate primary growth, and **lateral meristems** generate secondary growth. **Review Figure 24.6**
- Apical meristems at the tips of shoots and roots give rise to three **primary meristems** (**protoderm**, **ground meristem**, and **procam-**

bium), which in turn produce the three tissue systems of the plant body.

- The root apical meristem gives rise to the **root cap** and the three primary meristems. The cells in the root tip are arranged in three zones that grade into one another: the **zone of cell division**, **zone of cell elongation**, and **zone of cell maturation**. **Review Figure 24.7**
- The vascular tissue of roots is contained within the **stele**. It is arranged differently in eudicot and monocot roots. **Review Figure 24.8 and WEB ACTIVITIES 24.1 and 24.2**
- In stems, the vascular tissue is divided into **vascular bundles**, which containing both xylem and phloem. **Review Figure 24.10 and WEB ACTIVITIES 24.3 and 24.4**
- Eudicot leaves have two zones of photosynthetic **mesophyll** cells that are supplied by veins with water and minerals. **Review Figure 24.12 and WEB ACTIVITY 24.5**
- Two lateral meristems, the **vascular cambium** and **cork cambium**, are responsible for secondary growth. The vascular cambium produces secondary xylem (wood) and secondary phloem (inner bark). The cork cambium produces a protective tissue called **cork**. **Review Figures 24.13 and 24.14 and ANIMATED TUTORIAL 24.1**

concept 24.3 Domestication Has Altered Plant Form

- Although the plant body plan is simple, it can be changed dramatically by minor genetic differences, as evidenced by the natural diversity of wild plants.
- Crop domestication involves artificial selection of certain desirable traits found in wild populations. As a result of artificial selection over many generations, the body forms of crop plants are very different from those of their wild relatives. **Review Figure 24.15**

Plant Nutrition and Transport

25

The 2010 earthquake was a catastrophe for Haiti, the poorest country in the Western Hemisphere. Over 200,000 people died, and over a million people were left homeless. The urban infrastructure in the capital city was destroyed. Amid the outpouring of help from the rest of the world came a realization that another disaster has been occurring in Haiti for decades: the destruction of its forests and farms. Plants need fertile soil to grow, and in Haiti that has been in increasingly short supply.

Haiti shares the island of Hispaniola with the Dominican Republic. The two countries have had dramatically different policies with regard to land conservation, with equally dramatic results. While the Dominicans have carefully managed their land, the story of Haiti is one of overexploitation. First, Spanish colonists planted sugarcane, a crop that depleted the soil. Then the French colonists that followed them cut down forests to plant coffee and tobacco for export to Europe. After the former slaves revolted and expelled the Europeans in the early 1800s, land speculators chased out indigenous farmers from fertile valleys and planted export crops such as corn and beans. Today only 4 percent of the forests that existed when the Europeans arrived in 1492 remain. As Haitians have said, "Te a fatigue (The earth is tired)." Because there are few plant roots to stabilize the soil, especially in Haiti's many mountainous regions, rain washes the soil into the sea. From an airplane window it is easy to see the 120-mile-long border between the two countries. The Dominican side is

verdant and forested, while the Haitian side is devoid of plant life and has lost most of its soil.

As human land use intensifies, ecological disasters like Haiti's are becoming all too common. Today, parts of sub-Saharan Africa's farmland are losing their topsoil as a result of poor land management, swelling populations, and a challenging climate. Crop failures, starvation, and large-scale human displacements are inevitable consequences. The need for a better understanding of how plants interact with the soil is a pressing human concern.

How can soil be managed for optimal plant growth?

An aerial view of the border between Haiti (left) and the Dominican Republic (right) provides a dramatic illustration of the extent of soil degradation in Haiti.

KEY CONCEPTS

- 25.1** Plants Acquire Mineral Nutrients from the Soil
- 25.2** Soil Organisms Contribute to Plant Nutrition
- 25.3** Water and Solutes Are Transported in the Xylem by Transpiration–Cohesion–Tension
- 25.4** Solutes Are Transported in the Phloem by Pressure Flow

concept 25.1 Plants Acquire Mineral Nutrients from the Soil

Like all organisms, plants are made up primarily of water and molecules that contain the major elements of life. Plants are *autotrophs* that obtain carbon from atmospheric carbon dioxide through the carbon-fixation reactions of photosynthesis. They obtain hydrogen and oxygen mainly from water, so these elements are plentiful as long as plants have an adequate water supply.

LINK The major elements of life are described in Chapter 2, and the chemical reactions of photosynthesis in Concepts 6.5 and 6.6

The plant body contains other elements as well. Nitrogen, for example, is essential for the synthesis of proteins and nucleic acids. Plants obtain nitrogen, directly or indirectly, through the activities of bacteria, as we will see later in this chapter. In addition, proteins contain sulfur (S), nucleic acids contain phosphorus (P), and chlorophyll contains magnesium (Mg). Plants obtain these and other mineral nutrients mainly from the soil. Mineral nutrients dissolve in water in the soil as ions, forming a solution—called the **soil solution**—that surrounds the roots of plants.

Nutrients can be defined by their deficiency

A plant nutrient is called an **essential element** if its absence causes severe disruption of normal plant growth and reproduction. An essential element cannot be replaced by any other element. There are two categories of essential elements:

- **Macronutrients** have concentrations of at least 1 gram per kilogram of the plant's dry matter. There are six macronutrients:
 - Nitrogen (taken up as NO_3^-)
 - Phosphorus (taken up as PO_4^{3-})
 - Potassium (taken up as K^+)
 - Sulfur (taken up as SO_4^{2-})
 - Calcium (taken up as Ca^{2+})
 - Magnesium (taken up as Mg^{2+})
- **Micronutrients** have concentrations of less than 0.1g/kg of the plant's dry matter. They include iron (Fe^{2+}), chlorine (Cl^-), manganese

FIGURE 25.1 Mineral Nutrient Deficiency Symptoms The plants on the left were grown with a full complement of essential nutrients. The center plants were deprived of iron, while the plants on the right were deprived of nitrogen.

(Mn^{2+}), zinc (Zn^{2+}), copper (Cu^{2+}), nickel (Ni^{2+}), and molybdenum ($\text{Mo}(\text{O}_4)^{2-}$).

Plants show characteristic deficiency symptoms, most noticeable in leaves, that can be used to diagnose deficiencies of essential elements (**FIGURE 25.1**). With proper diagnosis, the missing nutrient(s) can be provided in the form of a supplement, or **fertilizer**.

Experiments using hydroponics have identified essential elements

The essential elements for plants were identified by growing plants **hydroponically**—that is, with their roots suspended in nutrient solutions instead of soil. Growing plants in this manner allows for greater control of nutrient availability than is possible in a complex medium like soil.

In the first successful experiments of this type, performed a century and a half ago, plants grew seemingly normally in solutions containing only calcium nitrate ($\text{Ca}(\text{NO}_3)_2$), magnesium sulfate (MgSO_4), and potassium phosphate (KH_2PO_4). A solution missing any of these compounds could not support normal plant growth. Tests with other compounds that included

yourBioPortal.com

Go to ANIMATED TUTORIAL 25.1
Nitrogen and Iron Deficiencies

various combinations of these same elements soon established the six macronutrients listed above.

Identifying micronutrients by this experimental approach proved to be more difficult because of the small amounts involved. Sufficient amounts of a micronutrient can be present in the environment used to grow plants. Therefore, nutrition experiments must be performed in tightly controlled laboratories

with special air filters that exclude microscopic mineral particles, and they must use only the purest available chemicals. Furthermore, a seed may contain enough of a micronutrient to supply the embryo and the resultant second-generation plant throughout its lifetime. There might even be enough left over to pass on to the next generation of plants. Thus, even if a plant is completely deprived of a micronutrient, it may take a long time for deficiency symptoms to appear. The most recent micronutrient to be listed as essential was nickel, in 1983 (FIGURE 25.2).

INVESTIGATION

FIGURE 25.2 Nickel Is an Essential Element for Plants Using highly purified minerals in a hydroponic solution, Patrick Brown and his colleagues tested whether barley can complete its life cycle in the absence of nickel. Other investigators showed that no other element could substitute for nickel.

HYPOTHESIS

Nickel is an essential element for plants.

METHOD

1. Grow barley plants for three generations in hydroponic solutions containing 0, 0.6, and 1.0 μM nickel sulfate (NiSO_4).
2. Harvest seeds from 5–6 third-generation plants in each of the groups.
3. Determine the nickel concentration in seeds from each plant.
4. Germinate other seeds from the same plants in a nickel-free hydroponic solution and plot the success of germination against nickel concentration.

RESULTS

There was a positive correlation between seed germination and nickel concentration. There was significantly less germination at the lowest nickel concentrations.

CONCLUSION

Barley seeds require nickel in order to germinate and complete their life cycle.

ANALYZE THE DATA

- A. What do the blue points have in common? Why are there five blue points instead of just one?
- B. What is the biological meaning of the zero/zero point?
- C. Why didn't the investigators examine only the plants grown without nickel in their hydroponic solution?
- D. Plant biologists define the *critical value* for a mineral nutrient as that concentration in plant tissue that results in a 15 percent reduction in the optimal yield of the plant. Using maximum germination percentage in this experiment as the optimal yield, calculate the critical value for nickel.

Soil provides nutrients for plants

Most terrestrial plants grow in soil. Plants derive a number of benefits from soil:

- Anchorage for mechanical support of the shoot
- Mineral nutrients and water from the soil solution
- O_2 for root respiration from air spaces between soil particles
- The services of other soil organisms, including bacteria, fungi, protists, and animals such as earthworms and arthropods

Although soils vary greatly, almost all of them have a *soil profile* consisting of several recognizable horizontal layers, called **horizons**, lying on top of one another. Soil scientists recognize three major horizons—termed A, B, and C—in a typical soil (FIGURE 25.3):

- The **A horizon** is the *topsoil* that supports the plant's mineral nutrient needs. It contains most of the soil's living and dead organic matter.

FIGURE 25.3 A Soil Profile The A, B, and C horizons of a soil can sometimes be seen in road cuts such as this one in Australia. The dark upper layer (the A horizon) is home to most of the living organisms in the soil.

- The **B horizon** is the *subsoil*, which accumulates materials from the topsoil above it and the parent rock below.
- The **C horizon** is the *parent rock* from which the soil arises.

Rocks are broken down into soil particles (*weathered*) in two ways. *Mechanical weathering* is the physical breakdown of materials by wetting, drying, and freezing. *Chemical weathering* is the alteration of the chemistry of the materials in the rocks by oxidation, water, and acids.

The soil's *fertility* (its ability to support plant growth) is determined by several factors. The size of the soil particles in the A horizon, for example, is important in determining nutrient retention and other soil characteristics. Mineral nutrients in the soil solution can be **leached** (washed away) from the A horizon downward by rain (or over-irrigation) and thereby become unavailable to plants. Tiny *clay* particles bind a lot of water, and mineral nutrients are not readily leached from them, but clay particles pack tightly and leave little room for air. Large *sand* particles present the opposite problems. A **loam** is a soil that is an optimal mixture of sand, silt, and clay, and thus has sufficient supplies of air, water, and nutrients for plants.

In addition to mineral particles, soils contain dead organic matter, largely from plants. Soil organisms break down dead leaves and other organic materials that fall to the ground into a substance called **humus**. This material is used as a food source by microbes that break down complex organic molecules and release simpler molecules into the soil solution. Humus also improves the texture of soil and provides air spaces that increase oxygen availability to plant roots.

Ion exchange makes nutrients available to plants

Chemical weathering results in clay particles covered with negatively charged chemical groups (**FIGURE 25.4**). These negatively charged clay particles bind the positively charged ions (cations) of many minerals that are important for plant nutrition, such as potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). This binding prevents the cations from being leached

out of the soil, but to become available to plants, they must be detached from the clay particles.

Recall that the root surface is covered with epidermal cells bearing root hairs (see Figure 24.7B). Proteins in the plasma membrane of these cells actively pump protons (H^+) out of the cells, as we'll describe in Concept 25.3. In addition, cellular respiration in the roots releases CO_2 , which dissolves in the soil water and reacts with it to form carbonic acid. This acid ionizes to form bicarbonate and free protons:

Proton pumping by the root cells and ionization of carbonic acid both act to increase the proton concentration in the soil surrounding the root. The protons bind more strongly to clay particles than do mineral cations; in essence, the protons trade places with the cations in a process called **ion exchange** (see Figure 25.4). Ion exchange releases mineral nutrient cations into the soil solution, where they are available to be taken up by roots. Soil fertility is determined in part by the soil's ability to provide nutrients in this manner.

FRONTIERS Some mineral ions are toxic to plants. At low soil pH, acids cause clay particles to release aluminum oxide (Al_2O_3), which is poisonous to the roots of many species. Its presence can severely reduce crop growth in areas with naturally acidic soils. In Colombia, plant breeders have produced several strains of crop plants that grow well in acidic soils. These plants are now being used in breeding programs to introduce their characteristics into commercial varieties of the same crops.

There is no comparable mechanism for binding and releasing negatively charged ions. As a result, important anions such as nitrate (NO_3^-) and sulfate (SO_4^{2-}) may be leached from the A horizon.

Fertilizers can be used to add nutrients to soil

Leaching and the harvesting of crops may deplete a soil of its nutrients, in which case the growth of subsequent crops on that soil will be reduced. There are three ways to restore the nutrient content of such a soil: shifting agriculture, organic fertilizers, and chemical fertilizers.

SHIFTING AGRICULTURE In the past, when the soil could no longer support a level of plant growth sufficient for agricultural purposes, people simply moved to another location. This *nomadic* existence allowed the soil to replenish its nutrients naturally, by weathering of the parent rock and gradual accumulation and breakdown of organic matter, building back up the soil's humus. Weathering is

FIGURE 25.4 Ion Exchange Plants obtain some mineral nutrients from the soil in the form of positive ions bound to clay particles in the soil.

a geological process that takes a long time, but that was not a problem as long as a lot of land was available. After many years in other locations, the people could return to their original land, which was again able to support farming. Today, the food needs of a large human population are too great to allow land to be left vacant for a long time; in addition, most people live more settled lives now and do not want to move.

ORGANIC FERTILIZERS Humus is used as a food source by soil organisms, which in turn release simpler molecules to the soil solution. For example:

These simpler molecules can dissolve in soil water and enter plant roots.

Farmers can increase the nutrient content of soil by adding organic materials such as *compost* (partially decomposed plant material). Another way to increase the fertility of soil is to add the waste from farm animals (*manure*), which is a particularly good source of nitrogen. In either case, these **organic fertilizers** add nutrients to the soil much more rapidly than natural weathering, but still allow for a slow release of ions, with little leaching, as the materials decompose.

INORGANIC FERTILIZERS Because organic fertilizers may still act too slowly to restore fertility if a soil is to be used every year, **inorganic fertilizers** are used to supply mineral nutrients directly in forms that can be immediately taken up by plants. Inorganic fertilizers are characterized by their “N-P-K” percentages. A 5-10-10 fertilizer, for example, contains 5 percent nitrogen, 10 percent phosphate (P_2O_5), and 10 percent potash (K_2O) by weight (of the nutrient-containing compound, not as weights of the elements N, P, and K). Sulfur, in the form of ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$), is also occasionally added to soils.

To return to our example of nitrogen, inorganic fertilizers reach plants by this process:

The manufacture of nitrogen fertilizer begins with an energy-intensive industrial process in which N_2 is combined with H_2 at high temperatures and pressures in the presence of a catalyst to form ammonia (NH_3). While organic and inorganic fertilizers have the same effects on crop nutrition, their costs are very different: animal manure and plant waste are free, whereas NH_4^+ made in a factory is very expensive because the manufacturing process requires large amounts of energy.

FRONTIERS About 100 million metric tons of ammonia are made industrially for use as fertilizer every year. The process of manufacturing ammonia, invented in 1909, combines N_2 and H_2 gases and is highly energy dependent. Ammonia production accounts for about 2 percent of the world’s energy use, mostly in the form of natural gas. As fossil fuel prices rise, so does the cost of inorganic fertilizer. Chemists are exploring ways to use renewable energy sources to lower the cost.

Do You Understand Concept 25.1?

- What are the differences between:
 - a. macronutrients and micronutrients?
 - b. organic and inorganic fertilizers?
 - c. the availability to plant roots of a cation and an anion?
- Outline an experimental method for determining whether an element is essential to a plant.
- A label on a bin in a market states “Organic apples, grown without chemical fertilizers.” Are these apples different in terms of plant molecules than they would be if they were grown with chemical fertilizers?

We have just described some of the physical and chemical aspects of soils that are vital to plant nutrition. But many other organisms besides plants inhabit soils. We will turn now to the effects of those organisms on plants.

concept 25.2 Soil Organisms Contribute to Plant Nutrition

One gram of soil contains from 6,000 to 50,000 bacterial species and up to 200 meters of fungal hyphae, although both are largely invisible to the naked eye. Many of these soil organisms consume living and dead plant materials. Plants have an array of defenses they can use against potentially harmful soil organisms (which we describe in Chapter 28). In a few cases, however, plants *actively encourage* fungi and bacteria to infect their roots. Here we describe the resulting “intercellular trading posts,” where products are exchanged to the mutual benefit of plants and a few very special soil microbes. In these interactions, the plants usually “trade” the products of photosynthesis, which the microbes use as an energy source, for other essential elements, such as phosphorus and nitrogen, which the microbes can supply. We’ll begin by describing how these associations form; then we’ll see how they benefit the plants and their microbial partners.

Plants send signals for colonization

In Concept 22.2 we described the association of fungi with plant roots, an interaction that occurs in over 90 percent of terrestrial plants. Our focus here is on arbuscular mycorrhizae, in which fungal hyphae penetrate roots (see Figure 22.9B). In Chapter 19 we introduced the nitrogen-fixing bacteria that convert atmospheric N_2 into ammonia. Here we also describe the close association between certain nitrogen-fixing bacteria called rhizobia and the roots of some plants. In the case of both arbuscular mycorrhizae and rhizobia, the plant roots send signals that attract the soil organisms, and the development of the association involves similar genes and cellular pathways.

FORMATION OF MYCORRHIZAE The events in the formation of arbuscular mycorrhizae are shown in **FIGURE 25.5A**. Plant

roots produce compounds called **strigolactones** that stimulate rapid growth of fungal hyphae toward the root. In response, the fungi produce signals that stimulate expression of plant symbiosis-related genes. The products of some of these genes give rise to the *prepenetration apparatus* (PPA), which guides the

growth of the fungal hyphae into the root cortex. The sites of nutrient exchange between fungus and plant are the *arbuscules*, which form at root cortical cells. Despite the intimacy of this association, the plant and fungal cytoplasm never mix—they are separated by two membranes, the fungal plasma membrane and the *periarbuscular membrane* (PAM), which is continuous with the plant plasma membrane.

FORMATION OF NITROGEN-FIXING NODULES A group of plants called *legumes* can form symbioses with several species of soil bacteria collectively known as *rhizobia*, which live in nodules that form on the legumes' roots. The roots of these plants release flavonoids and other chemical signals that attract the rhizobia to the vicinity of the roots (**FIGURE 25.5B**). The flavonoids also trigger the transcription of bacterial *nod* genes, the products of which synthesize Nod (nodulation) factors. These factors, when secreted by the bacteria, cause cells in the root

FIGURE 25.5 Roots Send Signals for Colonization Plant roots send chemical signals to arbuscular mycorrhizal fungi (A) and nitrogen-fixing bacteria (B) to stimulate colonization.

APPLY THE CONCEPT

Soil organisms contribute to plant nutrition

Researchers grew lemon seedlings in soils that contained phosphate fertilizer, arbuscular mycorrhizal fungi, or both. The table shows the mean dry weight of the seedlings after 6 months.

Use the data in the table to answer the following questions:

1. What do these results tell us about the role of phosphate fertilizer in the growth of lemon plants?
2. Why didn't the mean weight of the seedlings increase when the amount of phosphate fertilizer, in the absence of mycorrhizae, was doubled?

PHOSPHATE FERTILIZER ADDED (g)	MYCORRHIZAE PRESENT	SEEDLING DRY WEIGHT (g)
0	No	1
0	Yes	10
12	No	28
12	Yes	166
24	No	20
24	Yes	210

cortex to divide, leading to the formation of a *primary nodule meristem*. This meristem gives rise to the plant tissue that constitutes the root nodule. Bacteria enter the root via an infection thread, analogous to the PPA in mycorrhizal associations, and eventually reach cells inside the root nodule. There, the bacteria are released into the cytoplasm of the nodule cells and are enclosed in membrane vesicles similar to the PAM. Inside the vesicles, the bacteria differentiate into **bacteroids**—the form of the bacteria that can fix nitrogen.

Mycorrhizae expand the root system

In most cases, the roots of vascular plants cannot optimally support plant growth alone—they simply cannot reach all the nutrients available in the soil. Mycorrhizae expand the root surface area 10-fold to 1,000-fold, increasing the amount of soil the plant can explore for nutrients. In addition, because fungal hyphae are much finer than root hairs, they can get into pores in the soil that are inaccessible to roots. In this way, mycorrhizae probe a vast expanse of soil for nutrients and deliver them into root cortical cells.

The primary nutrient that the plant obtains from a mycorrhizal interaction is phosphorus. In exchange, the fungus obtains an energy source: the products of photosynthesis. In fact, up to 20 percent of the photosynthate of terrestrial plants is directed to and consumed by arbuscular mycorrhizal fungi. Such

associations are excellent examples of *mutualism*, an interaction between two species in which both species benefit (which is further discussed in Chapter 44). They are also examples of *symbiosis*, in which two different species live in close contact for a significant portion of their life cycles.

Rhizobia capture nitrogen from the air and make it available to plant cells

Although nitrogen is essential for their survival, plants cannot use atmospheric N_2 because the triple bond that links the two N atoms in N_2 requires a large amount of energy to break. Some bacteria, however, have an enzyme called **nitrogenase** that enables them to convert N_2 into a more reactive and biologically useful form, ammonia (NH_3), by a process called **nitrogen fixation**. This process is by far the most important route by which nitrogen enters biological systems. Biological nitrogen fixation is the *reduction* of nitrogen gas, and it requires a great deal of energy. It proceeds by the stepwise addition of three pairs of hydrogen atoms to N_2 (FIGURE 25.6).

FIGURE 25.6 Nitrogenase Fixes Nitrogen Throughout the chemical reactions of nitrogen fixation, the reactants are bound to the enzyme nitrogenase. A reducing agent transfers hydrogen atoms to a molecule of nitrogen gas (N_2), and eventually the final product—ammonia (NH_3)—is released. This reaction requires a large input of energy: about 16 ATPs.

Nitrogenase is strongly inhibited by oxygen. Many free-living nitrogen-fixing bacteria are anaerobes that live in environments that naturally contain little or no O_2 . In the aerobic environment of plant roots, the nodules provide the rhizobia with the conditions necessary for nitrogen fixation (see Figure 25.5B). Within a nodule, O_2 is maintained at a low level that is sufficient to support aerobic respiration by the bacteria (which is necessary to supply energy for the fixation reaction) but not so high as to inactivate nitrogenase. The O_2 level is regulated by a plant-produced protein called **leghemoglobin**, which is an O_2 carrier. Leghemoglobin is a close relative of hemoglobin, the red, oxygen-carrying pigment of animals, and is thus an evolutionarily ancient molecule.

LINK The cycling of nitrogen through biological systems is described in Chapter 46, and some of the prokaryotes that participate in that cycling are described in Concept 19.3

As with mycorrhizae, attracting and maintaining nitrogen-fixing bacteria is costly to the plant, consuming as much as 20 percent of all of the energy stored in photosynthate. Relatively few plant species are legumes, but those species are important to humans because they can be grown in nitrogen-poor soil. They include peas, soybeans, clover, alfalfa, and some tropical shrubs and trees. Most other plants depend on nitrogen fixed by free-living bacteria in the soil or released by the breakdown of proteins present in dead organic matter.

Some plants obtain nutrients directly from other organisms

Although the majority of plants obtain most of their mineral nutrients from the soil solution (with the help of fungi), some, such as carnivorous and parasitic plants, use other sources.

CARNIVOROUS PLANTS There are about 500 carnivorous plant species that obtain some of their nutrients by digesting arthropods. These plants typically grow in boggy soils where little nitrogen or phosphorus is available. Digestion (hydrolysis) of arthropod prey helps provide those missing nutrients. A well-known example of a carnivorous plant is the Venus flytrap (genus *Dionaea*; **FIGURE 25.7A**), which has a modified leaf with two halves that fold together. When an insect touches trigger hairs on the leaf, its two halves quickly come together, and their spiny margins interlock and trap the insect before it can escape. The leaf then secretes enzymes that digest the prey.

PARASITIC PLANTS Approximately 1 percent of flowering plant species derive some or all of their water, nutrients, and even photosynthate from other plants. **Hemiparasites** can photosynthesize but derive water and mineral nutrients from the living bodies of other plants. Mistletoes, for example, contain chlorophyll and carry out some photosynthesis, but they parasitize other plants for water and mineral nutrients and may derive some photosynthetic products from them as well. Dwarf mistletoe (*Arceuthobium americanum*) is a serious parasite in forests

FIGURE 25.7 Nutrients from Other Organisms (A) The Venus flytrap (*Dionaea muscipula*) obtains nitrogen from the bodies of arthropods trapped inside the plant when its specialized leaves snap shut. (B) Purple witchweed (*Striga hermonthica*) parasitizes sorghum plants.

of the western United States, destroying more than 3 billion board feet of lumber per year.

Holoparasites are completely parasitic and do not perform photosynthesis. Witchweed (*Striga*) is a serious parasite of crops, causing over \$1 billion a year in corn losses in Africa (**FIGURE 25.7B**). Interestingly, strigolactone, the molecule made by plant roots that attracts arbuscular mycorrhizal fungi, is closely related to the molecule that *Striga* responds to as well. Scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to take advantage of a compound that was already produced by plants to attract soil microbes.

Do You Understand Concept 25.2?

- Compare the events that occur when arbuscular mycorrhizal fungi and rhizobia infect a plant root. What is the nutritional advantage to the plant in each case?
- How might you turn wheat, a plant that does not have symbiotic relationships with nitrogen-fixing bacteria, into a nitrogen-fixing plant? What biochemical challenges would you face?
- How do the nutritional needs of holoparasitic plants differ from those of carnivorous plants?
- What characteristics are shared among nonparasitic plant–parasitic plant, plant–mycorrhizal fungus, and plant–rhizobia associations?

Now that we have learned about plant nutrients in the soil, let's consider how soil water, with its dissolved nutrients, enters the plant root, and how it moves from the root to the rest of the plant body.

concept
25.3

Water and Solutes Are Transported in the Xylem by Transpiration–Cohesion–Tension

Nutrients, as we have seen, enter plants as ions dissolved in soil water. But plants need that water as more than a solvent for nutrients. Plants require water to carry out photosynthesis, to transport solutes between plant organs, to cool their bodies by evaporation, and to maintain the internal pressure that supports their bodies.

Differences in water potential govern the direction of water movement

To enter a root cell, a solution must pass through the cell's plasma membrane. In Concept 5.2 we described *osmosis*, the movement of water through a selectively permeable membrane toward a region of higher solute concentration (that is, lower water concentration). Plant biologists define **water potential (psi, Ψ)** as the tendency of a solution (water plus solutes) to take up water from pure water across a membrane. By definition, the water potential of pure water is zero. Any solution with a water potential of less than zero has a tendency to take up water from pure water, and the lower (the more negative) the water potential, the greater the driving force for water movement across the membrane.

Water potential has two components:

- **Solute potential (Ψ_s):** Solutes affect the osmotic behavior of a solution. As solutes are added, the concentration of free water is reduced; the more solutes, the lower the water potential. So solute potential is usually negative.

- **Pressure potential (Ψ_p):** As plant cells take up water, they tend to swell. The presence of the cell wall, however, provides resistance to that swelling (see Figure 5.3C). The result is an increase in internal pressure in the cell (*turgor pressure*), which decreases the tendency of the cell to take up more water.

The water potential is the sum of the solute potential and the pressure potential:

$$\Psi = \Psi_s + \Psi_p$$

We can measure all three potentials in *megapascals (MPa)*, a unit of pressure. Atmospheric pressure—"one atmosphere"—is about 0.1 MPa, or 14.7 pounds per square inch (a typical pressure in an automobile tire is about 0.2 MPa).

Whenever water moves across a selectively permeable membrane by osmosis, it moves toward the region of lower (more negative) water potential (**FIGURE 25.8A**).

In a plant cell (**FIGURE 25.8B**), turgor pressure is equivalent to the pressure potential (Ψ_p) exerted by the piston in Figure 25.8A. Water will enter plant cells by osmosis until the pressure

Water Uptake in Plants

FIGURE 25.8 Water Potential, Solute Potential, and Pressure Potential (A) A theoretical illustration of water potential. (B) The effect of differences in water potential on a plant cell.

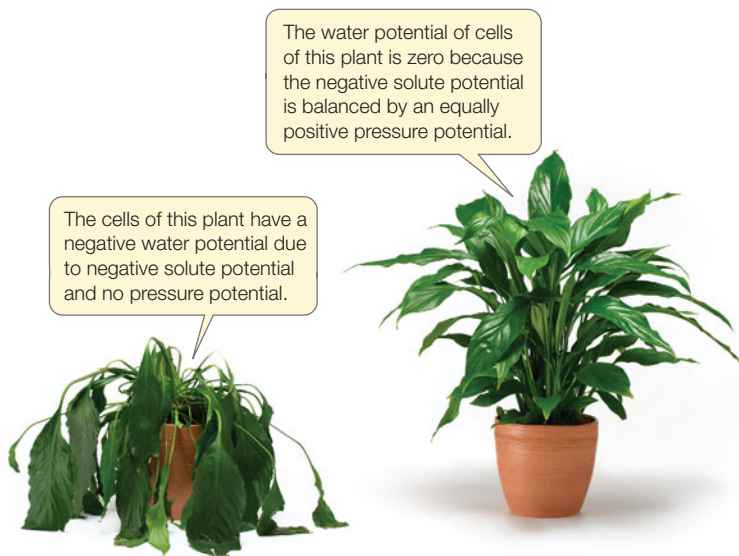

FIGURE 25.9 A Wilted Plant A plant wilts when the pressure potential of its cells drops.

potential exactly balances the solute potential. At this point, the cell is *turgid*; that is, it has a significant positive pressure potential. The physical structure of many plants is maintained by the (positive) pressure potential of their cells; if the pressure potential drops (for example, if the plant does not have enough water), the plant *wilts* (FIGURE 25.9).

Water and ions move across the root cell plasma membrane

The movement of a soil solution containing mineral ions across a root cell plasma membrane faces two major challenges:

- The membrane is hydrophobic, whereas water and mineral ions are polar.
- Some mineral ions must be moved against their concentration gradient.

These two challenges are met by membrane proteins.

LINK Review the structure and functions of biological membranes in Chapter 5

AQUAPORINS *Aquaporins* are membrane channels through which water can diffuse (see Figure 5.5). Although aquaporins were first discovered in animal cells, they are also abundant in plant plasma membranes. Their concentration in the plasma membrane and their function are both regulated so that the rate of osmosis can be changed. But the direction of osmosis always remains the same: water moves to the region of more negative water potential.

ION CHANNELS AND PROTON PUMPS When the concentration of an ion in the soil solution is greater than that in the root, transport proteins can move the ion into the plant by facilitated diffusion. The concentrations of many mineral ions in the soil solution, however, are lower than those required inside the plant. In addition, electric charge differences play a role in the uptake of mineral ions. For example, a negatively charged ion that moves into a negatively charged cellular compartment is moving against an *electrical gradient*, and this movement requires energy. Concentration and electrical gradients combine to form an *electrochemical gradient*. Uptake against an electrochemical gradient requires *active transport*.

LINK Electrochemical gradients are discussed in more detail in Concept 34.2

Animals use a $\text{Na}^+ - \text{K}^+$ pump to generate a Na^+ gradient that can be used to drive the uptake of other solutes (see Figure 5.7). Instead of a $\text{Na}^+ - \text{K}^+$ pump, plants have a **proton pump**, which uses energy from ATP to move protons out of the cell against a *proton concentration gradient* (FIGURE 25.10, STEP 1). Because protons (H^+) are positively charged, their accumulation outside the cell has two results:

- An electrical gradient is created such that the region just outside the cell becomes more positively charged than the inside of the cell.
- A proton concentration gradient develops, with more protons just outside the cell than inside the cell.

FIGURE 25.10 Ion Transport into Plant Cells The active transport of protons (H^+) out of the cell by a proton pump (step 1) drives the movement of both cations (step 2) and anions (step 3) into the cell.

Each of these results has consequences for the movement of other ions. Because the inside of the cell is now more negative than the outside, cations such as potassium (K^+) move into the cell by facilitated diffusion through their specific membrane channels (FIGURE 25.10, STEP 2). In addition, the proton concentration gradient can be harnessed to drive active transport. Anions such as chloride (Cl^-) are moved into the cell against an electrochemical gradient by a membrane transport protein that couples their movement with that of H^+ (FIGURE 25.10, STEP 3). This process is an example of secondary active transport.

Water and ions pass to the xylem by way of the apoplast and symplast

Water and ions from the soil solution move through the roots to the xylem by one of two pathways: the *apoplast* or the *symplast* (FIGURE 25.11).

- The **apoplast** (Greek *apo*, “away from”; *plast*, “living material”) consists of the cell walls, which lie outside the plasma

membranes, and intercellular spaces (spaces between cells), which are common in many plant tissues. The apoplast is a continuous meshwork through which water and solutes can flow without ever having to cross a membrane.

- The **symplast** (Greek *sym*, “together with”) passes through the continuous cytoplasm of the living cells connected by plasmodesmata. The selectively permeable plasma membranes of the root cells control access to the symplast, so movement of water and solutes into the symplast is tightly regulated.

Water and minerals that pass from the soil solution through the apoplast can travel freely as far as the endodermis, the

FIGURE 25.11 Apoplast and Symplast Plant cell walls and intercellular spaces constitute the apoplast. The symplast consists of the cytoplasm of living cells, which are connected by plasmodesmata. To enter the symplast, water and solutes must pass through a plasma membrane. No such selective barrier limits movement through the apoplast.

yourBioPortal.com

Go to WEB ACTIVITY 25.1
Apoplast and Symplast of the Root

innermost layer of the root cortex. The endodermis is distinguished from the rest of the ground tissue by the presence of the **Casparian strip**. This waxy, suberin-impregnated region of the endodermal cell wall forms a hydrophobic belt around each endodermal cell where it is in contact with other endodermal cells. The Casparian strip acts as a seal that prevents water and ions from moving through spaces between the endodermal cells; instead, water and ions enter the cytoplasm of the endodermal cells. (The Casparian strip is functionally equivalent to the tight junctions found in some animal tissues; see Figure 4.18.) Water and ions already in the symplast can enter the endodermal cells through plasmodesmata.

Once they have passed the endodermal barrier, water and minerals remain in the symplast until they reach parenchyma cells in the pericycle or xylem. These cells then actively transport mineral ions into the apoplast of the stele. As ions are transported into the solution in the cell walls of the stele, water potential in the apoplast becomes more negative; consequently, water moves out of the cells and into the apoplast by osmosis. In other words, ions are transported actively, and water follows passively. The end result is that water and minerals end up in the xylem, where they constitute the *xylem sap*.

Water moves through the xylem by the transpiration–cohesion–tension mechanism

Once water has arrived in the xylem, it is all uphill from there! Consider the magnitude of what xylem accomplishes. A single maple tree 15 m tall has been estimated to have some 177,000 leaves, with a total leaf surface area of 675 m²—1.5 times the area of a basketball court. During a summer day, that tree loses 220 liters of water *per hour* to the atmosphere by evaporation from its leaves. So, to prevent wilting, the xylem must transport 220 liters of water 15 m from the roots up to the leaves every hour.

How is the xylem able to move so much water to such great heights? Part of the answer lies in the structure of the xylem, which we described in Chapter 24. Recall that xylem vessels consist of a long “straw” of cell walls, which provide both structural support and the rigidity needed to maintain a pressure gradient within the xylem sap. Early experiments ruled out two possible ways that had been hypothesized for moving water up through these vessels from roots to leaves: upward pressure and capillary action.

Upward pressure would move water by “pushing the bottom.” A simple experiment in 1893 ruled out this mechanism: A tree was cut at its base, and the sawed-off part was placed in a vat of poison that killed living cells. (Recall that mature xylem is made up of dead cells.) The poison continued to rise through the trunk, even though cells were killed along the way. This observation showed that a living “pump” is not required to push the xylem sap up a tree. Furthermore, the roots were absent, yet upward flow in the trunk continued, demonstrating that the roots do not provide upward pressure. When the poison reached the leaves and killed them, however, all further movement up the trunk stopped, demonstrating that leaves must be alive for water to move in the xylem. *Capillary action* was also ruled out as the mechanism that makes water rise in

the xylem. Water molecules have strong cohesion, so a column of water can indeed rise in a thin tube (e.g., a straw or a xylem vessel) by capillary action, but calculations have shown that xylem vessels, at 100 μm in diameter, are simply too wide to get water to the top of a 15-m tree in this fashion. In fact, the maximum height for a water column raised by capillary action alone in a 100-μm-diameter vessel is only 0.15 m.

LINK Review the properties of water in Chapter 2

Almost a century ago, the **transpiration–cohesion–tension** theory was proposed to explain water transport in the xylem (**FIGURE 25.12**). According to this theory, the key elements of xylem transport are:

- *Transpiration*: evaporation of water from cells within the leaves
- *Cohesion* of water molecules in the xylem sap due to hydrogen bonding
- *Tension* on the xylem sap resulting from transpiration

The concentration of water vapor in the atmosphere is lower than that in the apoplast of a leaf. Because of this difference, water vapor diffuses from the intercellular spaces of the leaf and through the *stomata* to the outside air in a process called **transpiration**. Within the leaf, water evaporates from the moist walls of the mesophyll cells and enters the intercellular spaces. As water evaporates from the aqueous film coating each cell, the film shrinks back into tiny spaces in the cell walls, increasing the curvature of the water surface and thus increasing its surface tension. Because of hydrogen bonding, water molecules have cohesion, and therefore the increased *tension* (negative pressure potential) in the surface film draws more water into the cell walls, replacing that which was lost by evaporation. The resulting tension in the mesophyll draws water from the xylem of the nearest vein into the apoplast surrounding the mesophyll cells. The removal of water from the veins, in turn, establishes tension on the entire column of water contained in the xylem, so that the column is drawn upward all the way from the roots.

Each part of this theory is supported by evidence:

- The difference in water potential between the soil solution and air is huge, on the order of –100 MPa. This difference should generate more than enough tension to pull a water column up the tallest tree.
- There is a continuous column of water in the xylem, which is caused by cohesion.
- Measurements of xylem pressures in cut stems show a negative pressure potential, which indicates considerable tension.

In addition to its role in the transpiration–cohesion–tension mechanism, transpiration has the added benefit of cooling a plant’s leaves (much as humans sweat to cool off). The evaporation of water from mesophyll cells consumes heat, thereby decreasing the leaf temperature. A farmer can hold a leaf between thumb and forefinger to estimate its temperature; if the leaf doesn’t feel cool, that means transpiration is not occurring and it must be time to water.

FIGURE 25.12 The Transpiration–Cohesion–Tension Mechanism Transpiration causes evaporation from mesophyll cell walls, generating tension on the water in the xylem. Cohesion among water molecules in the xylem transmits the tension from the leaf to the root, causing water to flow through the xylem from the roots to the atmosphere.

Xylem Transport

Although transpiration provides the driving force for the transport of water and minerals in the xylem, it also results in the loss of tremendous quantities of water from the plant. How do plants control this loss?

Stomata control water loss and gas exchange

In Chapter 6 we describe photosynthesis, which has the general equation

Leaves are the chief organs of photosynthesis, so they must have a large surface area across which to exchange the gases O_2 and CO_2 . This surface area is provided by the mesophyll cells being surrounded by abundant air spaces inside the leaf (see Figure 25.12), which are also the location of the evaporation that drives water movement in the xylem. The epidermis of leaves and stems minimizes transpirational water loss by secreting a waxy cuticle, which is impermeable to water. However, the cuticle is also impermeable to CO_2 and O_2 . How can

the plant balance its need to retain water with its need to obtain CO_2 for photosynthesis?

Plants have met this challenge with the evolution of **stomata** (singular *stoma*): pores in the leaf epidermis, typically on the underside of the leaf (FIGURE 25.13A). There are up to 1,000 stomata per square millimeter in some leaves, constituting up to 3 percent of the total surface area of the shoot. Such an abundance of stomata could lead to excessive water loss. But stomata are not static structures. A pair of specialized epidermal cells, called **guard cells**, controls the opening and closing of each stoma.

When the stomata are open, CO_2 can enter the leaf by diffusion, but water vapor diffuses out of the leaf at the same time. Closed stomata prevent water loss but also exclude CO_2 from the leaf. Most plants open their stomata when the light intensity is sufficient to maintain a moderate rate of photosynthesis. At night, when darkness precludes photosynthesis, their stomata are closed; no CO_2 is needed at this time, and water is conserved. Even during the day, the stomata close if water is being lost at too great a rate.

FIGURE 25.13 Stomata Regulate Gas Exchange and Transpiration (A) Scanning electron micrograph of an open stoma formed by two sausage-shaped guard cells. (B) Potassium ion concentrations affect the water potential of the guard cells, controlling the opening and closing of stomata. Negatively charged ions (e.g., Cl^-) that accompany K^+ maintain electrical balance and contribute to the changes in water potential that open and close the stomata.

FRONTIERS Water-use efficiency is a measure of how much water is consumed (in kilograms) per kilogram of plant material produced. This measure varies among crop species, from water-hungry soybeans at 650 kg/kg to drought-adapted sorghum at 300 kg/kg. A single transcription factor, first found in *Arabidopsis*, improves water-use efficiency dramatically. Scientists are now trying to find out if genes encoding this transcription factor can be used to produce crop plants that need less water.

Guard cells can respond to changes in light and CO_2 concentration in a matter of minutes by changing their solute potential. These changes are driven by changes in the K^+ concentration in the guard cells. The absorption of light by a pigment in the guard cell plasma membrane activates a proton pump (see Figure 25.10), which actively transports H^+ out

of the guard cells and into the apoplast of the surrounding epidermis. The resulting electrochemical gradient drives K^+ into the guard cells, where it accumulates (FIGURE 25.13B). The increased internal concentration of K^+ makes the solute potential of the guard cells more negative. Negatively charged chloride ions and organic ions also move into and out of the

APPLY THE CONCEPT

Water and solutes are transported in the xylem by transpiration–cohesion–tension

Here are measurements of water potential (Ψ) in a 100-m-tall tree and its surroundings:

REGION	Ψ (MPa)
Soil water	-0.3
Xylem of root	-0.6
Xylem of trunk	-1.2
Inside of leaf	-2.0
Outside air	-58.5

Gravity exerts a force of -0.01 MPa per meter of height above ground.

1. Is the water potential in the leaf sufficiently low to draw water to the top of the tree?
2. Would transpiration continue if soil water potential decreased to -1.0 ?
3. What would you expect to happen to the xylem water potential if all of the stomata closed?

guard cells along with the K^+ ions, maintaining electrical balance and contributing to the change in the solute potential of the guard cells. Water then enters by osmosis (guard cell membranes are particularly rich in aquaporins), increasing the turgor pressure of the guard cells. The guard cells change their shape in response to the increase in pressure potential, so that a space—the stoma—appears between them. The stoma closes in the absence of light: the proton pump becomes less active, K^+ ions diffuse passively out of the guard cells, water follows by osmosis, the pressure potential decreases, and the guard cells sag together and seal off the stoma.

Do You Understand Concept 25.3?

- What distinguishes water potential, solute potential, and pressure potential?
- What are the roles of transpiration, cohesion, and tension in xylem transport?
- If *Arabidopsis* is exposed to high CO_2 concentrations, the new leaves that form on the plant have fewer stomata than they would have had under normal conditions. Why do you think this might be advantageous?
- When water is in short supply, some plants shed their leaves. Explain why this occurs.

Now that we understand how leaves obtain the water and CO_2 required for photosynthesis, let's examine how the products of photosynthesis are transported to other parts of the plant where they are needed.

concept 25.4 Solute Are Transported in the Phloem by Pressure Flow

As photosynthesis occurs in the leaf, the carbohydrate products of photosynthesis (mainly sucrose) diffuse to the nearest small vein, where they are actively transported into sieve tube elements. The movement of carbohydrates and other solutes through the plant in the phloem is called **translocation**. These solutes are translocated from *sources* to *sinks*:

- A **source** is an organ (such as a mature leaf or a storage root) that *produces* (by photosynthesis or by digestion of stored reserves) more photosynthate than it requires.
- A **sink** is an organ (such as a root, flower, developing fruit or tuber, or immature leaf) that *consumes* photosynthate for its own growth and storage needs.

Sources and sinks can change roles. For example, storage roots (such as sweet potatoes) are sinks when they accumulate photosynthate, but they are sources when their stored reserves are needed to nourish other organs in the plant.

LINK The anatomy of sieve tubes is described in Concept 24.1

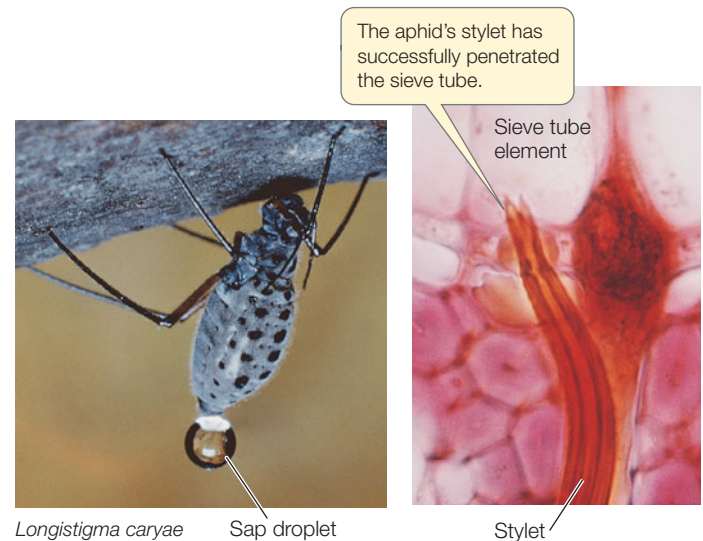

Sucrose and other solutes are carried in the phloem

Evidence that the phloem carries sucrose and other solutes initially came in the 1600s, when Marcello Malpighi removed a ring of bark (containing the phloem) from the trunk of a tree, while leaving the xylem intact—that is, he *girdled* the tree. Over time, the bark in the region above the girdle swelled:

Malpighi correctly concluded that the solution coming from the leaves above the girdle was trapped in the bark. Later, the bark below the girdle died because it was no longer receiving sugars from the leaves. Eventually the roots, and then the entire tree, died.

In the twentieth century, plant biologists analyzed the contents of phloem with the help of aphids. These insects feed on plants by drilling into sieve tube elements with a specialized organ, the *stylet*. The pressure potential in the sieve tube is higher than that outside the plant, so the nutritious phloem sap is forced through the stylet and into the aphid's digestive tract. So great is the pressure that sugary liquid is forced through the insect's body and out its anus:

If an aphid is frozen in the act of feeding, its body can be chopped off the plant stem, leaving the stylet intact. Phloem sap continues to flow out of the stylet for hours.

Several observations came from analyzing phloem sap in this way, as well as from other experiments:

- Ninety percent of the phloem solutes consist of sucrose, with the rest hormones, other small molecules such as mineral nutrients and amino acids, and viruses.
- The flow rate can be very high, as much as 100 centimeters per hour.
- Different sieve tube elements conduct their contents in different directions (up or down the stem, for example). Movement in the phloem as a whole is bidirectional, but it is unidirectional within an individual sieve tube.
- Movement of sap in the phloem requires living cells, in contrast to movement in the xylem.

The pressure flow model describes the movement of fluid in the phloem

The observations described above led to the **pressure flow model** as an explanation for translocation in the phloem (FIGURE 25.14). According to this model, sucrose is actively transported at a source into companion cells, from which it flows through plasmodesmata into the sieve tube elements. This gives those cells a higher sucrose concentration than the surrounding cells (a more negative solute potential), and water therefore enters the sieve tube elements from the xylem by osmosis. The entry of this water causes turgor pressure (a more positive pressure potential) at the source end of the sieve tube, so that the entire fluid content of the sieve tube is pushed toward the sink end of the tube—in other words, the sap moves in response to a pressure gradient. In the sink, the sucrose is unloaded both passively and by active transport, and water moves back into the xylem. In this way, the gradient of solute potential and pressure potential needed for the movement of phloem sap (translocation) is maintained.

Two steps in phloem translocation require metabolic energy:

- Transport of sucrose and other solutes from sources into companion cells and then into the sieve tubes; called *loading*
- Transport of solutes from the sieve tubes into sinks; called *unloading*

The need for metabolic energy is the reason why phloem transport, unlike xylem transport, requires living cells.

Two general routes can be taken by sucrose and other solutes as they move from the mesophyll cells

FIGURE 25.14 The Pressure Flow Model Differences in water potential produce a pressure gradient that moves phloem sap from sources to sinks.

into the phloem. In many plants, sucrose and other solutes follow an *apoplastic pathway*: they leave the mesophyll cells and enter the apoplast before they reach the sieve tube elements. Specific sugars and amino acids are then actively transported into cells of the phloem. Because the solutes cross at least one selectively permeable membrane in the apoplastic pathway, selective transport can be used to regulate which specific substances enter the phloem. In other plants, solutes follow a *symplastic pathway*: the solutes remain within the symplast all the way from the mesophyll cells to the sieve tube elements. Because no membranes are crossed in the symplastic pathway, a mechanism that does not involve membrane transport is used to load sucrose into the phloem.

In sink regions, the solutes are actively transported *out* of the sieve tube elements and into the surrounding tissues. This unloading serves two purposes: it helps maintain the gradient of solute potential, and hence of pressure potential, in the sieve tubes; and it helps build up high concentrations of carbohydrates in storage organs, such as developing fruits and seeds.

Do You Understand Concept 25.4?

- Deer sometimes graze on trees by eating bark during the winter when other food is scarce. By spring, those trees may be dead. How does this happen?
- What would happen if the ends of sieve tubes were blocked and did not allow phloem sap to flow through them?
- Make a table that compares the flow of fluids in xylem and in phloem with respect to the driving force for movement; where flow occurs and whether the tubes are alive; and whether the driving pressure is positive or negative.

Go to ANIMATED TUTORIAL 25.3
The Pressure Flow Model

How can soil be managed for optimal plant growth?

ANSWER Every year, 25 billion tons of topsoil (A horizon) are lost worldwide from potentially arable land. This loss reduces the nutrient content (Concept 25.1) and water-holding capacity (Concept 25.3) of the remaining soil. It therefore creates added demand for fertilizers and irrigation to restore the soils, but these inputs are too expensive in most areas of the world, and they can have adverse effects on the rest of the environment. For example, adding fertilizer to soils can pollute nearby waters, and huge irrigation projects destroy natural habitats and can lead to flooding.

Faced with these challenges, scientists and farmers (often the same people!) have invented methods of *sustainable farming*. In the United States, for example, a branch of the federal government called the Natural Resource Conservation Service (formerly the Soil Conservation Service) was established in response to the country's experiences with soil degradation during the Dust Bowl of the 1930s.

There are several strategies to sustain the structure, nutrient content, and water-holding capacity of soil. One of these strategies is *crop rotation*. Different plants have different nutritional requirements and so remove different nutrients from the soil as they grow and are harvested. For example, corn requires large amounts of nitrogen, whereas soybeans harbor nitrogen-fixing bacteroids in their roots (Concept 25.2). In the midwestern United States, corn and soybeans are planted in alternate growing seasons.

Another strategy is *conservation tillage*. This refers to methods such as plowing that are used to prepare soil for planting. Conservation tillage can help maintain soil and reduce soil losses. If you fly over any heavily farmed area of the

Seedlings of current crop

Residue from previous crop

FIGURE 25.15 Conservation Tillage These rye plants are growing amidst the residue of corn plants that were harvested for their grain. The crop residues help conserve the soil.

United States, look out the window and you will see contour plowing patterns; these patterns are used to control runoff of the topsoil during heavy rains. More recently, it has become increasingly common for farmers to leave behind on the field up to half of the stems and leaves of plants that are harvested for grain (FIGURE 25.15). The farmers plow these crop residues back into the soil, where they help maintain soil structure, bind water, and provide nutrients because they are organic matter that builds up humus. Over one-third of the farmland in the United States is now being farmed in this way.

Our increasing understanding of plants and their relationship to soils will doubtless lead to more sustainable practices in the future.

SUMMARY

concept 25.1

Plants Acquire Mineral Nutrients from the Soil

- Plants are photosynthetic autotrophs that require water and certain mineral nutrients to survive. They obtain most of these mineral nutrients as ions from the **soil solution**.
- The **essential elements** for plants include six **macronutrients** and several **micronutrients**. Plants that lack a particular nutrient show characteristic deficiency symptoms. **Review Figure 25.1 and ANIMATED TUTORIAL 25.1**
- The essential elements were discovered by growing plants **hydroponically** in solutions that lacked individual elements. **Review Figure 25.2 and WORKING WITH DATA 25.1**
- Soils supply plants with mechanical support, water and dissolved ions, air, and the services of other organisms. **Review Figure 25.3**

- Protons take the place of mineral nutrient cations bound to clay particles in soil in a process called **ion exchange**. **Review Figure 25.4**

- Farmers may use shifting agriculture or **fertilizer** to make up for nutrient deficiencies in soil.

concept 25.2

Soil Organisms Contribute to Plant Nutrition

- Signaling molecules called **strigolactones** induce the hyphae of arbuscular mycorrhizal fungi to invade root cortical cells and form arbuscules, which serve as sites of nutrient exchange between fungus and plant. **Review Figure 25.5A**
- Legumes signal nitrogen-fixing bacteria (rhizobia) to form **bacteroids** within nodules that form on their roots. **Review Figure 25.5B**

- In nitrogen fixation, nitrogen gas (N_2) is reduced to ammonia in a reaction catalyzed by **nitrogenase**. **Review Figure 25.6**
- Carnivorous plants supplement their nutrient supplies by trapping and digesting arthropods. Parasitic plants obtain minerals, water, or products of photosynthesis from other plants.

concept 25.3 **Water and Solutes Are Transported in the Xylem by Transpiration–Cohesion–Tension**

- Water moves through biological membranes by osmosis, always moving toward regions with a more negative water potential. The **water potential** (Ψ) of a cell or solution is the sum of its **solute potential** (Ψ_s) and its **pressure potential** (Ψ_p). **Review Figure 25.8 and INTERACTIVE TUTORIAL 25.1**
- The physical structure of many plants is maintained by the positive pressure potential of their cells (turgor pressure); if the pressure potential drops, the plant wilts.
- Water moves into root cells by osmosis through aquaporins. Mineral ions move into root cells through ion channels, by facilitated diffusion, and by secondary active transport. **Review Figure 25.10**
- Water and ions may pass from the soil into the root by way of the **apoplast** or the **symplast**, but they must pass through

the symplast to cross the endodermis and enter the xylem. The **Casparian strip** in the endodermis blocks the movement of water and ions through the apoplast. **Review Figure 25.11 and WEB ACTIVITY 25.1**

- Water is transported in the xylem by the **transpiration–cohesion–tension** mechanism. Evaporation from the leaf produces tension in the mesophyll, which pulls a column of water—held together by cohesion—up through the xylem from the root. **Review Figure 25.12 and ANIMATED TUTORIAL 25.2**
- **Stomata** allow a balance between water retention and CO_2 uptake. Their opening and closing is regulated by **guard cells**. **Review Figure 25.13**

concept 25.3 **Solutes Are Transported in the Phloem by Pressure Flow**

- **Translocation** is the movement of the products of photosynthesis, as well as some other small molecules, through sieve tubes in the phloem. The solutes move from **sources** to **sinks**.
- Translocation is explained by the **pressure flow model**: the difference in solute potential between sources and sinks creates a difference in pressure potential that pushes phloem sap along the sieve tubes. **Review Figure 25.14 and ANIMATED TUTORIAL 25.3**

Plant Growth and Development

26

In their constant search for ways to help farmers produce more food for a growing population, biologists have developed cereal crops whose physiology allows them to produce more grain per plant (a higher yield). When a plant produces a lot of seeds, however, the sheer weight of the seeds may cause the stem to bend over or even break. This makes harvesting the seeds impossible: think of how hard it would be to get enough food for your family if you had to pick up seeds on the ground, some of which had already sprouted.

In 1945, the U.S. Army temporarily occupied Japan, which it had defeated in World War II. During the war, Japan, an island nation with a limited amount of land suitable for farming, was blockaded and could not import food. How had Japan been able to grow enough grain to feed its people? The answer lay in the fields: the Japanese had bred genetic strains of rice and wheat with short, strong stems that could bear a high yield of grain without bending or breaking. This innovation made an impression on an agricultural advisor who happened to be among the first wave of U.S. occupiers, and seeds of the Japanese strains were sent back to the United States.

A decade later, Norman Borlaug, a plant geneticist who was working in Mexico at the time, began genetic crosses of what were known as semi-dwarf wheat plants from Japan with wheat varieties that had genes conferring rapid growth, adaptability to varying climates, and resistance to fungal diseases. The results were new genetic strains of wheat that produced record yields, first in Mexico and then in India and Pakistan in the 1960s. At about the same time, and using a similar

strategy, scientists in the Philippines developed new semi-dwarf strains of rice with equally spectacular results. People who had lived on the edge of starvation now produced enough food. Countries that had been relying on food aid from other countries were now growing so much grain that they could export the surplus. The development of these new semi-dwarf strains began what was called the “Green Revolution.” Borlaug was awarded the Nobel Peace Prize for his research on wheat, which is estimated to have saved a billion lives.

Plant geneticist Norman Borlaug, seen here in a field of semi-dwarf wheat, carried out a program of genetic crosses that led to high-yielding varieties of wheat and saved millions of people from starvation.

What changes in their growth patterns made the new strains of cereal crops produced by the Green Revolution so successful?

KEY CONCEPTS

- 26.4** Photoreceptors Initiate Developmental Responses to Light

concept 26.1 Plants Develop in Response to the Environment

Plants are sessile organisms that must seek out resources above and below the ground. To maximize their access to the resources they need to grow and reproduce, plants have constantly dividing meristems that form new organs throughout their lives. Thus they can respond to an ever-changing environment by selective growth of organs (see Chapter 24).

The *development* of a plant—the series of progressive changes that take place throughout its life—is regulated in many ways. Several key factors are involved in regulating plant growth and development:

- *Environmental cues*, such as day length
- *Receptors* that allow a plant to sense environmental cues, such as photoreceptors that absorb light
- *Hormones*—chemical signals that mediate the effects of environmental cues, including those sensed by receptors
- The plant's *genome*, which encodes regulatory proteins and enzymes that catalyze the biochemical reactions of development

We will explore these factors in more detail later in this chapter. But first let's look at the initial steps of plant development—from seed to seedling—and the environmental cues and internal responses that guide them.

The seed germinates and forms a growing seedling

Concepts 24.1 and 27.1 describe the events of plant reproduction and development that lead to the formation of seeds. Here we begin with the seed, the structure that contains the early embryo. Unlike most animal embryos, plant seeds may be held in “suspended animation,” with development of the embryo halted, for long periods. If development stops, even when external conditions (such as water supply) are adequate for growth, the seed is said to be **dormant**.

DORMANCY Seed dormancy may last for weeks, months, years, or even centuries: in 2005, a botanist was able to germinate a date palm seed recovered from a 2,000-year-old storage bin at Masada in Israel. Plants use several mechanisms to maintain dormancy:

- *Exclusion of water or oxygen* from the embryo by an impermeable seed coat
- *Mechanical restraint* of the embryo by a tough seed coat
- *Chemical inhibition* of germination

Dormancy can be broken by factors that overcome these mechanisms. For example, the seed coat may be damaged by passage through an animal's digestive system, or heavy rains may wash away chemical inhibitors.

Seed dormancy is a common phenomenon, so it must have selective advantages for plants. Dormancy ensures survival during unfavorable conditions and results in germination

when conditions are most favorable for growth. For example, to avoid germination in the dry days of late summer, some seeds require exposure to a long cold period (winter) before they will germinate. Dormancy also helps seeds survive long-distance dispersal, allowing plants to colonize new territory.

GERMINATION Seeds begin to **germinate**, or sprout, when dormancy is broken and environmental conditions are satisfactory. For example, a seed may have a germination inhibitor that gets washed away in heavy rain, which means the soils will have plenty of water and germination will be possible. The first step in germination is the uptake of water, called **imbibition** (from *imbibe*, “to drink in”). A dormant seed contains very little water: only 5–15 percent of its weight is water, compared with 80–95 percent for most other plant parts. Seeds also contain polar macromolecules, such as cellulose and starch, that attract and bind polar water molecules. Consequently, a seed has a very negative water potential (see Concept 25.3) and will take up water if the seed coat is permeable. The force exerted by imbibing seeds, which expand severalfold in volume, demonstrates the magnitude of their water potential. Imbibing cocklebur seeds can exert a pressure of up to 1,000 atmospheres (approximately 100 kilopascals, or 15,000 pounds per square inch).

As a seed takes up water, it undergoes metabolic changes: enzymes are activated upon hydration, RNA and then proteins are synthesized, the rate of cellular respiration increases, and other metabolic pathways are activated. In many seeds, cell division is not initiated during the early stages of germination. Instead, growth results solely from the expansion of small pre-formed cells.

As the seed begins to germinate, the growing embryo obtains chemical building blocks for its development—carbohydrates, amino acids, and lipid monomers—by hydrolyzing starch, proteins, and lipids stored in the seed. These reserves are stored in the *cotyledons* or in the *endosperm*. Germination is completed when the **radicle** (embryonic root) emerges from the seed coat. The plant is then called a **seedling**.

If the seed germinates underground, the new seedling must elongate rapidly (in the right direction!) and cope with a period of life in darkness or dim light. A series of photoreceptors direct this stage of development and prepare the seedling for growth in the light.

The pattern of early shoot development varies among the flowering plants. **FIGURE 26.1** shows the shoot development patterns of monocots and eudicots. In monocots, the growing shoot is protected by a cylindrical sheath of cells called the **coleoptile** as it pushes its way through the soil. In eudicots, the shoot is protected by the cotyledons.

Several hormones and photoreceptors help regulate plant growth

This survey of the early stages of plant development illustrates the many environmental cues that influence plant growth. A plant's responses to these cues are initiated and maintained by two types of regulators: *hormones* and *photoreceptors*. Both types of regulators act through signal transduction pathways

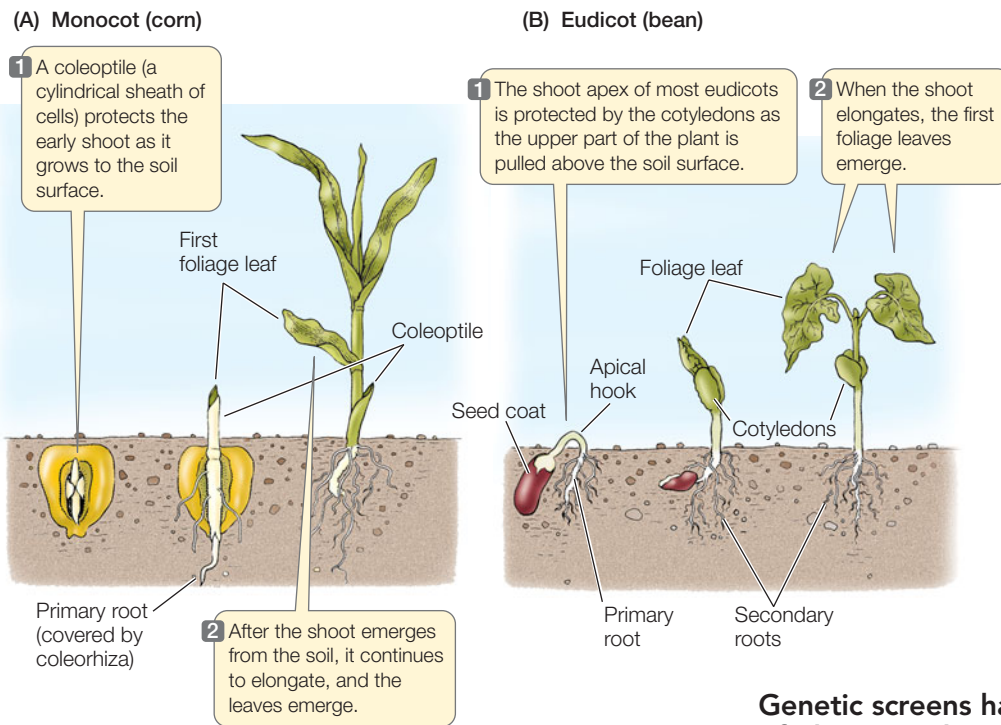

FIGURE 26.1 Patterns of Early Shoot Development (A) In grasses and some other monocots, growing shoots are protected by a coleoptile until they reach the soil surface. (B) In most eudicots, the growing point of the shoot is protected within the cotyledons.

Eudicot Shoot Development

(series of biochemical steps within a cell that occur between a stimulus and a response).

LINK The general characteristics of signal transduction pathways are discussed in Concepts 5.5 and 5.6

Hormones are chemical signals that act at very low concentrations at sites often distant from where they are produced. Plant hormones are very different from animal hormones (TABLE 26.1; see also Chapter 30). Each plant hormone plays multiple regulatory roles, and interactions among them can be complex. Several hormones regulate the growth and development of plants from seedling to adult (TABLE 26.2). Other hormones are involved in the plant's defenses against herbivores and microorganisms (which we discuss in Chapter 28).

Photoreceptors are pigments associated with proteins. Light acts directly on photoreceptors, which in turn regulate developmental processes that need to be responsive to light, such as the many changes that occur as a seed germinates and a seedling emerges from the soil.

Genetic screens have increased our understanding of plant signal transduction

In Chapter 14 we describe how genetic studies can be used to identify the steps along a developmental pathway. You will recall the reasoning behind these experiments: if a mutation of a gene involved in a certain biochemical process disrupts a developmental event, then that biochemical process must be essential for that developmental event. Similarly, genetic studies can be used to analyze pathways of receptor activation and signal transduction in plants: if proper signaling does not occur in a mutant strain, then the mutant gene must be involved in the signal transduction process. Mapping the mutant gene and identifying its function are starting points for understanding the signaling pathway. *Arabidopsis thaliana*, a member of the mustard family, has been a major model organism for plant biologists investigating signal transduction.

One technique for identifying the genes involved in a plant signal transduction pathway is illustrated in FIGURE 26.2. This technique, called a **genetic screen**, involves creating a large collection of randomly mutated plants and identifying those individuals that are likely to have a defect in the pathway of interest. Plant genes can be randomly mutated in two ways: by insertion of transposons (see Concept 12.3) and by treatment of seeds with

chemical mutagens, most commonly ethyl methane sulfonate. In both cases, the treated plants are grown and then examined for a specific phenotype, usually a characteristic that is known to be influenced by the pathway of interest. Once mutant plants have been selected, their genotypes are compared with those of wild-type plants. *Arabidopsis* mutants with altered developmental patterns have provided a wealth of new information about the hormones present in plants and the mechanisms of hormone and photoreceptor action.

TABLE 26.1 Comparison of Plant and Animal Hormones

CHARACTERISTIC	PLANT HORMONES	ANIMAL HORMONES
Size, chemistry	Small organic molecules	Peptides, proteins, small molecules
Site of synthesis	Throughout the plant	Specialized glands or cells
Site of action	Local or distant	Distant, transported
Effects	Diverse	Often specific
Regulation	Decentralized	By central nervous system

RESEARCH TOOLS

FIGURE 26.2 A Genetic Screen Genetics of the model plant *Arabidopsis thaliana* can be used to identify the steps of a signal transduction pathway. If a mutant strain does not respond to a hormone (in this case, ethylene), the corresponding wild-type gene must be essential for the pathway (in this case, ethylene response). This method has been instrumental to scientists in understanding plant growth regulation.

1 A phenotype of interest is chosen, in this case response to ethylene. Elongation of wild-type seedlings in the dark is inhibited by ethylene (right).

2 Seeds are treated with a mutagen and then planted.

3 The treated plants are grown in the dark in the presence of ethylene and then screened. One mutant individual shows insensitivity to the hormone (uninhibited growth).

4 The gene involved in ethylene signaling is mapped, cloned, and studied.

With this overview of plant development, we will begin our examination of the specific mechanisms that underlie these events. Two hormones—gibberellins and auxin—have prominent roles in plant development.

concept
26.2

Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action

The discovery of two key plant hormones exemplifies the experimental approaches that plant biologists have used to investigate the mechanisms of plant development. **Gibberellins** (of which there are several active forms) and **auxin** were the first plant hormones to be identified, early in the twentieth century. In both cases, the discoveries came from observations of natural phenomena:

- **Gibberellins:** In rice plants, a disease caused by the fungus *Gibberella fujikuroi* resulted in plants that grew overly tall and spindly.
- **Auxin:** Charles Darwin and his son Francis noted that canary grass seedlings would bend toward the light when placed near a light source.

In both cases, a chemical substance was isolated that could cause the phenomenon:

- Gibberellic acid (see Table 26.2) made by the fungus caused rice plants to overgrow. Later, it was found that plants also make gibberellic acid, and that applying it to plants causes growth.
- Auxin made by the growing tip of the canary grass coleoptile diffused asymmetrically, causing cell elongation on the side away from the light, which resulted in the coleoptile bending toward the light.

In each case, mutant plants that do not make the hormone exhibit a phenotype expected in the absence of the hormone, and adding the hormone reverses that phenotype (**FIGURE 26.3**):

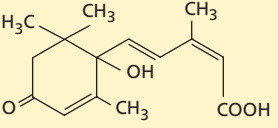

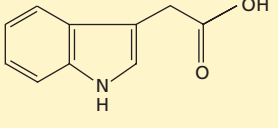

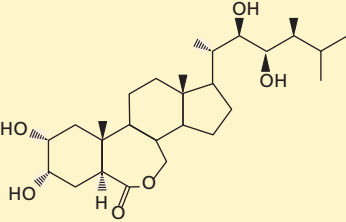

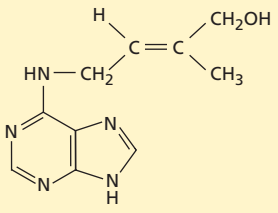

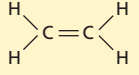

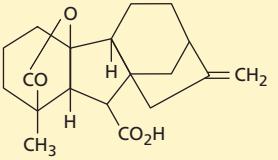

- Tomato plants that do not make gibberellic acid are very short; supplying them with the hormone results in normal growth.
- *Arabidopsis thaliana* individuals that do not make auxin are also short; supplying them with that hormone reverses that phenotype.

Note that the phenotype involved—short stature, or *dwarfism*—is similar in both cases. This observation exemplifies a concept that is important to keep in mind when studying plant hormones: their actions are not unique and specific, as is the case with animal hormones (see Table 26.1).

The three-part approach outlined above for gibberellins and auxin—observation, hormone isolation, and analysis of mutants—has been used to identify other plant hormones.

Do You Understand Concept 26.1?

- Describe how monocots and eudicots differ in their early development.
- Seeds of the Australian shrub *Acacia myrtifolia* require extreme heat (fire) to germinate. How do you think fire might work as an environmental cue to break dormancy? What would be the selective advantage of this mechanism for breaking dormancy?
- Seedlings grown in the dark grow thin and tall, a phenomenon called *etiolation*. How would you set up a genetic screen using *Arabidopsis* to investigate the signaling pathway that controls etiolation?

TABLE 26.2 Plant Growth Hormones		
HORMONE	STRUCTURE	TYPICAL ACTIVITIES
Abscisic acid		Maintains seed dormancy; closes stomata
Auxin (indole-3-acetic acid)		Promotes stem elongation, lateral root initiation, and fruit development; inhibits axillary bud outgrowth, leaf abscission, and root elongation
Brassinosteroids		Promote stem and pollen tube elongation; promote vascular tissue differentiation
Cytokinins		Inhibit leaf senescence; promote cell division and axillary bud outgrowth; affect root growth
Ethylene		Promotes fruit ripening and leaf abscission; inhibits stem elongation
Gibberellins		Promote seed germination, stem growth, and fruit development; break winter dormancy; mobilize nutrient reserves in grass seeds

Gibberellins have many effects on plant growth and development

The functions of gibberellins can be inferred from the effects of experimentally decreasing concentrations of gibberellins or blocking their action at various times in plant development. Such experiments reveal that gibberellins have multiple roles in regulating plant growth.

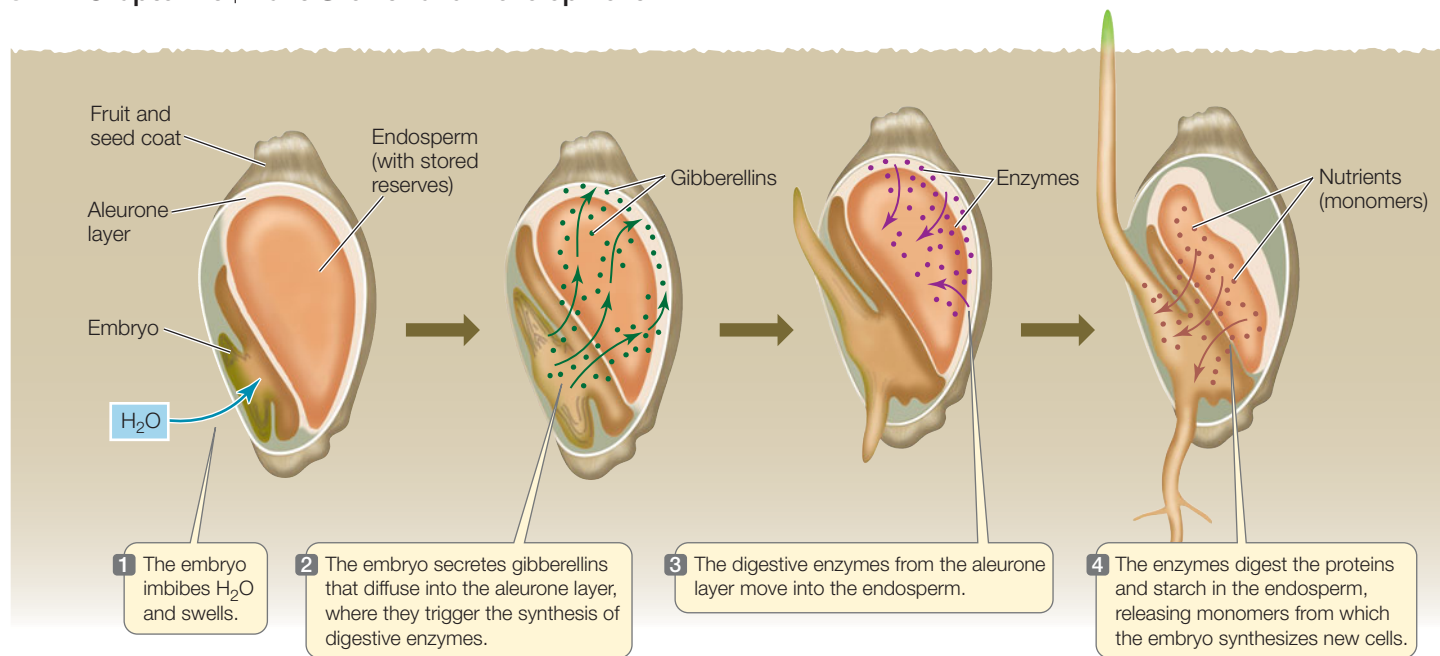

STEM ELONGATION The effects of gibberellins on wild-type plants are not as dramatic as their effects on dwarf plants. We know, however, that gibberellins are indeed active in wild-type plants because inhibitors of gibberellin synthesis cause a reduction in stem elongation. Such inhibitors can be put to practical uses. For example, plants such as chrysanthemums that are grown in greenhouses tend to get tall and spindly, but such plants do not appeal to consumers. Flower growers spray such plants with gibberellin synthesis inhibitors to control their height.

FRUIT GROWTH Gibberellins can regulate the growth of fruit. Grapevines that produce seedless grapes develop smaller fruit than varieties that produce seed-bearing grapes. Biologists wanting to explain this

FIGURE 26.3 Hormones Reverse a Mutant Phenotype

(A) The two mutant dwarf tomato plants in this photograph were the same size when the one on the right was treated with gibberellins. (B) The short phenotype of this *Arabidopsis* mutant was reversed in the plant on the right by supplying auxin.

phenomenon removed seeds from immature seeded grapes and found that this prevented normal fruit growth. This suggested that the seeds are sources of a growth regulator. Biochemical studies showed that developing seeds produce gibberellins, which diffuse out into the immature fruit tissue. Spraying young seedless grapes with a gibberellin solution, which causes them to grow as large as seeded ones, is now a standard commercial practice.

MOBILIZATION OF SEED RESERVES As noted in Concept 26.1, an important event early in seed germination is the hydrolysis of stored starch, proteins, and lipids. In germinating seeds of barley and other cereal crops, the embryo secretes gibberellins just after imbibition. The hormones diffuse through the endosperm to a surrounding tissue called the **aleurone layer**, which lies underneath the seed coat. The gibberellins trigger a cascade of events in the aleurone layer, causing it to synthesize and secrete enzymes that digest proteins and starch stored in the endosperm (**FIGURE 26.4**). These observations have practical importance: in the beer-brewing industry, gibberellins are used to enhance the “malting” (germination) of barley and the

FIGURE 26.4 Gibberellins and Seed Germination During seed germination in cereal crops, gibberellins trigger a cascade of events that result in the conversion of starch and protein stores in the endosperm into monomers that can be used by the developing embryo.

Events of Seed Germination

breakdown of its endosperm, producing glucose that is fermented into alcohol.

The transport of auxin mediates some of its effects

As we noted above, auxin was discovered in the context of **phototropism**: a response to light in which plant stems bend toward a light source. Auxin is made in the shoot apex and diffuses down the shoot in a *polar* (unidirectional) fashion, stimulating cell elongation. Unidirectional longitudinal movement of auxin occurs in other plant organs as well. For example, in a leaf petiole, which connects the leaf blade to the stem, auxin moves from the leaf blade end toward the stem. In roots, auxin moves unidirectionally toward the root tip.

Polar transport of auxin depends on four biochemical processes that may be familiar from earlier chapters (**FIGURE 26.5**):

- **Diffusion across a plasma membrane.** Polar molecules diffuse across plasma membranes less readily than nonpolar molecules (see Concept 5.2).
- **Membrane protein asymmetry.** Active transport, or efflux, carriers (see Concept 5.3) for auxin are located only in the portion of the plasma membrane at the basal (bottom) end of the cell.
- **Proton pumping/chemiosmosis.** Proton pumps (see Concept 25.3) remove H⁺ from the cell, thereby increasing the intracellular pH and decreasing the pH in the cell wall. Proton

FIGURE 26.5 Polar Transport of Auxin Proton pumps set up a chemiosmotic gradient that drives the uptake of non-ionized auxin (HA) and the efflux of ionized auxin (A^-) through the basally placed auxin anion efflux carriers, leading to a net movement of auxin in a basal direction.

pumping also sets up an electrochemical gradient, which provides potential energy to drive the transport of auxin by the carriers mentioned above.

- **Ionization of a weak acid.** Indole-3-acetic acid (the chemical name for auxin; see Table 26.2) is a weak acid; it forms ions (H^+ and A^- , where A^- stands for indole acetate) in solution that also tend to recombine to form the acid (HA):

When the pH is low, the increased H^+ concentration drives this reaction to the right, and HA (non-ionized auxin) is the predominant form. When the pH is higher, there is more A^- (ionized auxin).

Whereas polar auxin transport distributes the hormone along the longitudinal axis of the plant, *lateral* (side-to-side) redistribution of auxin is responsible for directional plant growth. This redistribution is carried out by auxin efflux carriers that move from the base of the cell to one side; because of this, auxin exits the cell only on that side of the cell, rather than at the base, and moves sideways within the tissue.

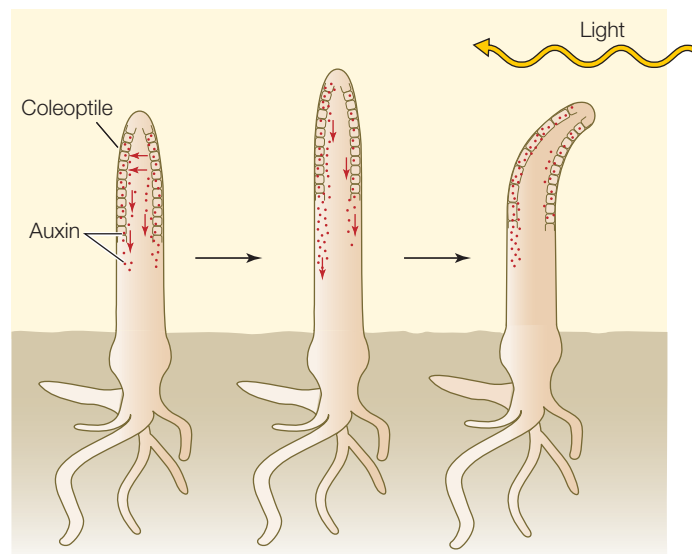

This lateral movement of auxin explains the bending of canary grass seedlings toward light. When light strikes a canary grass coleoptile on one side, auxin at the tip moves laterally toward the shaded side. The asymmetry thus established is maintained as polar transport moves auxin down the coleoptile, so that in the growing region below, the auxin concentration is

(A) Phototropism

1 Auxin moves to the shaded side within the tip.

2 The redistributed auxin moves down the coleoptile.

3 A higher auxin concentration causes more rapid growth by cell elongation on the shaded side. The tip curves toward the light.

(B) Negative gravitropism of shoot

FIGURE 26.6 Plants Respond to Light and Gravity Phototropism (A) and gravitropism (B) occur in shoot apices in response to a redistribution of auxin.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 26.1**
Tropisms

highest on the shaded side. Cell elongation is thus speeded up on that side, causing the coleoptile to bend toward the light (**FIGURE 26.6A**). The same type of bending also occurs in eudicots:

Light is not the only signal that can cause redistribution of auxin. Auxin moves to the lower side of a shoot that has been tipped sideways, causing more rapid growth in the lower side and hence an upward bending of the shoot. Such growth in a direction determined by gravity is called **gravitropism** (FIGURE 26.6B). The upward gravitropic response of shoots is defined as *negative gravitropism*; that of roots, which bend downward, is *positive gravitropism*.

Auxin plays many roles in plant growth and development

Like the gibberellins, auxin has multiple roles in plant growth and development.

ROOT INITIATION Cuttings from the shoots of some plants can produce roots and develop into entire new plants. For this to occur, cells in the interior of the shoot, originally destined to function only in food storage, must change their fate and become organized into the apical meristem of a new root (this is an example of the remarkable totipotency of plant cells; see Concept 14.1). Shoot cuttings of many species can be made to develop roots by dipping the cut surfaces into an auxin solution. These observations suggest that in an intact plant, the plant's own auxin plays a role in the initiation of lateral roots.

LEAF ABSCISSION In contrast to its stimulatory effect on root initiation, auxin inhibits the detachment of old leaves from stems. This detachment process, called **abscission**, is the cause of autumn leaf fall. Recall that the blade of a leaf produces auxin that moves toward the petiole. If the blade is cut off, the petiole falls from the plant more rapidly than if the leaf had remained intact. If the cut surface is treated with an auxin solution, however, the petiole remains attached to the plant, often longer than an intact leaf would have. The timing of leaf abscission in nature appears to be determined in part by a decrease in the movement of auxin through the petiole.

APICAL DOMINANCE Auxin helps maintain **apical dominance**, a phenomenon in which apical buds inhibit the growth of axillary buds (see Figure 24.1), resulting in the growth of a single

main stem with minimal branching. A diffusion gradient of auxin from the apex of the shoot down the stem results in lower branches receiving less auxin and therefore branching more, while higher branches receive more auxin and branch less. The effect of the auxin gradient is apparent in conifers: next time you see a decorated tree during the winter holidays, think of auxin and apical dominance.

FRUIT DEVELOPMENT Fruit development normally depends on prior fertilization of the ovule (egg), but in many species, treatment of an unfertilized ovary with auxin or gibberellins causes **parthenocarp**y: fruit formation without fertilization. Parthenocarpic fruits form spontaneously in some cultivated varieties of plants, including seedless grapes, bananas, and some cucumbers.

CELL ELONGATION The elongation of plant cells is a key process in plant growth. Because the plant cell wall normally prevents expansion of the cell, it plays a key role in controlling the rate and direction of plant cell growth. Auxin acts on the cell wall to regulate this process.

The expansion of a plant cell is driven primarily by the uptake of water, which enters the cell by osmosis. As it expands, the cell contents press against the cell wall, which resists this force (producing turgor pressure). The cell wall is an extensively cross-linked network of polysaccharides and proteins, dominated by cellulose fibrils. If the cell is to expand, some adjustments must be made in the wall structure to allow the wall to “give” under turgor pressure. Think of a balloon (the cell surrounded by a membrane) inside a box (the cell wall).

LINK Water movement and turgor pressure in plant cells are discussed in Concept 25.3

APPLY THE CONCEPT

Gibberellins and auxin have diverse effects but a similar mechanism of action

Oat seedlings with coleoptiles 20 mm long were exposed to light from one side and checked for bending after 6 hours. Various regions of the seedlings were covered with foil to block the light. The results varied depending on which region of the coleoptile was covered (see table).

1. Which part of the coleoptile senses the light?
2. For each treatment, what would happen if supplementary auxin were applied to the coleoptiles on the same side as the light? On the side away from the light?

REGION COVERED	BENDING
None	Yes
All	No
Apical 5 mm	No
Apical 10 mm	No
Apical 5–10 mm	Yes
Apical 10–15 mm	Yes

The **acid growth hypothesis** explains auxin-induced cell expansion (FIGURE 26.7). This hypothesis proposes that protons (H^+) are pumped from the cytoplasm into the cell wall, lowering the pH of the wall and activating enzymes called *expansins*, which catalyze changes in the cell wall structure such that the polysaccharides adhere to each other less strongly. This change loosens the cell wall, allowing it to stretch as the cell expands. Auxin is believed to have two roles in this process: to increase the synthesis of proton pumps, and to guide their insertion into the plasma membrane. Several lines of evidence support the acid growth hypothesis. For example, adding acid to the cell wall to lower the pH stimulates cell expansion even in the absence of auxin. Conversely, when a buffer is used to prevent the wall from becoming more acidic, auxin-induced cell expansion is blocked.

At the molecular level, auxin and gibberellins act similarly

The molecular mechanisms underlying both auxin and gibberellin action have been worked out with the help of genetic screens (see Figure 26.2). Biologists started by identifying mutant plants whose growth and development are *insensitive* to the hormones; that is, plants that are *not* affected by added hormone. Such mutants fall into two general categories:

- *Excessively tall plants.* These plants resemble wild-type plants given an excess of hormone, and they grow no taller when given extra hormone. They grow tall even when treated with inhibitors of hormone synthesis. Their hormone response is always “on,” even in the absence of the hormone. It is presumed that the normal allele for the mutant gene codes for an *inhibitor* of the hormone signal transduction pathway. In wild-type plants, that pathway is “off,” but in the mutant plants the pathway is “on,” and the plant grows tall.
- *Dwarf plants.* These plants resemble dwarf plants that are deficient in hormone synthesis (see Figure 26.3), but they *do not respond* to added hormone. In these mutants the hormone response is always “off,” regardless of the presence of the hormone.

Remarkably, some mutations of both types *affect the same protein*, which turns out to be a *repressor* of a transcription factor that stimulates the expression of growth-promoting genes. The repressor protein has two important domains, which explains how mutations in the same protein can have seemingly opposite effects:

- *One region of the repressor protein binds to the transcription complex to inhibit transcription.* This is the mutant region in the excessively tall plants: the growth-promoting genes are always “on” because the repressor does not bind to the transcription complex.
- *Another region of the repressor protein causes it to be removed from the transcription complex.* This is the mutant region in the dwarf plants: the growth-promoting genes are always “off” because the repressor is always bound to the complex.

LINK Review the process of transcription initiation in Concept 11.3

These observations allowed biologists to figure out how auxin and gibberellins work in wild-type plants. Of course, the actual proteins involved with the two hormones are different, but the actions of both

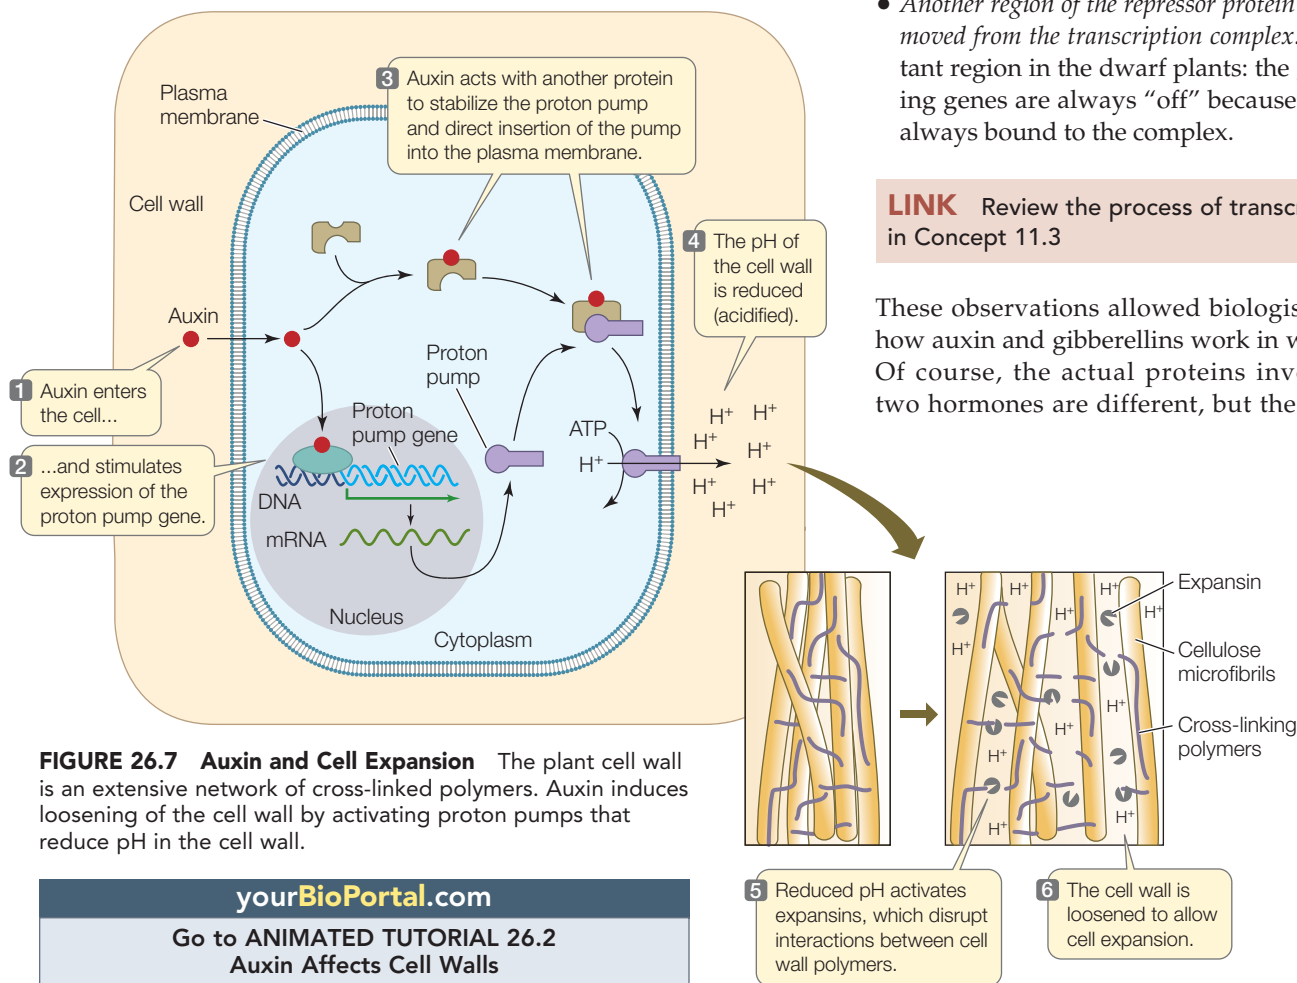

FIGURE 26.7 Auxin and Cell Expansion The plant cell wall is an extensive network of cross-linked polymers. Auxin induces loosening of the cell wall by activating proton pumps that reduce pH in the cell wall.

Auxin Affects Cell Walls

APPLY THE CONCEPT

Gibberellins and auxin have diverse effects but a similar mechanism of action

The aleurone layer of germinating barley can be isolated and studied for the induction of α -amylase, the enzyme that catalyzes starch hydrolysis. Predict the amount of α -amylase activity in aleurone layers subjected to the following treatments:

1. Incubation with gibberellic acid
2. Incubation with auxin
3. Incubation with gibberellic acid in the presence of an inhibitor of DNA transcription to mRNA
4. Incubation without gibberellic acid
5. Incubation without gibberellic acid in the presence of an inhibitor of transcription
6. Incubation with gibberellic acid in the presence of an inhibitor of the proteasome
7. Incubation without gibberellic acid in the presence of an inhibitor of the proteasome

FIGURE 26.8 Gibberellins and Auxin Have Similar Signal Transduction Pathways Both hormones act to stimulate gene transcription by inactivating a repressor protein.

hormones are similar: they *act by removing the repressor from the transcription complex* (FIGURE 26.8). The hormones do this by binding to a receptor protein, which in turn binds to the repressor. Binding of the hormone-receptor complex stimulates polyubiquitination of the repressor, targeting it for breakdown in the proteasome (see Figure 11.19). The receptors for both auxin and gibberellins contain a region called an **F-box** that facilitates protein-protein interactions necessary for protein breakdown. While animal genomes have few F-box-containing proteins, plant genomes have hundreds, an indication that this type of gene regulation is common in plants.

Do You Understand Concept 26.2?

- Make a table for two activities each for auxin and gibberellin with three column headings: site of synthesis, site of action, and effect.
- Explain why, even though auxin moves away from the lighted side of a coleoptile tip, the coleoptile bends toward the light.
- What would be the phenotype, in terms of seed germination, of a plant that has a mutation that disables the F-box region of the receptor for gibberellin?

The same approaches that led to the discovery of auxin and gibberellins have revealed several other classes of plant hormones. These hormones are diverse in their actions and affect many of the same developmental processes as auxin and gibberellins.

concept 26.3 Other Plant Hormones Have Diverse Effects on Plant Development

The discoveries of gibberellins and auxin have led to the isolation of additional classes of plant hormones (see Table 26.2). These hormones are diverse in their actions, and they interact with one another in many cases.

Ethylene is a gaseous hormone that promotes senescence

Whereas the cytokinins delay senescence, another plant hormone promotes it: the gas **ethylene** (see Table 26.2), which is sometimes called the senescence hormone. When streets were lit by gas rather than by electricity, leaves on trees near street lamps dropped earlier in the fall than those on trees farther from the lamps. We now know why: ethylene, a combustion product of the illuminating gas, caused the early abscission. While auxin inhibits leaf abscission, ethylene strongly promotes it; thus the balance of auxin and ethylene controls abscission.

FRUIT RIPENING By promoting senescence, ethylene speeds the ripening of fruit. As a fruit ripens, it loses chlorophyll and its cell walls break down, making the fruit softer; ethylene promotes both of these processes. Ethylene also causes an increase in its own production. Thus once ripening begins, more and more ethylene forms, and because it is a gas, it diffuses readily throughout the fruit and even to neighboring fruits on the same or other plants. The old saying that “one rotten apple spoils the barrel” is true. That rotten apple is a rich source of ethylene, which speeds the ripening and subsequent rotting of the other fruit in a barrel or other confined space.

LINK The action of ethylene in fruit ripening is an example of positive feedback; see Concept 29.2

Farmers in ancient times poked holes in developing figs to make them ripen faster. Wounding causes an increase in ethylene production by the fruit, and that increase promotes ripening. Today commercial shippers and storers of fruit hasten ripening by adding ethylene to storage chambers. This use of ethylene is the single most important use of a natural plant hormone in agriculture and commerce. Conversely, ripening can be delayed by the use of “scrubbers” and adsorbents that remove ethylene from the atmosphere in fruit storage chambers.

These stored tomatoes were treated with ethylene to promote ripening.

As flowers senesce, their petals may abscise, which decreases their value in the cut-flower industry. Growers and florists often immerse the cut stems of ethylene-sensitive flowers in dilute solutions of silver thiosulfate before selling them. Silver salts inhibit ethylene action by interacting directly with the ethylene receptor—thus they delay senescence, keeping flowers “fresh” for a longer time.

STEM GROWTH The stems of many eudicot seedlings (which lack protective coleoptiles) form an **apical hook** that protects

the delicate shoot apex while the stem grows through the soil (see Figure 26.1B). The apical hook is maintained through an asymmetrical production of ethylene, which inhibits the elongation of cells on the inner surface of the hook. Once the seedling breaks through the soil surface and is exposed to light, ethylene synthesis stops, and the cells of the inner surface are no longer inhibited. Those cells now elongate, and the hook unfolds, raising the shoot apex and the expanding leaves into the sun. Ethylene also inhibits stem elongation in general, promotes lateral swelling of stems (as do the cytokinins), and decreases the sensitivity of stems to gravitropic stimulation. Together, these three phenomena constitute the *triple response*, a well-characterized stunted growth habit observed when plants are treated with ethylene.

FRONTIERS Ethylene is a gas, and its ready diffusion in plant tissues aids the hormone’s signal transduction. The receptor for ethylene is a protein on the endoplasmic reticulum. Because ethylene is hydrophobic, binding to the receptor occurs at the interior of the protein. How does a dissolved gas that diffuses rapidly (an unusual type of receptor ligand) bind to a receptor that initiates further events in the cell? Mutants for the ethylene signal transduction pathway may be useful in answering this question.

Cytokinins are active from seed to senescence

Like bacteria and yeasts, some plant cells, such as parenchyma cells, can be grown in a liquid or solidified medium containing sugars and salts. For continuous cell division, cultured plant cells also require a type of hormone called a **cytokinin**, first isolated from corn. Over 150 different cytokinins have been isolated, and most are derivatives of adenine.

Cytokinins have a number of different effects (see Table 26.2), in many cases by interacting with auxin:

- Adding an appropriate combination of auxin and cytokinins to a growth medium induces rapid proliferation of cultured plant cells.
- In cell cultures, a high cytokinin-to-auxin ratio promotes the formation of shoots; a low ratio promotes the formation of roots.
- Cytokinins can cause certain light-requiring seeds to germinate even when they are kept in constant darkness.
- Cytokinins usually inhibit the elongation of stems, but they cause lateral swelling of stems and roots (the fleshy roots of radishes are an extreme example).
- Cytokinins stimulate axillary buds to grow into branches; the auxin-to-cytokinin ratio controls the extent of branching (bushiness) of a plant.
- Cytokinins delay the senescence of leaves. If leaf blades are detached from a plant and floated on water or a nutrient solution, they gradually turn yellow and show other signs of senescence. If instead they are floated on a solution containing a cytokinin, they remain green and senesce much more

FIGURE 26.9 The Cytokinin Signal Transduction Pathway Plant cells respond to cytokinins through a two-component signal transduction pathway involving a receptor and a target protein.

slowly. Roots contain abundant cytokinins, and cytokinin transport to the leaves delays senescence.

Cytokinin appears to act through a pathway that includes proteins with amino acid sequences similar to those of proteins in *two-component systems*, a type of signal transduction pathway commonly found in bacteria. Indeed, this pathway was one of the first of its kind discovered in eukaryotes. The two components in such a system are:

- a *receptor* that can act as a protein kinase, phosphorylating itself as well as a target protein
- a *target protein*, generally a transcription factor, that regulates the response

Genetic screens in *Arabidopsis* for abnormalities in the response to cytokinin have identified the receptor (AHK; *Arabidopsis* histidine kinase) and the target protein (ARR; *Arabidopsis* response regulator) involved. The target protein acts as a transcription factor when phosphorylated. The cytokinin signal transduction pathway also includes a third protein (AHP; *Arabidopsis* histidine phosphotransfer protein), which transfers phosphates from the receptor to the target protein (**FIGURE 26.9**). The plant genome has over 20 genes that are expressed in response to this signaling pathway.

Brassinosteroids are plant steroid hormones

In animals, steroid hormones such as cortisol and estrogen, which are formed from cholesterol, have been well studied for decades (see Chapter 30). In the 1970s, biologists isolated a steroid from the pollen of rape (*Brassica napus*), a member of the mustard family. When applied to various plant tissues, this hormone stimulated cell elongation, pollen tube elongation, and vascular tissue differentiation, but it inhibited root elongation. Since then, dozens of chemically related, growth-affecting **brassinosteroids** have been found in plants. Like other plant hormones, brassinosteroids have diverse effects (see Table 26.2):

- They enhance cell elongation and cell division in shoots.
- They promote xylem differentiation.
- They promote growth of pollen tubes during reproduction.
- They promote seed germination.
- They promote apical dominance and leaf senescence.

The signaling pathway for these plant steroids differs sharply from those for steroid hormones in animals. In animals, steroids diffuse through the plasma membrane and bind to receptors in

the cytoplasm. In contrast, the receptor for brassinosteroids is an integral protein in the plasma membrane.

Absciscic acid acts by inhibiting development

The hormone **abscisic acid** is found in most plant tissues. Many of its actions involve inhibition of other hormones' actions in the plant (see Table 26.2):

- **Prevention of seed germination.** Abscisic acid prevents seeds from germinating on the parent plant before the seeds are dry. Premature germination, termed *vivipary*, is undesirable in cereal crops because the grain is ruined if it has started to sprout. Viviparous seedlings are unlikely to survive if they remain attached to the parent plant and are unable to establish themselves in the soil.
- **Promotion of seed dormancy.** Abscisic acid promotes seed dormancy and inhibits the initiation of germination events, such as the hydrolysis of stored macromolecules, by gibberellins.
- **Reaction to stress.** Abscisic acid is a “stress hormone” that mediates a number of plant responses to pathogens and environmental stresses. We describe some of these effects in Chapter 28. For now, consider that when the air is dry, abscisic acid stimulates the closure of stomata to prevent water loss by transpiration (see Concept 25.3).

FRONTIERS Abscisic acid provides an example of the complex interactions between plant hormones. Whereas abscisic acid promotes seed dormancy, gibberellic acid inhibits it; whereas abscisic acid inhibits seed germination, both gibberellic acid and ethylene promote it. The exact mechanism of this hormonal cross-talk is not clear. Molecular studies of the signal transduction pathways for these hormones may reveal common intermediates where the pathways intersect and influence one another.

Do You Understand Concept 26.3?

- Which plant hormones affect cell elongation, and what is the effect in each case?
- At the grocery store, you can buy plastic bags that keep fruit fresh for a much longer period than other containers. How do you think they work?
- A mutant strain of corn shows vivipary. Why is this a disadvantage for the plant and the crop, and what gene might be involved?

As we have seen, plant development is strongly influenced by the environment. For example, in Concept 26.1 we alluded to the role of photoreceptors whose responses to light guide the early growth of seedlings. We will now turn to the molecular nature of these and other plant photoreceptors.

concept 26.4 Photoreceptors Initiate Developmental Responses to Light

Plants are completely dependent on sunlight for energy, so it is not surprising that they have multiple ways to sense light and respond appropriately. A number of physiological and developmental events in plants are controlled by light, a process called **photomorphogenesis**. Plants respond to two aspects of light: its *quality*—that is, the wavelengths of light to which the plant is exposed; and its *quantity*—that is, the intensity and duration of light exposure.

Chapter 6 describes how chlorophyll and other photosynthetic pigments absorb light of certain wavelengths (see Figure 6.17). Here we consider how light affects plant development. Light influences seed germination, phototropism, shoot elongation, initiation of flowering, and many other important aspects of plant development. Several photoreceptors take part in these processes.

Phototropin, cryptochromes, and zeaxanthin are blue-light receptors

An action spectrum for the phototropic response of a coleoptile (**FIGURE 26.10**) shows that blue light at 436 nm is the most

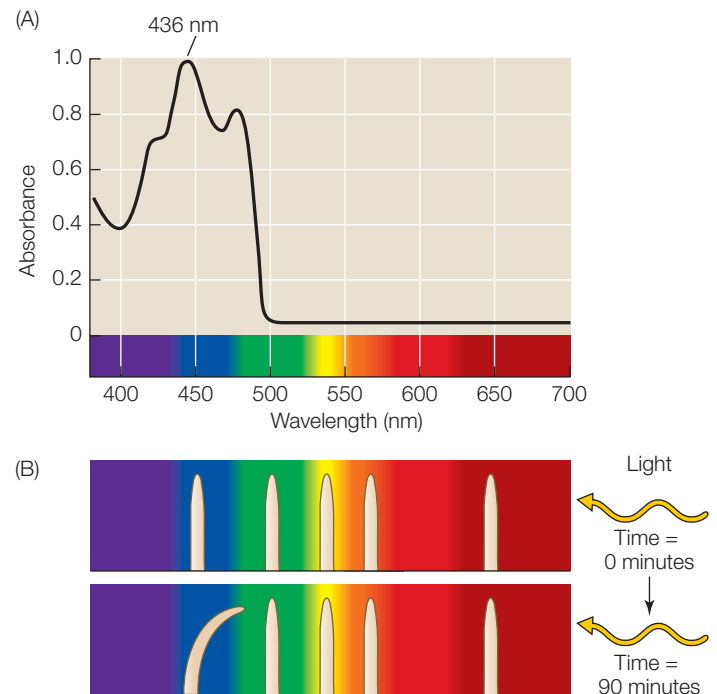

FIGURE 26.10 Action Spectrum for Phototropism The absorption spectrum for phototropin (A) is similar to the action spectrum for the bending of a coleoptile toward light (B). After 90 minutes, only the coleoptiles exposed to blue light bend.

effective in stimulating that response. To identify the blue-light-absorbing molecule involved, biologists have taken a genetic approach using the model plant *Arabidopsis*.

LINK Action spectra are discussed in Concept 6.5; see Figure 6.17

By recovering blue-light-insensitive *Arabidopsis* mutants from a genetic screen, researchers were able to identify the gene for a blue-light receptor protein located in the plasma membrane, called **phototropin**. This protein has a flavin mononucleotide associated with it that absorbs blue light at 436 nm. Light absorption leads to a change in the shape of the protein that exposes an active site for a protein kinase, which in turn initiates a signal transduction cascade that ultimately results in stimulation of cell elongation by auxin. Phototropin also participates with another type of blue-light receptor, the plastid pigment **zeaxanthin**, in the light-induced opening of stomata.

FRONTIERS In bright sunlight, chloroplasts in leaves move to the edges of cells, making the leaves look pale green. When the weather is cloudy, chloroplasts move toward the center of cells to maximize light exposure. Genetic screens of *Arabidopsis* show that these responses are mediated by phototropin. Studying this photoreceptor's signal transduction pathway may allow scientists to manipulate pigment-mediated chloroplast movements. This ability could be useful in increasing the efficiency of photosynthesis, which often limits the production of crops.

A third class of blue-light receptors is the **cryptochromes**, which are yellow pigments that absorb blue and ultraviolet light. These pigments are located primarily in the plant cell nucleus and affect seedling development and flowering. The exact mechanism of cryptochrome action is not yet known. Strong blue light inhibits cell elongation through the action of cryptochromes, although the most rapid responses are mediated by phototropin.

Phytochrome mediates the effects of red and far-red light

Plants also have responses that are specific to light in the red region of the spectrum. Here are two examples:

- Lettuce seeds spread on soil will germinate only in response to light. Even a brief flash of dim light will suffice. This response prevents the seeds from germinating in the shade of other plants or so deep in the soil that the seedlings will not be able to reach the light before their seed reserves run out.
- Adult cocklebur plants flower when they are exposed to long nights. If there is a brief flash of light in the middle of the night, they do not flower. This response enables plants to flower in the appropriate season.

INVESTIGATION

FIGURE 26.11 Photomorphogenesis and Red Light Lettuce seeds will germinate if exposed to a brief period of light. The action spectrum for germination indicated that red light was most effective in promoting it, but far-red light would reverse the effect if presented right after a red-light flash. Harry Borthwick and his colleagues asked what the effect of repeated alternating flashes of red and far-red light would be. In each case, the final exposure determined the germination response. This observation led to the conclusion that a single, photo-reversible molecule was involved. That molecule turned out to be phytochrome.

HYPOTHESIS

The effects of red and far-red light on lettuce seed germination are mutually reversible.

METHOD

Expose lettuce seeds to alternating periods of red light **R** for 1 minute and far-red light **FR** for 4 minutes.

R **R FR** ... **R FR R FR R FR R FR** **R FR R FR R FR R FR**

RESULTS

CONCLUSION

Red light and far-red light reverse each other's effects.

ANALYZE THE DATA

Seven groups of 200 lettuce seeds each were incubated in water for 16 hours in the dark. One group was then exposed to white light for 1 min. A second group (controls) remained in the dark. Five other groups were exposed to red (R) and/or far-red (FR) light. All the seeds were then returned to darkness for 2 more days. Germination was then observed.

Condition	Seeds germinated
1. White light	199
2. Dark	17
3. R	196
4. R then FR	108
5. R then FR then R	200
6. R then FR then R then FR	86
7. R then FR then R then FR then R	198

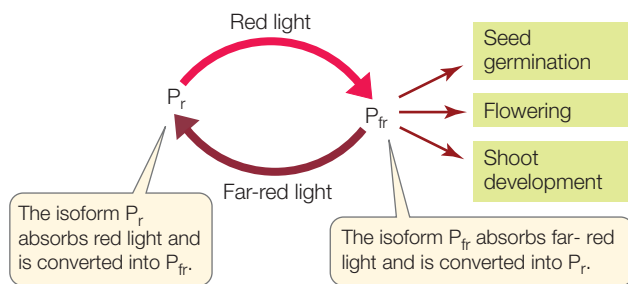

- Calculate the percentage of seeds that germinated in each case.
- What can you conclude about the photoreceptors involved?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

The action spectra of these processes show that they are induced by red light (650–680 nm). This indicates that plants must have a photoreceptor that absorbs red light.

What is especially remarkable about these red light responses is that *they are reversible by far-red light* (710–740 nm). For example, if lettuce seeds are exposed to brief, alternating periods of red and far-red light in close succession, they respond only to the final exposure. If it is red, they germinate; if it is far-red, they remain dormant (FIGURE 26.11). This reversibility of the effects of red and far-red light regulates many other aspects of plant development, including flowering and shoot development.

The basis for the effects of red and far-red light is a bluish photoreceptor in the cytosol of plants called **phytochrome**. Phytochrome exists in two interconvertible *isoforms*, or states. The molecule undergoes a conformational change when it absorbs light at particular wavelengths. The default or “ground” state, which absorbs principally red light, is called P_r . When P_r absorbs a photon of red light, it is converted into the other isoform, P_{fr} . The P_{fr} isoform preferentially absorbs far-red light; when it does so, it is converted back into P_r :

P_{fr} , not P_r , is the active isoform of phytochrome—the form that triggers important biological processes in various plants. These processes include seed germination, shoot development after etiolation (growth in the dark), and flowering.

The ratio of red to far-red light determines whether a phytochrome-mediated response will occur. For example, during daylight, the ratio is about 1.2:1; because there is more red than far-red light, the P_{fr} isoform predominates. But for a plant growing in the shade of other plants, the ratio may be as low as 0.13:1, and most phytochrome is in the P_r isoform. The low ratio of red to far-red light in the shade results from absorption of red light by chlorophyll in the leaves overhead, so less of the red light gets through to the plants below. Shade-intolerant species respond by stimulating cell elongation in the stem and thus growing taller to escape the shade (similar to the behavior of etiolated seedlings grown in the dark). Similarly, shade cast by other plants prevents germination of seeds that require red light to germinate (see Figure 26.11).

Phytochrome stimulates gene transcription

How does phytochrome—or more specifically, P_{fr} —work? Phytochrome is a cytoplasmic protein composed of two subunits, each containing a protein chain and a nonprotein pigment called a *chromophore*. In *Arabidopsis*, there is a gene family that encodes five slightly different phytochromes, each functioning in different photomorphogenic responses.

The transcription of genes involved in phytochrome responses is changed when P_r is converted into the P_{fr} isoform. When P_r absorbs red light, the chromophore changes shape, which leads to a change in the conformation of the phytochrome protein from the P_r isoform to the P_{fr} isoform. Conversion to the P_{fr} isoform exposes two important regions of the protein (see Figure 26.12), both of which affect transcriptional activity:

- Exposure of a *nuclear localization signal sequence* (see Figure 10.20) results in movement of P_{fr} from the cytosol to the nucleus. Once in the nucleus, P_{fr} binds to transcription factors and thereby stimulates expression of genes involved in photomorphogenesis.
- Exposure of a *protein kinase domain* causes the P_{fr} protein to phosphorylate itself and other proteins involved in red-light signal transduction. Those proteins change the activity of other transcription factors.

FIGURE 26.12 Phytochrome Stimulates Gene Transcription

Phytochrome is composed of two subunits, each containing a protein chain and a chromophore. When the chromophore absorbs red light, phytochrome is converted into the P_{fr} isoform, which activates transcription of phytochrome-responsive genes.

The effect of this activation of transcription factors is quite large: in *Arabidopsis*, phytochrome affects an amazing 2,500 genes (10 percent of the entire genome) by either increasing or decreasing their expression. Some of these genes are related to other hormones. For example, when P_{fr} is formed at the time of seed germination, genes for gibberellin synthesis are activated and genes for gibberellin breakdown are repressed. As a result, gibberellins accumulate and seed reserves are mobilized (see Figure 26.4).

Circadian rhythms are entrained by photoreceptors

The timing and duration of biological activities in living organisms are governed in all eukaryotes and some prokaryotes by what is commonly called a “biological clock”: an oscillator within cells that alternates back and forth between two states at roughly 12-hour intervals. The major outward manifestations of this clock are known as **circadian rhythms** (Latin *circa*, “about,” and *dies*, “day”). In plants, circadian rhythms influence, for example, the opening (during the day) and closing (at night) of stomata in *Arabidopsis* and the elevation toward the sun (during the day) and lowering (at night) of leaves in bean plants.

LINK For a description of the role of circadian rhythms in animal behavior, see Concept 41.4

The circadian rhythms of plants can be reset, or *entrained*, within limits, by light–dark cycles that change. Consider what happens when plants adapt to day length as the seasons change during the year. The action spectrum for plant entrainment indicates that phytochrome (and to a lesser extent, blue-light receptors) is very likely involved. At sundown, phytochrome is mostly in the active P_{fr} isoform. But as the night progresses, P_{fr} is gradually converted back into the inactive P_r isoform. By dawn, most phytochrome is in the P_r state, but as daylight begins, it is rapidly converted into P_{fr} . The switch to the P_{fr} isoform resets the plant’s biological clock. However long the night, the clock is still reset at dawn every day. Thus while the total period measured by the clock does not change, the clock adjusts to changes in day length over the course of the year.

Do You Understand Concept 26.4?

- Trace the events that occur in the phytochrome-mediated germination response of lettuce seeds, from the reception of light to alteration in gene expression.
- Compare the wavelengths of light absorbed by chlorophyll (see Figure 6.17) and by phototropin (see Figure 26.10). How does the difference influence a plant’s responses to light when a plant grows beneath a forest canopy?
- How would you show that a physiological process in a plant is mediated by phytochrome?

What changes in their growth patterns made the new strains of cereal crops produced by the Green Revolution so successful?

ANSWER It is only recently that plant biologists have discovered why semi-dwarf wheat and rice have short stems (FIGURE 26.13). This knowledge has come from an understanding of the effects of various hormones on plant growth and development (Concept 26.1), the signal transduction pathways for response to these hormones (Concepts 26.2 and 26.3), and the biochemical pathways for the synthesis of these hormones. It turns out that the genes involved in wheat and in rice are different.

In semi-dwarf wheat, the mutant allele that produces short plants is involved in signal transduction in response to gibberellin. The gene involved is called *Rht* (“reduced height”). The mutant allele was first seen in Japanese semi-dwarf varieties. It is dominant, so its phenotypes are readily seen. Norman Borlaug used conventional plant breeding to transfer the *Rht* mutant allele into wheat strains in Mexico. In addition to having short stature and not falling over when bearing a high grain yield, *Rht* mutant plants put a greater proportion of their photosynthate into making seeds than wild-type plants do. This higher *harvest index* is also a major reason why most wheat varieties today carry an *Rht* mutation.

FIGURE 26.13 Semi-Dwarf Rice This short variety of rice (left) produces higher yields of grain than its taller counterpart (right). The semi-dwarf rice produces less than normal amounts of gibberellins.

A hint that *Rht* might be involved in hormone regulation came when semi-dwarf plants harboring *Rht* mutations were found to be insensitive to added gibberellin and did not grow to normal height when the hormone was applied. *Rht* encodes the transcriptional repressor in the gibberellin signal transduction pathway (see Figure 26.8). Mutations in semi-dwarf plants are in the region that binds the gibberellin receptor and that signals polyubiquitination and degradation in the proteasome. Thus in the mutant plants, the repressor is always bound to the transcription factor, inhibiting its activity and keeping the gibberellin response “off.” This mutation therefore results in shorter stature.

In semi-dwarf rice, the mutant allele that produces short plants is involved with gibberellin *synthesis*. The gene involved is called *sd-1* (“semi-dwarf”). In contrast to semi-dwarf wheat, rice plants with mutations in *sd-1* are sensitive to gibberellin—that is, the semi-dwarf phenotype can be corrected by supplying gibberellin. This observation indicates that the mutant plants have the signal transduction machinery intact but lack the hormone. Indeed, *sd-1* encodes an enzyme that catalyzes one of the last steps in gibberellin synthesis.

26

SUMMARY

concept 26.1 Plants Develop in Response to the Environment

- Plant development is regulated by environmental cues, receptors, hormones, and the plant’s genome.
- Seed **dormancy**, which has adaptive advantages, is maintained by a variety of mechanisms. When dormancy ends, the seed **imbibes** water, **germinates**, and develops into a **seedling**. **Review Figure 26.1 and WEB ACTIVITIES 26.1 and 26.2**
- **Hormones** and **photoreceptors** act through signal transduction pathways to regulate plant growth and development.
- **Genetic screens** using the model organism *Arabidopsis thaliana* have contributed greatly to our understanding of signal transduction pathways in plants. **Review Figure 26.2**

concept 26.2 Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action

- **Gibberellins** stimulate growth of stems and fruits as well as mobilization of seed reserves in cereal crops. **Review Figure 26.4 and WEB ACTIVITY 26.3**
- **Auxin** is made in cells at the shoot apex and moves down to the growing region in a polar manner. **Review Figure 26.5**
- Lateral movement of auxin, mediated by auxin efflux carriers, is responsible for **phototropism** and **gravitropism**. **Review Figure 26.6 and ANIMATED TUTORIAL 26.1**
- Auxin plays roles in lateral root formation, leaf **abscission**, and **apical dominance**.
- The **acid growth hypothesis** explains how auxin promotes cell expansion by increasing proton pumps in the plasma membrane, which loosens the cell wall. **Review Figure 26.7 and ANIMATED TUTORIAL 26.2**
- Both auxin and gibberellins act by binding to their respective receptors, which then bind to a transcriptional repressor, leading to the repressor’s breakdown in the proteasome. **Review Figure 26.8**

concept 26.3 Other Plant Hormones Have Diverse Effects on Plant Development

- **Cytokinins** are adenine derivatives that often interact with auxin. They promote plant cell division, promote seed germination in some species, and inhibit stem elongation, among other activities.
- Cytokinins act on plant cells through a two-component signal transduction pathway. **Review Figure 26.9**
- A balance between auxin and **ethylene** controls leaf abscission. Ethylene promotes senescence and fruit ripening. It causes the stems of eudicot seedlings to form a protective **apical hook**. In stems, it inhibits elongation, promotes lateral swelling, and decreases sensitivity to gravitropic stimulation.
- **Brassinosteroids** promote cell elongation, pollen tube elongation, and vascular tissue differentiation but inhibit root elongation. Unlike animal steroids, these hormones act at a plasma membrane receptor.
- **Abscisic acid** inhibits seed germination, promotes dormancy, and stimulates stomatal closing in response to dry conditions in the environment.

concept 26.4 Photoreceptors Initiate Developmental Responses to Light

- **Phototropin** is a blue-light receptor protein involved in phototropism. **Zeaxanthin** acts in conjunction with phototropin to mediate the light-induced opening of stomata. **Cryptochromes** are blue-light receptors that affect seedling development and flowering and inhibit cell elongation. **Review Figure 26.10**
- **Phytochrome** is a photoreceptor that exists in the cytosol in two interconvertible isoforms, P_r and P_{fr} . The relative amounts of these two isoforms are a function of the ratio of red to far-red light. Phytochrome plays a number of roles in **photomorphogenesis**. **Review Figure 26.11**
- The phytochrome signal transduction pathway affects transcription in two ways: the P_{fr} isoform interacts directly with some transcription factors and influences transcription indirectly by phosphorylating other proteins. **Review Figure 26.12**
- **Circadian rhythms** are changes that occur on a daily cycle. Light can entrain circadian rhythms through photoreceptors such as phytochrome.

Reproduction of Flowering Plants

27

Dairy farmer Albert Ecke was fascinated by the red and green shrubs that grew all over southern California and were used by Mexican-Americans for red dye. The shrub, *Euphorbia pulcherrima*, got the name “poinsettia” from the man who first brought it to the United States: the first U.S. ambassador to Mexico, Joel Roberts Poinsett. In the early 1900s, Ecke started selling the plants at his farm in Hollywood. But two challenges stood in the way of his making this plant a commercial success.

First, although poinsettias generally bloomed in the fall and early winter in the mild climate of southern California, when Ecke grew them in fields in Hollywood, the formation of flowers was unreliable. Biologists later found that the flowering of poinsettias required at least a 14-hour night for several weeks. Any interruption in the long night—by passing cars or street lamps, for example—inhibited flowering. So Ecke’s son Paul moved the growing operation south, to isolated fields far from Los Angeles. A second challenge was that the plants were tall and gangly. Although pretty, they were hard to transport and not attractive indoors. Paul Ecke found a variety of poinsettia that was much more compact. He propagated this variety and eventually developed it into the short potted plant that is so popular today. The Eckes decided that the time of flowering was just right for making the poinsettia a “Christmas flower,” so they promoted this now portable plant as a holiday decoration, blanketing live television shows with free plants between Thanksgiving and Christmas. The campaign was successful: over 100 million poinsettias are

now sold in the United States during the winter holidays every year, making it the nation’s best-selling potted plant.

Breeding more attractive flowering plants that are easier to grow is an ongoing part of *floriculture*, the industry involved with the production of floral crops. You may be surprised to learn that the brightly colored “flowers” of poinsettias are not flowers at all. The red parts of the plant that we most notice and appreciate are actually specialized leaves called *bracts*. The poinsettia has a single tiny yellow female flower, without petals, surrounded by male flowers.

The poinsettia is a popular Christmas flower. But the red “flowers” are not flowers at all; instead, they are leaves (bracts). The flower is the yellow structure in the center of a group of red leaves.

How did an understanding of angiosperm reproduction allow floriculturists to develop a commercially successful poinsettia?

KEY CONCEPTS

- 27.1** Most Angiosperms Reproduce Sexually
- 27.2** Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State
- 27.3** Angiosperms Can Reproduce Asexually

concept 27.1 Most Angiosperms Reproduce Sexually

Most angiosperms (flowering plants) have evolved to reproduce sexually because this strategy results in the genetic diversity that is the raw material for evolution. Sexual reproduction in angiosperms involves mitosis, meiosis, and the alternation of haploid and diploid generations (see Figure 7.3). There are several important differences between sexual reproduction in angiosperms and in vertebrate animals (see Chapter 32):

- Meiosis in plants produces spores, after which mitosis produces gametes; in animals, meiosis usually produces gametes directly.
- In most plants, there are multicellular diploid (*sporophyte*) and haploid (*gametophyte*) life stages (alternation of generations); in animals, there is no multicellular haploid stage.
- In plants, the cells that will form gametes are determined in the adult organism, usually in response to environmental conditions; in animals, the germline cells are determined before birth.

LINK The life cycles of plants have many unique characteristics, which are detailed in Chapter 21

The flower is the reproductive organ of angiosperms

In angiosperms, male or female gametophytes (and sometimes both) are contained in flowers. As we saw in Concept 21.5, a complete flower consists of four concentric groups of organs arising from modified leaves: the *carpels*, *stamens*, *petals*, and *sepals*.

The parts of the flower are all derived from a modified shoot apical meristem.

- The carpels are the female sex organs that contain the developing female gametophytes.
- The stamens are the male sex organs that contain the developing male gametophytes.

The differentiation of these organs is controlled by specific transcription factors (see Figure 14.11).

As you know, flowers come in many shapes, sizes, and forms. Some have both stamens (male sex organs) and carpels (female sex organs); such flowers are termed *perfect* (FIGURE 27.1A). *Imperfect* flowers, by contrast, are those with only male or only female sex organs. Male flowers have stamens but not carpels, and female flowers have carpels but not stamens. Some plants, such as corn, bear both male and female flowers on

(A) Perfect: lily (*Lilium* sp.)

(B) Imperfect monoecious: corn (*Zea mays*)

FIGURE 27.1 Perfect and Imperfect Flowers (A) A lily is an example of a perfect flower, meaning one that has both male and female sex organs. (B) Imperfect flowers are either male or female. Corn is a monoecious species: both types of imperfect flowers are borne on the same plant. (C) American holly is a dioecious species; some American holly plants bear male imperfect flowers, and others bear female imperfect flowers.

(C) Imperfect dioecious: American holly (*Ilex opaca*)

Male flower with stamens

Female flower with carpels

the same individual plant; such species are called **monoecious** (“one housed”; FIGURE 27.1B). In **dioecious** (“two-housed”) species, individual plants bear either male-only or female-only flowers; an example is American holly (FIGURE 27.1C).

LINK Review the diverse structures and functions of flowers in Concept 21.5

Angiosperms have microscopic gametophytes

FIGURE 27.2 offers a detailed look at angiosperm gametophytes. These haploid, microscopic gamete-producing structures develop from haploid spores in the flower:

- Female gametophytes (*megagametophytes*), which are also called **embryo sacs**, develop in megasporangia. The meiotic products that give rise to megagametophytes are called *megaspores*.
- Male gametophytes (*microgametophytes*), which are also called **pollen grains**, develop in microsporangia. The meiotic products that give rise to microgametophytes are called *microspores*.

FEMALE GAMETOPHYTE Of the four haploid megaspores resulting from meiosis, three undergo apoptosis (programmed cell death). Typically, the remaining megaspore undergoes three mitotic divisions without cytokinesis, producing eight haploid nuclei, all initially contained within a single cell—three nuclei at one end, three at the other, and two in the middle. Subse-

quent cell wall formation leads to an elliptical, seven-celled megagametophyte with a total of eight nuclei:

- At one end of the megagametophyte are three small cells: the *egg cell* and two cells called *synergids*. The egg cell is the female gamete, and the synergids participate in fertilization by attracting the *pollen tube* and receiving the sperm nuclei prior to their movement to the egg cell and the central cell.
- At the opposite end of the megagametophyte are three *antipodal* cells, which eventually degenerate.
- In the large central cell are two **polar nuclei**.

The megagametophyte, or embryo sac, is the entire seven-cell, eight-nucleus structure.

MALE GAMETOPHYTE The four haploid products of meiosis in the microsporangia each develop a cell wall and undergo a single mitotic division, producing four two-celled pollen grains that are released into the environment. The two cells in a pollen grain have different roles:

- The *generative cell* divides by mitosis to form two *sperm* cells that participate in fertilization.
- The *tube cell* forms the elongating pollen tube that delivers the sperm to the embryo sac.

FIGURE 27.2 Sexual Reproduction in Angiosperms The embryo sac is the female gametophyte; the pollen grain is the male gametophyte. The male and female nuclei meet and fuse in the embryo sac. Angiosperms have double fertilization, in which a zygote and an endosperm nucleus form from separate fusion events—the zygote from one sperm and the egg, and the endosperm from the other sperm and the two polar nuclei.

These events occur after the pollen grain is transferred to a stigma (part of the female reproductive organ)—a process called *pollination*.

Angiosperms have mechanisms to prevent inbreeding

As we discuss in Concept 21.4, the evolution of pollen in the seed plants made it possible for male gametes to reach the female gametophyte in the absence of liquid water. The transfer of pollen from plant to plant presents its own challenges, however. In the first seed plants to evolve, tiny pollen grains were carried to stigmas by wind. Wind-pollinated flowers have sticky or featherlike stigmas, and they produce a great number of pollen grains because of the low probability of an individual grain encountering a suitable stigma. More recently in evolutionary time, most angiosperms have come to rely on animals for pollination. Pollen transport by animals greatly increases the probability that pollen will get to a female gametophyte of the same species.

LINK The evolution of plant–pollinator interactions and their effects on plant speciation are described in Concepts 17.4 and 21.5

Some plants *self-pollinate*: that is, they are fertilized by pollen that lands on the stigma of a flower on the same plant, or even the same flower. Mendel’s garden peas, for example, reproduce in this way, so he had to remove stamens to control the parentage of his genetic crosses (see Figure 8.1). Self-pollination mitigates the difficulties of wind or animal pollination of a distant flower. However, “selfing” leads to homozygosity, which can reduce the reproductive fitness of offspring (known as inbreeding depression). Most plants have evolved mechanisms that prevent self-pollination and self-fertilization.

SEPARATION OF MALE AND FEMALE GAMETOPHYTES Self-fertilization is not possible in dioecious species, which bear only male or female flowers on an individual plant. Pollination in dioecious species is accomplished only when one plant pollinates another. In monoecious plants, which bear both male and female flowers on the same plant, the physical separation of male and female flowers is often sufficient to prevent self-fertilization. Some monoecious species prevent self-fertilization by staggering the development of male and female flowers so they do not bloom at the same time, making these species functionally dioecious.

GENETIC SELF-INCOMPATIBILITY A pollen grain that lands on a stigma of the same plant will fertilize the female gamete only if the plant is *self-compatible* (capable of self-fertilization). To prevent self-fertilization, many plants are **self-incompatible**. This mechanism depends on the ability of a plant to determine whether pollen is genetically similar or genetically different from “self.” Rejection of “same-as-self” pollen prevents self-fertilization.

Self-incompatibility in plants is controlled by a cluster of tightly linked genes called the *S* locus (for self-incompatibility). The *S* locus encodes proteins in the pollen and style that interact during the recognition process. A self-incompatible species typically has many alleles of the *S* locus, and when the pollen carries an allele that matches one of the alleles of the recipient pistil, the pollen is rejected. Depending on the type of self-incompatibility system, the rejected pollen either fails to germinate or the pollen tube is prevented from growing through the style (FIGURE 27.3); either way, self-fertilization is prevented.

A pollen tube delivers sperm cells to the embryo sac

When a genetically appropriate pollen grain lands on the stigma of a compatible pistil, it germinates. As with seed germination, a key event is water uptake by pollen, this time from the stigma. Germination involves the development of a pollen tube. The pollen tube either traverses the spongy tissue of the style or, if the style is hollow, grows on the inner surface of the style until it reaches an ovule. The pollen tube typically grows at the rate of 1.5–3 millimeters per hour, taking just an hour or two to reach its destination, the female gametophyte.

The growth of the pollen tube may be guided in part by a chemical signal produced by the synergids in the ovule. If one synergid is destroyed, the ovule still attracts pollen tubes, but destruction of both synergids renders the ovule unable to attract pollen tubes, and fertilization does not occur. The attractant appears to be species-specific: in some cases, isolated

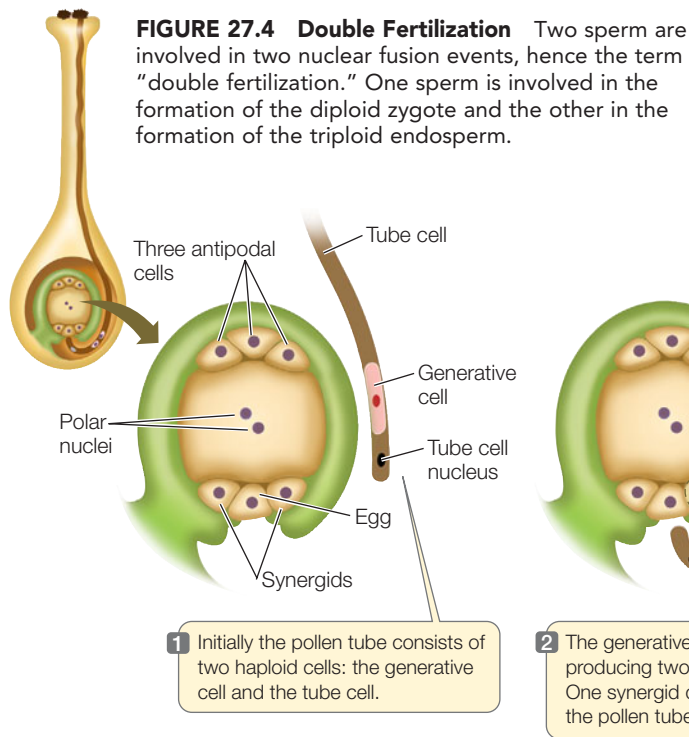

FIGURE 27.3 Self-incompatibility In a self-incompatible plant, pollen is rejected if it expresses an *S* allele that matches one of the *S* alleles of the stigma and style. There are two mechanisms of rejection: (A) the pollen may fail to germinate, or (B) the pollen tube may die before reaching an ovule. Both mechanisms prevent the egg from being fertilized by a sperm from the same plant.

Double Fertilization

female gametophytes attract only pollen tubes of the same species.

FRONTIERS What is the nature of the pollen tube attractant produced by the synergids? Plant biologist Tetsuya Higashiyama at Nagoya University in Japan recently examined 2,000 proteins expressed in synergid cells of the wishbone flower (*Torenia fournieri*) and identified a pollen tube attractant. The protein, called LURE1, attracted pollen tubes to isolated female gametophytes in a test tube assay. When synthesis of LURE1 was blocked in intact plants, pollen tube growth down the style did not occur. Plant biologists are now looking for similar attractant proteins in other plants.

Angiosperms perform double fertilization

The pollen tube grows down the style, under the direction of the haploid tube cell. Meanwhile, the generative cell divides once to form two haploid sperm cells. Once the pollen tube reaches the embryo sac, one of the two synergids degenerates, and the two sperm cells are released into its remains. *Two fertilization events occur (FIGURE 27.4):*

- One sperm cell fuses with the egg cell, producing the diploid zygote, which forms the new sporophyte embryo.
- The other sperm cell fuses with the two polar nuclei in the central cell of the embryo sac. This fusion forms a triploid nucleus that undergoes rapid mitosis to form a specialized nutritive tissue, the *endosperm*. The endosperm contains the reserves that will provide chemical building blocks for the developing embryo while it is underground and cannot perform photosynthesis.

This process of *double fertilization* is a characteristic feature of angiosperm reproduction. The remaining cells of the female gametophyte—the antipodal cells and the remaining synergid—eventually degenerate, as does the pollen tube nucleus.

Embryos develop within seeds contained in fruits

Fertilization initiates the highly coordinated growth and development of the embryo, endosperm, integuments, and carpel. The *integuments*—tissue layers immediately surrounding the megasporangium—develop into the seed coat, and the carpel ultimately becomes the wall of the fruit that encloses the seed (see Figure 27.2).

In Chapter 26 we described the events in plant embryonic development and its hormonal control. As seeds develop, they prepare for dispersal and dormancy by losing up to 95 percent of their water content. You can see this desiccation by comparing corn grains (e.g., popcorn) with ripe corn from the cob or a can. A dry seed is still alive; it has protective proteins that keep its cells in a viscous state.

In angiosperms, the ovary—together with the seeds it contains—develops into a fruit after fertilization has occurred. Fruits have two main functions:

- They protect the seed from damage by animals and infection by microbial pathogens.
- They aid in seed dispersal.

A **fruit** may consist of only the mature ovary and seeds, or it may include other parts of the flower. Some species produce fleshy, edible fruits, such as peaches and tomatoes, whereas the fruits of other species are dry or inedible (FIGURE 27.5; see also Figure 21.24).

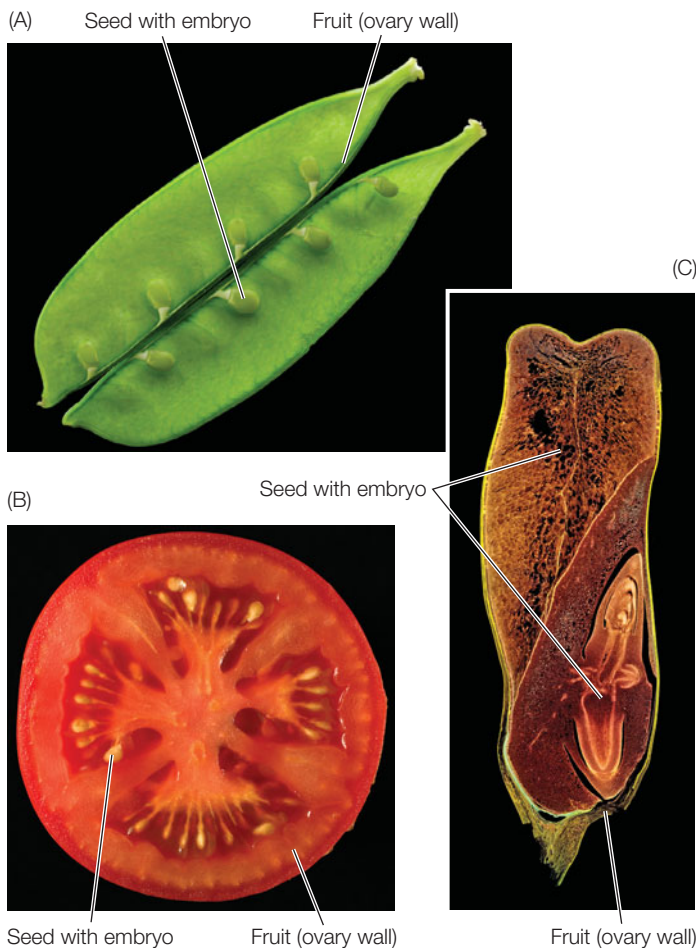

FIGURE 27.5 Angiosperm Fruits There are a variety of fruits, but all have seed containing the embryo, surrounded by a fruit that derives from the wall of the ovary. (A) Garden pea. (B) Tomato. (C) Corn.

The diverse forms of fruits reflect the varied strategies plants use to disperse their progeny. Because plants cannot move, their progeny need some mechanism for separating themselves from their parent. Fruits are clearly an important way to move seeds away from the parent plant. Wide dispersal of progeny may not always be advantageous, however. If a plant has successfully grown and reproduced, its location is likely to be favorable for the next generation too. Some offspring do indeed stay near the parent, as is the case in many tree species, whose seeds simply fall to the ground. This strategy, however, has several potential disadvantages. If the species is a *perennial*, offspring that germinate near their parent will be competing with their parent for resources, which may be too limited to support a dense population. Furthermore, even though local conditions were good enough for the parent to produce at least some seeds, there is no guarantee that conditions will still be good the next year, or that they won't be better elsewhere. Thus in many cases, seed dispersal is vital to a species' survival.

Some fruits help disperse seeds over substantial distances, increasing the probability that at least a few of the many seeds produced by a plant will find suitable conditions for

germination and growth to sexual maturity. Some, like those of the thistle, are carried to new locations by wind:

Others attach themselves to animals (or to your clothes and shoes):

Water disperses some fruits; coconuts have been known to float thousands of miles between islands. Seeds swallowed whole by an animal along with fruits such as berries travel through the animal's digestive tract and are deposited some distance from the parent plant (see Apply the Concept in Chapter 21, p.430).

Do You Understand Concept 27.1?

- Make a table that compares the haploid and diploid life stages of a human and a corn plant with regard to (1) the relative sizes of the haploid and diploid stages, (2) how many cells are in the haploid stage, (3) the names of the haploid cells, (4) the time in the life cycle that the haploid stage occurs, (5) the location of the haploid cells, and (6) how the haploid stages develop in males and females.
- Describe the processes that angiosperms use to ensure a genetically diverse population.
- The two sperm that participate in plant double fertilization are genetically identical. Are the two products of fertilization genetically identical?

Now that we have described the cellular aspects of angiosperm reproduction, let's turn to the events that signal a transition from vegetative growth of the shoot to the formation of flowers.

concept
27.2

Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State

Flowering represents a reallocation of energy and materials away from making more roots, stems, and leaves (*vegetative growth*) to making flowers and gametes (*reproductive growth*). Flowering can happen at maturity as part of a predetermined developmental program (as in a dandelion plant in summer) or in response to environmental cues such as light or temperature (as with the poinsettias we described at the opening of this chapter). In either case, flowering is initiated through a cascade of gene expression.

Plants fall into three categories based on when they mature and initiate flowering and what happens after they flower:

- **Annuals** complete their lives within a year. Annuals include many crops important to humans, such as corn, wheat, rice, and soybeans. When the environment is suitable, annuals grow rapidly. After flowering, they channel most of their energy into the development of seeds and fruits. Then the rest of the plant withers and dies.
- **Biennials** take two years to complete their lives. They are much less common than annuals and include carrots, cabbage, and onions. Typically, biennials produce only vegetative growth during their first year and store carbohydrates in underground roots (carrots) or stems (onions). In their second year, they use most of the stored carbohydrates to produce flowers and seeds rather than vegetative growth, and the plant dies after seeds form.
- **Perennials** live three or more—sometimes many more—years. Maple trees, for example, can live up to 400 years. Perennials include many wildflowers as well as trees and shrubs. Typically these plants flower each year but stay alive and keep growing the next seasons.

Shoot apical meristems can become inflorescence meristems

The transition from purely vegetative growth to the flowering state requires a change in one or more apical meristems in the shoot system. As we described in Chapter 24, shoot apical meristems continually produce leaves, axillary buds, and stem tissues (**FIGURE 27.6A**) in a kind of unrestricted growth called *indeterminate growth*.

A shoot apical meristem becomes an **inflorescence meristem** (recall that an *inflorescence* is a cluster of flowers) when it ceases production of leaves and stems and produces other structures: smaller leafy structures called *bracts* (such as the red leaves in poinsettias), as well as new meristems

in the angles between the bracts and the stem (**FIGURE 27.6B**). These new meristems may also be inflorescence meristems, or they may be **floral meristems**, each of which gives rise to a single flower.

Each floral meristem typically produces four consecutive *whorls*, or spirals, of organs—the sepals, petals, stamens, and carpels—separated by very short internodes, which keep the flower compact (**FIGURE 27.6C**). In contrast to shoot apical meristems and some inflorescence meristems, floral meristems are responsible for *determinate growth*—growth of limited extent, like that of leaves.

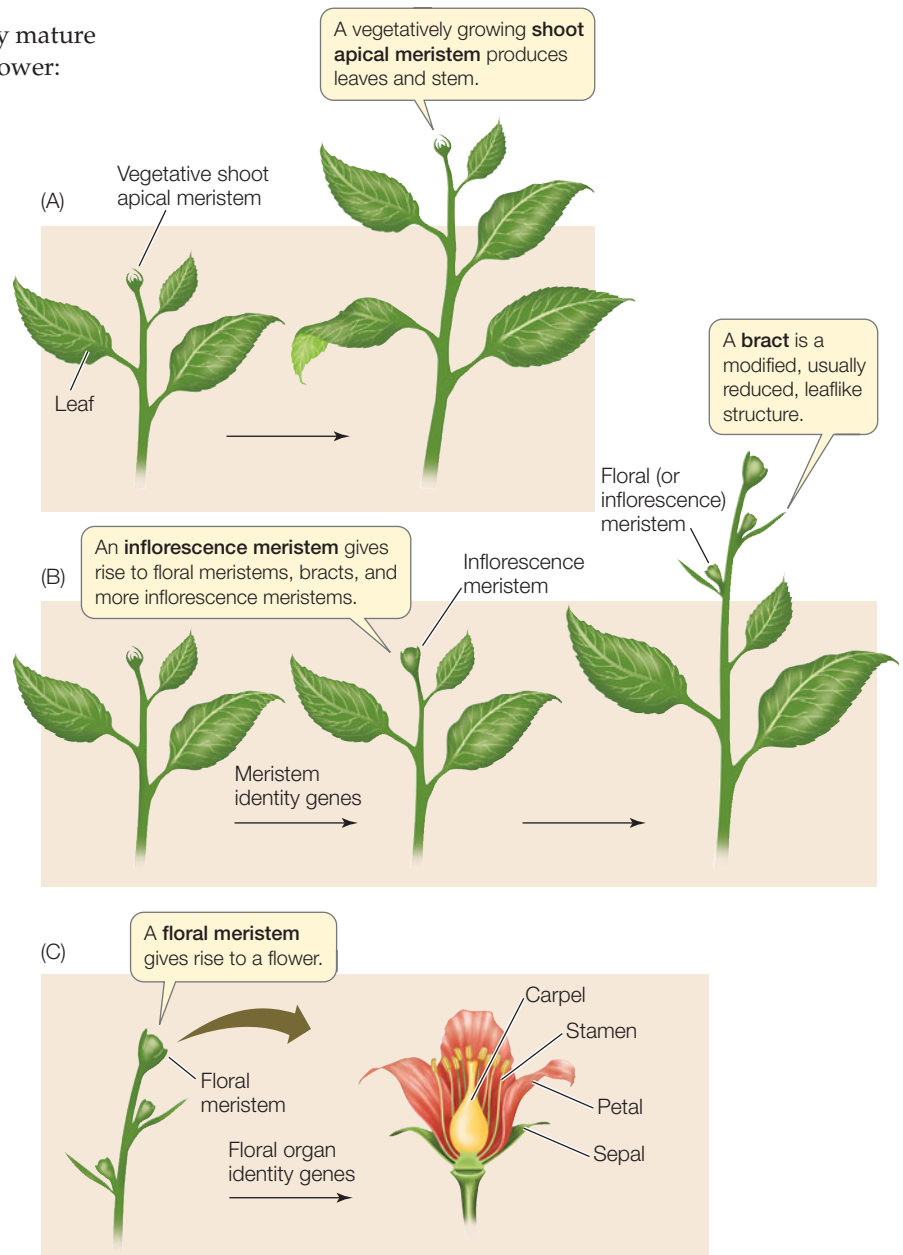

FIGURE 27.6 The Transition to Flowering (A) A shoot apical meristem produces vegetative organs without producing flowers. (B) A shoot apical meristem becomes an inflorescence meristem when it ceases production of leaves and stems and produces other structures. (C) A floral meristem becomes a single flower.

A cascade of gene expression leads to flowering

The genes that determine the transition from shoot apical meristems to inflorescence meristems and from inflorescence meristems to floral meristems have been studied in model organisms such as *Arabidopsis*.

MERISTEM IDENTITY GENES Expression of two **meristem identity genes** initiates a cascade of further gene expression that leads to flower formation. Expression of the genes *LEAFY* and *APETALA1* is both necessary and sufficient for flowering. Evidence for the role of these genes is both genetic and molecular. For example, a mutant allele of *APETALA1* leads to continued vegetative growth, even if conditions are suitable for flowering. However, if the wild-type *APETALA1* gene is coupled to an active promoter and introduced into a shoot apical meristem, the plant will flower regardless of environmental conditions. This is powerful evidence that *APETALA1* plays a role in switching shoot apical meristem cells from a vegetative to a reproductive fate (see Figure 27.6B).

FLORAL ORGAN IDENTITY GENES The products of the meristem identity genes trigger the expression of **floral organ identity genes**, which work in concert to specify the successive whorls of the flower (see Figure 27.6C). Floral organ identity genes are homeotic genes whose products are transcription factors that determine whether cells in the floral meristem will be sepals, petals, stamens, or carpels. An example is the gene *AGAMOUS*, a class C gene that causes florally determined cells to form stamens and carpels in the “ABC” system described in Chapter 14 (see Figure 14.11).

Depending on the species, plants initiate these gene expression changes, and the events that follow, in response to either internal or external cues. Among external clues, the best studied are *photoperiod* (day length) and temperature. We will begin with photoperiod.

Photoperiodic cues can initiate flowering

The study of how light affects the transition to flowering began with two observations in the early twentieth century:

- A mutant tobacco strain appropriately called Maryland Mammoth grew 5 m tall (normal tobacco is about 1.5 m tall). Instead of flowering in summer, it continued to grow until the late fall frost killed it. Farmers in Virginia were frustrated because they could not get seed of this luxuriant plant for the next year’s crop.
- Because of improvements in agricultural techniques, soybean yields became so great that it was hard for farmers to harvest all the plants at once. So they tried planting the seeds in groups, several weeks apart. Unfortunately, the resulting plants all formed flowers and seeds at the same time.

The explanation for both of these observations was the same: the signal that set the plants’ shoot apical meristems on the path to flowering was the length of daylight, or **photoperiod**. When soybeans experienced days of a certain length, they flowered,

FIGURE 27.7 Photoperiod and Flowering By artificially varying the length of daylight in a 24-hour period, biologists showed that the flowering of Maryland Mammoth tobacco is initiated when the days become shorter than a critical length. Maryland Mammoth tobacco is thus called a short-day plant. Henbane, a long-day plant, shows an inverse pattern of flowering.

regardless of how “old” they were. Maryland Mammoth tobacco *could* flower, but it did not do so in Virginia because it died when the weather got cold. When the plant was grown in a greenhouse to prevent freezing, however, it flowered in December, when the days were short. Maryland Mammoth is now grown commercially in Florida.

Greenhouse experiments measured the day length required for different plant species to flower. Maryland Mammoth tobacco did not flower if exposed to more than 14 hours of light per day; flowering was only initiated once day length became shorter than 14 hours, as it does in December. Other plants (such as soybeans and henbane) flowered only when the days were long (**FIGURE 27.7**).

Plants vary in their responses to photoperiodic cues

Plants that flower in response to photoperiodic stimuli fall into two main classes, although there are variations on these patterns:

- **Short-day plants (SDPs)** flower only when the day is *shorter* than a critical maximum. They include poinsettias and chrysanthemums as well as Maryland Mammoth tobacco. Thus, for example, we see chrysanthemums in nurseries in fall and poinsettias in winter (as noted at the opening of this chapter).

- **Long-day plants (LDPs)** flower only when the day is *longer* than a critical minimum. Spinach and clover are examples of LDPs. Spinach, for example, tends to flower and become bitter in the summer and is therefore normally planted in early spring.

Photoperiodic control of flowering serves an important role: it synchronizes the flowering of plants of the same species in a local population. This synchronization promotes cross-pollination and successful reproduction. It also means that floriculturists can vary light exposures in greenhouses to produce flowers at any time of year.

Night length is the key photoperiodic cue that determines flowering

The terms “short-day plant” and “long-day plant” assume that the key events that induce flowering occur in the daytime. What about the night? After all, short-day plants could just as easily be called “long-night” plants, and long-day plants could be called “short-night plants.” As it turns out, *night length is indeed the critical factor that induces flowering*, as a series of greenhouse experiments confirmed (FIGURE 27.8). In a greenhouse, the overall length of a day or night can be varied irrespective of the 24-hour natural cycle. For example, if cocklebur, a SDP, is exposed to several long periods of light (16 hours each), it will still flower as long as the dark period between them is 9 hours or longer. This 9-hour inductive dark period also induces flowering even if the light period varies from 8 hours to 12 hours.

Biologists noticed that when the inductive dark period was interrupted by a brief period of light, the flowering signal generated by the long night disappeared. It took several days of long nights for the plant to recover and initiate flowering. Interrupting the day with a dark period had no effect on flowering. A clue as to what occurred in the plant when the flash of light was given came when biologists determined the action spectrum for the wavelengths of light that were effective. As with lettuce seed germination (see Figure 26.11), red light was most effective at breaking the “night” stimulus, and its effect was

FIGURE 27.8 Night Length and Flowering Greenhouse experiments using cocklebur, a SDP, demonstrated that night length, not day length, is the environmental cue that initiates flowering.

reversible by far-red light. This indicated that the photoreceptor involved in flowering is phytochrome.

LINK The properties of phytochrome as a photoreversible photoreceptor are described in Concept 26.4

The Effect of Interrupted Days and Nights

Plants sense night length by measuring the ratio of the P_{fr} and P_r isoforms of phytochrome. During the day, there is more light in the red than in the far-red range. By the end of the day,

APPLY THE CONCEPT

Hormones and signaling determine the transition from the vegetative to the flowering state

The experiments reported on in Figure 27.8 were repeated using a long-day plant (LDP) that normally flowers with a 16-hour photoperiod. The plant was subjected to the light regimes listed in the table.

1. List the light regimes that should have resulted in flowering.
2. Predict the effect of adding a brief period of far-red light in the middle of the dark period of each light regime.
3. Predict the effect of adding a brief period of red light in the middle of the dark period of each light regime.

- | | |
|-----------------------------------|-----------------------------------|
| A. 14 hours light + 6 hours dark | G. 8 hours light + 8 hours dark |
| B. 14 hours light + 7 hours dark | H. 10 hours light + 8 hours dark |
| C. 14 hours light + 8 hours dark | I. 12 hours light + 8 hours dark |
| D. 14 hours light + 10 hours dark | J. 8 hours light + 10 hours dark |
| E. 14 hours light + 12 hours dark | K. 10 hours light + 10 hours dark |
| F. 14 hours light + 14 hours dark | L. 12 hours light + 10 hours dark |

much of the P_r has absorbed red light and been converted to P_{fr} . At night, there is a gradual, spontaneous conversion of this P_{fr} back to P_r . The longer the night, the more P_r there is at the beginning of the next day. A SDP flowers when the ratio of P_{fr} to P_r is low at the end of the night, whereas a LDP flowers when this ratio is high. You can compare this mechanism to an hourglass egg timer. The sand in the top chamber is analogous to P_{fr} and gradually runs down (is converted to P_r) over the course of the night; the shorter the night, the more sand remains at the top at dawn. To “reset” an hourglass timer, you simply turn it over; this would be analogous to dawn of the next day, when P_r begins being converted back to P_{fr} .

The flowering stimulus originates in the leaf

The photoperiodic receptor, phytochrome, is located in the leaf, not in the shoot apical meristem. “Masking” experiments can show this: if a single leaf of a SDP growing under short-night conditions is covered to simulate a long-night exposure, the shoot apical meristems will transition to flowering as if the entire plant were exposed to long nights (FIGURE 27.9). Reversing the masking (leaves exposed, buds covered) does not induce flowering.

Because the receptor of the photoperiodic stimulus (phytochrome in the leaf) is physically separated from the tissue on which the stimulus acts (the shoot apical meristem), the inference can be drawn that a signal travels from the leaf through the plant’s tissues to the shoot apical meristem. Unlike animals, plants do not have a nervous system, so the signal must be a diffusible chemical. Biologists have found additional evidence that a diffusible signal travels from the leaf to the shoot apical meristem:

- If a photoperiodically induced leaf is immediately removed from a plant after the inductive dark period, the plant does not flower. If the induced leaf remains attached to the plant for several hours, however, the plant flowers. This result suggests that something is synthesized in the leaf in response to the inductive dark period, and then moves out of the leaf to induce flowering.
- If two or more cocklebur plants are grafted together, and if one plant is exposed to inductive long nights and its graft partners are exposed to noninductive short nights, all of the plants flower.
- In several species, if an induced leaf from one species is grafted onto another, noninduced plant of a different species, the recipient plant flowers. This indicates that the same diffusible chemical signal is used by both species.

Although the diffusible signal was given a name, **florigen** (“flower inducing”), decades ago, the nature of the signal has only recently been explained.

Florigen is a small protein

The characterization of the protein florigen (FT) was made possible by genetic and molecular studies of the model

INVESTIGATION

FIGURE 27.9 The Flowering Signal Moves from Leaf to Bud Phytochrome, the receptor for photoperiod, is in the leaf, but flowering occurs in the shoot apical meristem. To investigate whether there is a diffusible substance that travels from leaf to bud, James Knott exposed a single leaf of cocklebur plants to the inductive dark period.

HYPOTHESIS

The leaves measure the photoperiod.

METHOD Grow cocklebur plants under long days and short nights. Mask a leaf on some plants and see if flowering occurs.

RESULTS If even one leaf is masked for part of the day—thus shifting that leaf to short days and long nights—the plant will flower.

CONCLUSION

The leaves measure the photoperiod. Therefore, some signal must move from the induced leaf to the flowering parts of the plant.

ANALYZE THE DATA

In related experiments, leaves were removed from plants before the plants were exposed to the inductive dark period. There were six plants in each condition.

Condition	Number of plants that flowered
No inductive dark period, intact plant	0
Inductive dark period, intact plant	6
Inductive dark period, all leaves removed	0
Inductive dark period, all but one leaf removed	6

- Based on these data, which part of the plant senses photoperiod?
- What do these data tell you about the signal that is generated by the plant in response to the photoperiod and that induces the shoot apical meristem to produce flowers?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

FIGURE 27.10 Molecular Biology of Flowering The protein florigen (FT) is made in the phloem companion cells of a leaf and travels in the sieve tube elements from the leaf to the shoot apical meristem. There, FT combines with another protein to stimulate transcription of genes that initiate flowering.

organism *Arabidopsis*, a LDP. Three genes are involved (**FIGURE 27.10**):

- *FT* (*FLOWERING LOCUS T*) codes for florigen. FT is a small protein (20 kDa molecular weight) that can travel through plasmodesmata. It is synthesized in phloem companion cells in the leaf and diffuses into the adjacent sieve tube elements, where it moves with the phloem to the shoot apical meristem.
- *CO* (*CONSTANS*) codes for a transcription factor that activates the synthesis of FT. Like FT, CO is expressed in phloem companion cells in the leaf. CO protein is expressed all the time but is unstable; an appropriate photoperiodic stimulus stabilizes CO so that there is enough to turn on FT synthesis.
- *FD* (*FLOWERING LOCUS D*) codes for a protein that binds to FT protein when it arrives in the shoot apical meristem. The FD protein is a transcription factor that forms a complex with FT protein; the complex activates promoters for meristem identity genes, such as *APETALA1*.

Genetic studies have shown that the *FT* gene is involved in photoperiod signaling in many species:

- Transgenic plants (e.g., tobacco and tomato) that express the *Arabidopsis FT* gene at high levels flower regardless of day length.
- Transgenic *Arabidopsis* plants that express high levels of *FT* orthologs from other plants (e.g., rice and tomato) flower regardless of day length.

FRONTIERS The events that occur between signal reception by phytochrome and the molecular events of flowering are not clear. Researchers are using molecular and genetic approaches to determine whether altered gene transcription caused by P_r or P_{fr} directly or indirectly affects expression of the *FT* gene. The identification of all the photoperiodic signal transduction steps will advance our understanding of the mechanisms that control flowering.

Whereas photoperiod induces flowering via the FT–FD pathway in some plants, in many other species flowering is induced by other stimuli through other pathways.

Flowering can be induced by temperature or gibberellins

TEMPERATURE In some plant species, notably certain cereal crops, the environmental signal for flowering is exposure to cold temperatures, or **vernalization** (Latin *vernus*, “spring”). In both wheat and rye, we can distinguish two categories of flowering behavior. Spring wheat, for example, is a typical annual plant: it is sown in the spring and flowers in the same year. Winter wheat is sown in the fall, grows into a seedling, overwinters (often covered by snow), and flowers the following summer. If winter wheat is not exposed to cold in its first year, it will not flower normally the next year.

Some strains of *Arabidopsis* require vernalization, and those strains have been useful in elucidating the molecular pathway

APPLY THE CONCEPT

Hormones and signaling determine the transition from the vegetative to the flowering state

Describe the genes and mutations that could be involved in each of the following observations:

1. A mutant plant flowers without its normal inductive dark period. When a leaf from the mutant plant is grafted onto an unexposed wild-type plant, the recipient plant flowers.
2. A mutant plant does not flower when exposed to the normal inductive dark period. When a leaf from a mutant plant that has been exposed to the inductive dark period is grafted onto an unexposed wild-type plant, the recipient plant flowers.
3. A plant flowers only after exposure to cold.
4. If a gene is coupled to an active promoter and expressed at high levels in the shoot apical meristem, flowering is induced even in the absence of an appropriate photoperiodic stimulus.
5. If a gene is experimentally overexpressed in the leaf, flowering is induced. Overexpression of the gene in the shoot apical meristem does not, however, induce flowering.

involved (**FIGURE 27.11**). The gene *FLC* (*FLOWERING LOCUS C*) encodes a transcription factor that blocks the FT–FD pathway by inhibiting expression of FT and FD. Cold temperatures inhibit the synthesis of FLC protein, allowing FT and FD proteins to be expressed and flowering to proceed. Similar proteins control some steps in vernalization in cereals.

GIBBERELLINS *Arabidopsis* plants do not flower if they are genetically deficient in gibberellin synthesis or if they are treated with an inhibitor of gibberellin synthesis. These observations implicate gibberellins in flowering. Direct application of gibberellins to buds in *Arabidopsis* results in activation of the meristem identity gene *LEAFY*, which in turn promotes the transition to flowering (see Concept 14.3).

Some plants do not require an environmental cue to flower

Some plants flower in response to cues from an “internal clock.” For example, flowering in some strains of tobacco is initiated in the apical bud when the stem has grown four phytomers in length (recall that stems are composed of repeating

units called *phytomers*; see Figure 24.1). If a terminal bud and a single adjacent phytomer are removed from a plant this size and planted, the cutting will flower because the bud has already received the cue for flowering. But the rest of the shoot below the bud that has been removed will not flower because it is only three phytomers long. After it grows an additional phytomer, it will flower. These results suggest that there is something about the *position* of the bud (atop four phytomers of stem) that determines its transition to flowering.

LINK The role of positional information in morphogenesis in both plants and animals is described in Concept 14.3

The bud might “know” its position by the concentration of some substance that forms a positional gradient along the apical–basal axis of the plant. Such a gradient could be formed, for example, if the root makes a diffusible inhibitor of flowering whose concentration diminishes with plant height. When the plant reached a certain height, the concentration of the inhibitor would become sufficiently low at the tip of the shoot to allow flowering. What this inhibitor might be is unclear, but there is evidence that it acts by decreasing the amount of FLC, allowing the FT–FD pathway to proceed (just as cold acts on FLC in vernalization). A positional gradient that acts on FLC would be consistent with other mechanisms affecting

FIGURE 27.11 Vernalization A genetic strain of *Arabidopsis* (winter-annual *Arabidopsis*) requires vernalization for flowering. Without it, the plant is large and vegetative (left), but when exposed to a cold period, it is smaller and flowers (right).

flowering, which all converge on the meristem identity genes, *LEAFY* and *APETALA1*:

Do You Understand Concept 27.2?

- How do shoot apical meristems, inflorescence meristems, and floral meristems differ, and what are the genes that control the transitions between them?
- Explain why “short-day plant” is a misleading term.
- If a LDP is exposed to its inductive dark period and one of its leaves is removed and grafted onto a SDP that has not been exposed to its inductive dark period, what will happen?
- How would you show that vernalization acts through the *FLC* gene?

Sexual reproduction is not the only way in which angiosperms give rise to more plants. We will now turn to some ways in which plants can reproduce asexually.

concept 27.3 Angiosperms Can Reproduce Asexually

A plant that reproduces asexually produces progeny genetically identical to itself (*clones*). This mode of reproduction has the disadvantage of not generating the diversity of offspring that sexual reproduction can produce. But if a plant is well

adapted to its environment, the parent plant can pass on to all its progeny a combination of alleles that function well in that environment, and which might otherwise be separated by sexual recombination. Furthermore, the plant avoids the costs of producing flowers and the potentially unreliable processes of cross-pollination and seed germination.

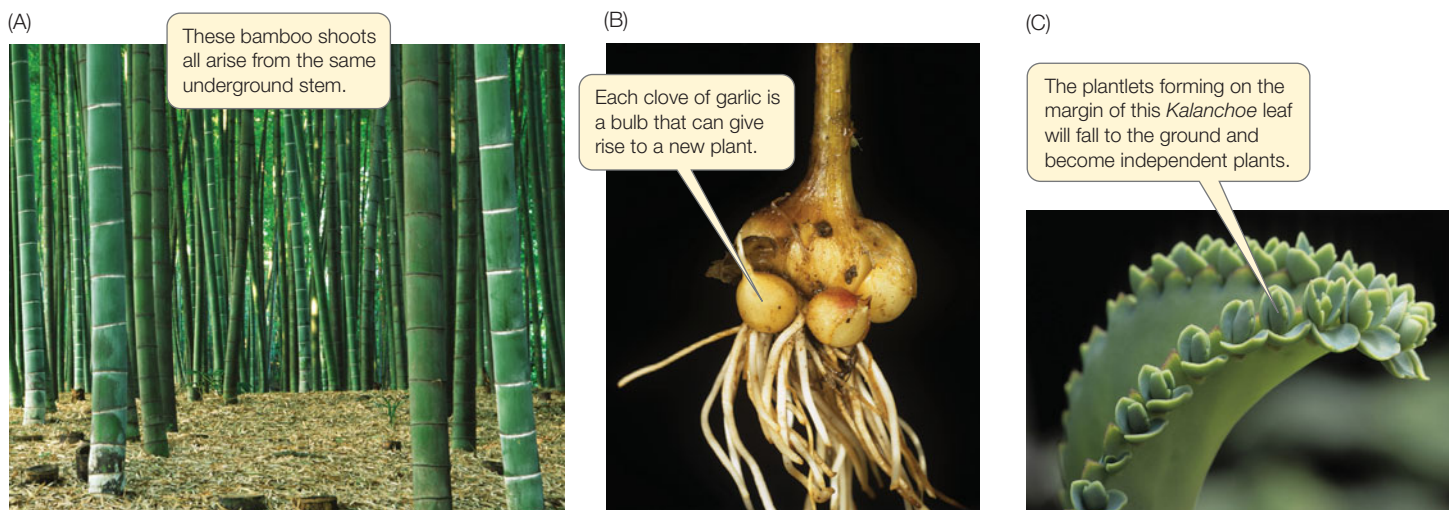

Angiosperms use many forms of asexual reproduction

Asexual reproduction is often accomplished through the modification of vegetative organs such as roots, stems, or leaves, which is why the term **vegetative reproduction** is sometimes used to describe asexual reproduction in plants. Another type of asexual reproduction, **apomixis**, involves flowers but no fertilization.

VEGETATIVE REPRODUCTION The totipotency of plant cells is dramatically shown when a cell from a fully differentiated organ gives rise to an entire new plant. Strawberries, for example, produce horizontal stems, called *stolons* or runners, that grow along the soil surface, form roots at intervals, and establish potentially independent plants (see Figure 24.11C). Another example is bamboo, which has underground stems called *rhizomes* that can form an entire forest (FIGURE 27.12A). Fleshy underground stems, such as potato tubers, produce multiple plants from “eyes” (see Figure 24.11A). Garlic can produce multiple plants from bulbs, which are also modified stems (FIGURE 27.12B). Even leaves can be the source of new plants, as in the succulent *Kalanchoe* (FIGURE 27.12C).

Plants that reproduce vegetatively often grow in physically unstable environments, such as eroding hillsides, or places where conditions for seed germination are unreliable. Plants with stolons or rhizomes, such as beach grasses, rushes, and

FIGURE 27.12 Vegetative Reproduction (A) The rhizomes of bamboo are underground stems that produce plants at intervals. (B) Bulbs are short stems with large leaves that store nutrients and can give rise to new plants. (C) In *Kalanchoe*, new plantlets can form on leaves.

sand verbena, are common on coastal sand dunes. Rapid vegetative reproduction enables these plants, once introduced, not only to multiply but also to stay ahead of the shifting sand; in addition, the dunes are stabilized by the extensive network of rhizomes or stolons that develops. Vegetative reproduction is also common in some deserts, where for much of the time the environment is unsuitable for seed germination and the establishment of seedlings.

APOMIXIS Some plants produce flowers but use them to reproduce asexually rather than sexually. Dandelions, blackberries, some citrus trees, and some other plants reproduce by the asexual production of seeds, called *apomixis*. In sexual reproduction, seeds form from the union of haploid gametes in the embryo sac. But in apomixis, one of two other things happens:

- The megasporocyte in the ovule that is supposed to undergo meiosis fails to do so, resulting in a diploid egg cell, which then goes on to form an embryo and seed.
- Diploid cells from the integument surrounding the embryo sac form a diploid embryo sac, which goes on to form an embryo and seed.

In both cases, seed and fruit development proceed normally. But the genetic consequences are profound: *apomixis produces clones*.

Some agriculturally important plants are hybrids that are derived from the crossing of two genetically different species. Because these hybrids have two sets of chromosomes that are not homologous to one another, they cannot undergo meiosis and are sterile. This means they cannot form the seeds and

fruits that are desired by people. In citrus, apomixis occurs naturally, which gets around this problem. Kentucky bluegrass, a mainstay of lawns, reproduces in this manner as well.

Many important crops, such as corn, are grown as hybrids because the progeny of a cross between two inbred, homozygous genetic strains are often superior to either of their parents, a phenomenon called *hybrid vigor* (see Concept 8.2). Unfortunately, once farmers have obtained a hybrid with desirable characteristics, they cannot use those plants for further crosses with themselves (selfing) to get more seeds for the next generation. You can imagine the genetic chaos when a hybrid, which is heterozygous at many of its loci (e.g., $AaBbCcDdEe$, etc.), is crossed with itself: there will be many new combinations of alleles (e.g., $AabbCCDdee$, etc.), resulting in highly variable progeny. The only way to reliably reproduce the hybrid is to maintain populations of the original parents to cross again each year. That is exactly what seed companies do. For farmers, it means buying new seeds every year—an expensive proposition.

If a hybrid carried a gene for apomixis, however, it could reproduce asexually, and its offspring would be genetically identical to itself (FIGURE 27.13). New hybrids could be developed that would be adapted to specific environments and could be propagated by the farmers on the spot. So an intensive search is on for genes for apomixis that could be introduced into desirable crops and allow them to be propagated indefinitely. Such a gene has been identified in corn, but the yield of the variety that contains it is low.

FRONTIERS In *Arabidopsis* a gene called *dyad* has been identified that causes apomixis when mutated, because the *dyad* protein is necessary for chromosome segregation in meiosis I. Plant scientists are searching for an analogous gene in crop plants and for ways of transferring the mutant *Arabidopsis dyad* gene to crop plants to produce apomictic hybrids.

FIGURE 27.13 The Advantage of Asexual Reproduction by Apomixis Hybrid corn with genes for apomixis could be planted by farmers for use in the next generation of plantings.

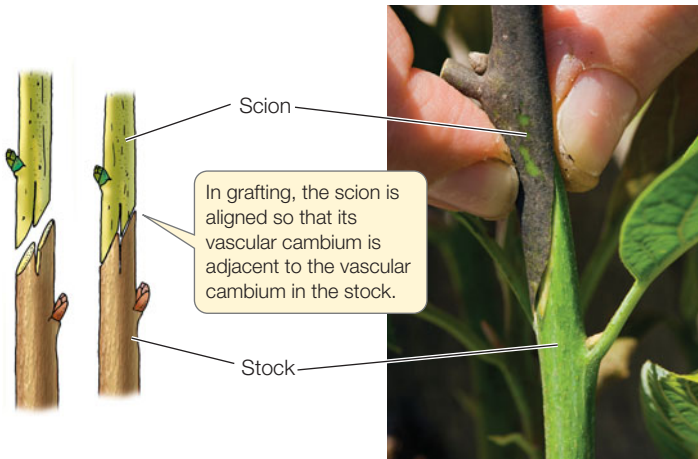

FIGURE 27.14 Grafting Grafting—attaching a piece of a plant to the root or root-bearing stem of another plant—is a common horticultural technique. The “host” root or stem is the stock; the upper grafted piece is the scion. In the photo, an avocado scion is being grafted onto a stock of a different variety of avocado.

Vegetative reproduction is important in agriculture

One of the oldest methods of vegetative reproduction used in agriculture consists of simply making cuttings of stems, inserting them in soil, and waiting for them to form roots and become autonomous plants. The cuttings are usually encouraged to root by treatment with auxin, as described in Concept 26.2.

Woody plants can be propagated asexually by **grafting**: attaching a bud or a piece of stem from one plant to a root or root-bearing stem of another plant. The part of the resulting plant that comes from the root-bearing “host” is called the **stock**; the part grafted on is the **scion** (FIGURE 27.14). The vascular cambium of the scion associates with that of the stock, forming a continuous cambium that produces xylem and phloem. The cambium allows the transport of water and minerals to the scion and of photosynthate to the stock. Much of the fruit grown for market in the United States is produced on grafted trees, as are wine grapes.

Another method widely used for asexual plant propagation is **meristem culture**, in which pieces of shoot apical meristem are cultured on growth media to generate plantlets, which can then be planted in the field. This strategy is vital when uniformity is desired, as in forestry, or when virus-free plants are the goal, as with strawberries and potatoes.

Do You Understand Concept 27.3?

- What are the advantages and disadvantages of asexual as compared with sexual reproduction in plants?
- In addition to the *dyad* mutation, what other kinds of apomixis genes would you search for?
- Most of the navel orange trees that once grew all over southern California are derived by grafting and apomixis from a single tree that still exists in Riverside, CA. How would you prove this?

How did an understanding of angiosperm reproduction allow floriculturists to develop a commercially successful poinsettia?

ANSWER The poinsettia illustrates well how the concepts of plant physiology and reproduction are used in floriculture. As Albert Ecke found, poinsettias are short-day plants, using the long nights of winter as a signal for flowering (Concept 27.2). In fact, the poinsettia’s inductive dark period of 14 hours was among the first described in a flowering plant. The Eckes’ plants did not flower consistently until they moved their growing operations from urban Los Angeles to an isolated rural region with less light pollution. Today the plants are grown in greenhouses, where the photoperiod is carefully regulated.

A second important factor in the poinsettia’s commercial success was the plant’s growth habit. In Mexico, the wild relatives of cultivated varieties grow up to 3 meters tall, with few branches (FIGURE 27.15; compare these plants with the 0.5-meter-tall plants in the photograph at the opening of this chapter). Paul Ecke found a variety that was much shorter and formed an attractive branching plant with axillary shoots. These compact poinsettias were initially propagated asexually by grafting to native plants (Concept 27.3).

The cause of the compact phenotype was assumed to be a dwarfing gene, but several observations cast doubt on this assumption. First, heat treatment of short, branching plants changed their phenotype to the tall, less branched growth habit. Second, heat-treated plants would regain their short, branching growth habit if they were grafted onto untreated short, branching plants. These and other results pointed to a *transmissible infective agent* as the cause of the short, branching phenotype.

FIGURE 27.15 A Wild Relative of Poinsettia Poinsettias growing in the wild in Mexico have an entirely different growth habit from the commercially propagated plants sold for holiday decorations.

Dr. Ing-Ming Lee at the U.S. Department of Agriculture isolated a bacterium called *Phytoplasma* from the short, branching plants and proved by experiments that it was the causative agent of the compact growth habit: when young plants with the tall growth habit were inoculated with the bacteria, they grew up short and branching. It is suspected that

the bacteria change cytokinin levels in the plants, since this hormone regulates branching (see Concept 26.3).

Many new varieties of poinsettias have been generated by conventional sexual reproduction (Concept 27.1). You can look for the phenotypes of these varieties next holiday season. They include stiff stems, new colors (such as white), and longer lifetimes for the colorful bracts.

27

SUMMARY

concept
27.1

Most Angiosperms Reproduce Sexually

- Sexual reproduction promotes genetic diversity in a population. The flower is an angiosperm's structure for sexual reproduction.
- Flowering plants have microscopic gametophytes. The megagametophyte is the **embryo sac**, which typically contains eight nuclei in seven cells. The microgametophyte is the two-celled **pollen grain**. **Review Figure 27.2**
- Following pollination, the pollen grain delivers sperm cells to the embryo sac by means of a pollen tube.
- Angiosperms exhibit double fertilization, forming a diploid zygote that becomes the embryo and a triploid endosperm that stores reserves. **Review Figure 27.4 and ANIMATED TUTORIAL 27.1**

concept
27.2

Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State

- In **annuals** and **biennials**, flowering and seed formation are followed by the death of the rest of the plant. **Perennials** live longer and reproduce repeatedly.
- For a vegetatively growing plant to flower, a shoot apical meristem must become an **inflorescence meristem**, which in turn must give rise to one or more **floral meristems**. These events are determined by specific genes. **Review Figure 27.6**

- Some plants flower in response to **photoperiod**. **Short-day plants (SDPs)** flower when nights are longer than a critical length specific to each species; **long-day plants (LDPs)** flower when nights are shorter than a critical length. **Review Figures 27.7 and 27.8 and ANIMATED TUTORIAL 27.2**
- The mechanism of photoperiodic control of flowering involves phytochromes and a diffusible protein signal, **florigen (FT)**, which is formed in the leaf and is translocated to the shoot apical meristem. **Review Figures 27.9 and 27.10**
- In some angiosperms, exposure to cold—called **vernalization**—is required for flowering. In others, internal signals (such as gibberellin) induce flowering. All of these stimuli converge on the **meristem identity genes**.

concept
27.3

Angiosperms Can Reproduce Asexually

- Asexual reproduction allows rapid multiplication of organisms that are well suited to their environment.
- **Vegetative reproduction** involves the modification of a vegetative organ for reproduction. **Review Figure 27.12**
- Some plant species produce seeds asexually by **apomixis**. **Review Figure 27.13**
- Woody plants can be propagated asexually by **grafting**.

Plants in the Environment

28

In late 1998, William Wagoire, a plant geneticist in Uganda, was astounded when he noticed some red blotches on the stems of wheat plants he was breeding. Wheat rust (*Puccinia graminis*), the fungus that causes the blotches, had supposedly been rendered almost extinct 25 years previously by the “Green Revolution,” when a gene from rye plants had been crossed into wheat, making it resistant to this fungal disease. This landmark achievement had protected the crop that provides one-third of the human diet from a mold that can devastate it.

Two generations of farmers worldwide had never seen an epidemic of wheat rust, but its presence in history is vivid. Even the ancient Romans feared this disease, worshipping a god, “Robigus,” who was thought to help their crop ward off the mold. In the seventeenth century, the early colonists in Massachusetts almost starved because the wheat they planted got infected with wheat rust. In 1917, an epidemic of wheat rust in the United States reduced the crop by one-third, leading to widespread panic.

Wagoire used DNA markers to identify the strain of wheat rust he had found. When he compared it with known strains, which are stored in a few laboratories, he found that his strain was new and unique. Clearly, Ug99 (for Uganda 1999) had evolved a way to get around the resistance genes in modern wheat.

When the blotches of wheat rust on a stem burst, they release thousands of spores, any one of which can be carried by the wind to a susceptible plant. When you consider that 1 hectare of an infected

wheat field can release over 10 billion spores, the possibility of epidemic spread becomes apparent. Ug99 has begun a relentless path of infection, carried by prevailing winds. By 2001 it had wreaked havoc on wheat in Kenya; in 2003 it was in Ethiopia; in 2006 it crossed the Red Sea to Yemen; and in 2009 it was in Iran and Iraq. Biologists now fear that Ug99 could reach North America by the “747 route,” accidentally dusting a traveler’s clothes somewhere in the now widespread infective region. A Global Rust Initiative has been set up to try to use knowledge of plant and fungal biology to stop the spread of this disease before it is too late.

A field of wheat infected with the wheat rust fungus (right) has a much reduced growth rate and produces much less grain than an uninfected field of wheat that is resistant to the fungus (left).

How can knowledge of plant and fungal biology be used to prevent the spread of wheat rust?

KEY CONCEPTS

- 28.1** Plants Have Constitutive and Induced Responses to Pathogens
- 28.2** Plants Have Mechanical and Chemical Defenses against Herbivores
- 28.3** Plants Adapt to Environmental Stresses

concept 28.1 Plants Have Constitutive and Induced Responses to Pathogens

Botanists know of dozens of diseases that can kill a wheat plant, each of them caused by a different pathogen, each of which in turn has many different genetic strains. Plant pathogens—which include fungi, bacteria, protists, and viruses—are part of nature, and for that reason alone they merit our study in biology. Because we humans depend on plants for our food, however, the stakes in our effort to understand plant pathology are especially high. That is why, just as medical schools have departments of pathology, universities in agricultural regions have departments of plant pathology.

Successful infection by a pathogen can have significant effects on a plant, reducing photosynthesis and causing massive cell and tissue death. Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms with which to attack plants, and plants have evolved mechanisms for defending themselves against those attacks. Like the responses of the human immune system, the responses by which plants fight off infection can be either **constitutive**—always present in the plant—or **induced**—produced in reaction to the presence of a pathogen.

LINK The human immune system, with its constitutive and induced defenses, is described in Chapter 31

Physical barriers form constitutive defenses

As with humans and their skin, a plant’s first line of defense is its outer surfaces, which can prevent the entry of pathogens. The parts of stems and leaves exposed to the outside environment are covered with cutin, suberin, and waxes. These substances not only prevent water loss by evaporation but can also prevent fungal spores and bacteria from entering the underlying tissues.

In addition to using physical barriers to prevent infection, plants use chemical warfare. Unlike animals, plants cannot flee from animals that eat them, so they make molecules that deter or destroy herbivores, as we will see in Concept 28.2. Some of these constitutively synthesized molecules also inhibit pathogens. For example, in plantains (*Plantago*) and some other plants, *iridoid glycosides*, which are glucose molecules covalently linked to short-chain fatty acids, inhibit the growth of fungal pathogens.

When constitutive defenses fail to deter a pathogen, plants initiate *induced resistance mechanisms*. As we discuss these mechanisms, refer to the overview in **FIGURE 28.1**.

Induced responses to pathogens may be genetically determined

Plant pathogens *induce* the host plant to activate various chemical defense responses. Many distinctive molecules called

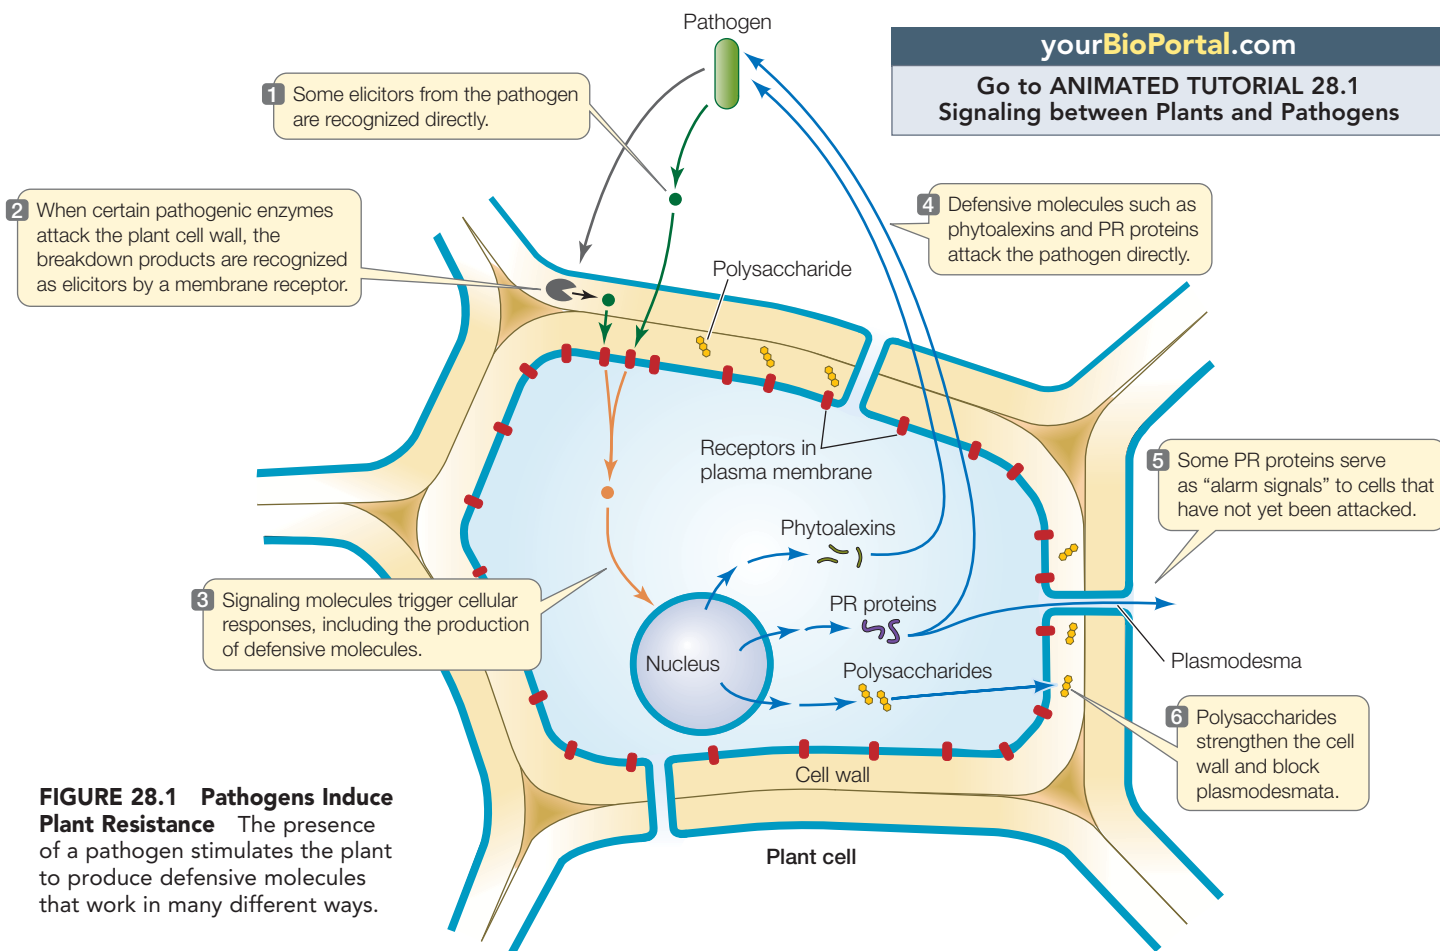

FIGURE 28.1 Pathogens Induce Plant Resistance The presence of a pathogen stimulates the plant to produce defensive molecules that work in many different ways.

elicitors have been identified that trigger these plant defenses. These molecules vary in character, from peptides made by bacteria to cell wall fragments from fungi. Elicitors can also be derived from fragments of plant cell wall components broken down by pathogens (see Figure 28.1, steps 1 and 2). Pathogen genes that code for elicitors are called **avirulence (*Avr*) genes**; there are hundreds of such genes, and they vary among pathogen species and strains.

When an elicitor meets a plant cell, it may encounter a membrane receptor protein encoded by a **resistance (*R*) gene**. There are hundreds of *R* genes, each encoding a receptor that is specific for one or a few elicitors. If a plant receptor binds to an elicitor, a signal transduction pathway is set in motion that leads to the plant's defensive response. This type of resistance is called **gene-for-gene resistance** because it involves a recognition event between two specific molecules: one determined by an *Avr* gene in the pathogen and the other determined by an *R* gene in the plant (FIGURE 28.2).

If the plant has no receptor to bind to the elicitor made by a particular species or strain of pathogen, the plant does not recognize the pathogen and does not turn on its inducible defenses. The lack of a receptor makes the plant especially susceptible to that pathogen. There is an ongoing coevolutionary "arms race" between the ability of pathogens to evade detection by plants and the ability of plants to detect them. A major goal of plant breeders for the past 50 years has been to identify *R* and *Avr* genes and to breed new *R* genes into crops to make them more resistant to pathogens. This effort speeds up the arms race that occurs naturally.

The signal transduction pathway started by receptor–elicitor binding involves the production of nitric oxide and the toxic peroxide H_2O_2 . Together, these substances initiate *local defenses* and, later, *systemic defenses* (defenses in parts of the plant distant from the attack site).

The hypersensitive response fights pathogens at the site of infection

The **hypersensitive response** is a local defense induced by pathogen invasion. This response has three components: the production of *phytoalexins*, the synthesis of *pathogenesis-related (PR) proteins*, and *physical isolation* of the pathogen (see Figure 28.1, steps 3 and 4).

PHYTOALEXINS Phytoalexins are small molecules produced within hours of an infection by plant cells near the infection site. They are antibiotics, toxic to pathogens. An example is *camalexin*, a phy-

FIGURE 28.2 Genes and the Response to a Pathogen If an *Avr* gene in a pathogen that codes for an elicitor "matches" an *R* gene in a plant that codes for a receptor, the receptor binds the elicitor, and a defensive response results. In addition to the production of H_2O_2 and NO, responses may include gene activation and modifications of signaling proteins.

toalexin made by the model organism *Arabidopsis thaliana* from the amino acid tryptophan:

FRONTIERS Why phytoalexins such as camalexin are toxic to pathogens is not clear. However, plant biologists are interested in developing phytoalexins as fungicides that could be sprayed on crops to protect them, especially strains that are not resistant to fungal infection by other means such as *R* genes. To make phytoalexin fungicides work, biologists will have to determine how to get plants to absorb the chemicals and how to prevent possible adverse environmental effects.

PATHOGENESIS-RELATED PROTEINS Plants produce several types of **pathogenesis-related, or PR, proteins**. Some are enzymes that break down the cell walls of pathogens. Chitinase, for example, is a PR protein that breaks down chitin, a distinctive component of fungal cell walls. In some cases, the breakdown products of the pathogen's cell walls serve as elicitors that trigger further defensive responses. Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked, so they can initiate defensive responses of their own (see Figure 28.1, step 5). PR proteins are not rapid-response weapons; rather, they act more slowly, perhaps after other mechanisms have blunted the pathogen's attack.

PHYSICAL ISOLATION A third component of the hypersensitive response seals off the damaged plant tissue and the pathogen

FIGURE 28.3 Sealing Off the Pathogen and the Damage
These necrotic lesions on a peanut leaflet are a response to infection by a strain of early leaf spot fungus (*Cercospora arachidicola*).

from the rest of the plant. Cells around the site of infection undergo apoptosis, preventing the spread of the pathogen by depriving it of nutrients. Some of these cells produce phytoalexins and other toxic chemicals before they die. Others produce cell wall polysaccharides to seal off plasmodesmata and prevent the spread of the pathogen to healthy tissues (see Figure 28.1, step 6). The dead tissue, called a *necrotic lesion*, contains and isolates what is left of the infection (FIGURE 28.3). The rest of the plant remains free of the infecting pathogen.

Plants can develop systemic resistance to pathogens

Systemic acquired resistance is a *general increase in the resistance of the entire plant* to a wide range of pathogens. It is not localized and not limited to the pathogen that originally triggered it, and its effect may last as long as an entire growing season.

This defensive response is initiated by salicylic acid, a chemical produced during the local hypersensitive response:

Systemic acquired resistance is accompanied by the synthesis of PR proteins. Infection in one part of a plant can lead to the export of salicylic acid to other parts, where it triggers the production of PR proteins ahead of the spread of infection. Infected plant parts also produce the closely related compound methyl salicylate (also known as oil of wintergreen). This volatile substance travels to other plant parts through the air and may trigger the production of PR proteins in neighboring plants that have not yet been infected.

Another type of systemic acquired resistance is a more specific defense against viruses whose genomes are made of RNA. The plant uses its own enzymes to convert some of the single-stranded RNA of the invading virus into double-stranded RNA (dsRNA) and to chop that dsRNA into small pieces called small interfering RNAs (siRNAs). The siRNAs interact with another cellular component to degrade viral mRNAs, blocking viral replication. This phenomenon is an example of *RNA interference* (RNAi) (see Figure 13.9). The siRNAs spread rapidly through the plant by way of plasmodesmata, providing systemic resistance.

Do You Understand Concept 28.1?

- Compare constitutive and induced responses to pathogens.
- Explain how inherited traits are involved in both constitutive and induced responses to pathogens.
- If a group of plants is sprayed with oil of wintergreen, they all show resistance to a variety of pathogens. Explain how this occurs.

APPLY THE CONCEPT

Plants have constitutive and induced responses to pathogens

Because you are a biology student, your nonscientist neighbors are confident that you know all about plants. A neighbor brings you a potted plant he bought 3 weeks ago from a nursery. The leaves have brown spots. He bought another plant of the same species from a different nursery 3 weeks ago, and that plant has no spots.

1. You suspect that the spots are caused by either a disease or a nutritional deficiency. Given a large supply of the plants and soils involved, how would you distinguish between these possibilities?
2. Assuming that the spots are caused by a fungal disease, how would you investigate at the molecular level the mechanism for formation of the brown leaf spots?
3. You go to the nursery where the neighbor bought the infected plant and find several pots of plants with no brown spots on their leaves. What mechanisms might account for the absence of spots?

Because they are sessile, plants must deal with herbivores, as they do with pathogens, where they are. But that does not mean they are defenseless against their would-be consumers, as we will see next.

concept 28.2 Plants Have Mechanical and Chemical Defenses against Herbivores

Herbivores—animals that eat plants—depend on plants for energy and nutrients. Their foraging activities cause physical damage to plants, and they often spread pathogens among plants as well. While the majority of herbivores are insects (FIGURE 28.4), most other groups of animals also include some herbivores. Plants have both constitutive and induced mechanisms to protect themselves from herbivory.

Constitutive defenses are physical and chemical

Plants have a number of *constitutive anatomical features*, such as trichomes (leaf hairs), thorns, and spines that may be specialized for defense. In addition, normal plant features, including thick cell walls and tree bark, may deter some herbivores.

Plants revert to “chemical warfare” to repel or inhibit other herbivores, using special chemicals called **secondary metabolites**. These substances are referred to as “secondary” because, unlike proteins and nucleic acids, they are not used for basic cellular processes. The more than 10,000 known secondary metabolites range in molecular mass from about 70 to more than 390,000 daltons, but most are small (TABLE 28.1). Some are produced by only a single plant species, whereas others are characteristic of entire genera or even families. The effects of defensive secondary metabolites on animals are diverse. Some act on the nervous systems of herbivorous insects, mollusks, or mammals. Others mimic the natural hormones of insects, causing some larvae to fail to develop into adults. Still others damage the digestive tracts of herbivores, and others are toxic to fungal pathogens.

An example of a secondary metabolite is *canavanine*, an amino acid that is similar to the amino acid arginine:

(A) *Locusta migratoria*

(B) *Manduca sexta*

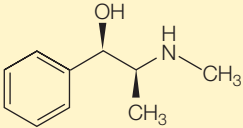

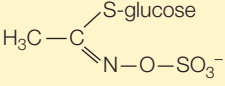

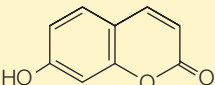

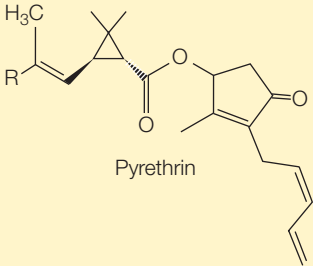

FIGURE 28.4 Insect Herbivores The great majority of herbivores are insects. (A) Some herbivores, such as this locust, are generalists that will attack nearly any plant. (B) Others are specialists, like this tobacco hornworm (the caterpillar of the Carolina sphinx moth), which feeds only on tobacco plants and a few closely related species.

When an insect larva consumes canavanine-containing plant tissue, the canavanine is incorporated into the insect’s proteins in some of the places where the insect’s mRNA codes for arginine. The enzyme that charges the tRNA specific for arginine fails to discriminate accurately between the two amino acids. The structure of canavanine, however, is different enough from that of arginine that some of the resulting proteins end up with a modified tertiary structure and hence reduced biological activity. These defects in protein structure and function lead to developmental abnormalities that kill the insect.

LINK The charging of tRNA is described in Concept 10.4

While the mechanisms of action of secondary metabolites and their presence in plant tissues are circumstantial evidence of their role in defense, experiments can be done to provide cause-and-effect evidence. Nicotine, for example, kills insects by acting as an inhibitor of nervous system function, and its function in tobacco is presumed to be insecticidal. Yet commercial varieties of tobacco and related plants that produce nicotine are still attacked, with moderate damage, by pests such as the tobacco hornworm (see Figure 28.4B). Given that observation, does nicotine really deter herbivores? Biologists answered this question conclusively with a study that used tobacco plants in which an enzyme involved in nicotine biosynthesis had been

TABLE 28.1 Secondary Metabolites Used in Plant Defense

CLASS	TYPE	ROLE	EXAMPLE
Nitrogen-containing	Alkaloids	Neurotoxin	Nicotine in tobacco
	Glycosides	Inhibit electron transport	Dhurrin in sorghum
	Nonprotein amino acids	Disrupt protein structure	Canavanine in jack bean
	Ephedrine (an alkaloid)		
Nitrogen- and sulfur-containing	Glucosinolates	Inhibit respiration	Methylglucosinolate in cabbage
	Methylglucosinolate		
Phenolics	Coumarins	Block cell division	Umbelliferone in carrots
	Flavonoids	Phytoalexins	Capsidol in peppers
	Tannins	Inhibit enzymes	Gallotannin in oak trees
	Umbelliferone		
Terpenes	Monoterpenes	Neurotoxins	Pyrethrin in chrysanthemums
	Diterpenes	Disrupt reproduction and muscle function	Gossypol in cotton
	Triterpenes	Inhibit ion transport	Digitalis in foxglove
	Sterols	Block animal hormones	Spinasterol in spinach
	Polyterpenes	Deter feeding	Latex in <i>Euphorbia</i>
		Pyrethrin	

inhibited, lowering the nicotine concentration in the plants by more than 95 percent. These low-nicotine plants suffered much more damage from insect herbivory than normal plants did (**FIGURE 28.5**).

FRONTIERS Secondary metabolites have long been used by people as medicines. Salicylic acid, for example, is the basis of aspirin (see Chapter 3). Screening metabolites for pharmaceutical activity is a major activity in drug development. The foods we eat also contain many secondary metabolites, and scientists are trying to determine their effects on human health. Some cause diseases such as cancer, and others prevent them.

Plants respond to herbivory with induced defenses

The first step in a plant's response to herbivory is to sense the attack, either by means of changes in membrane potential or by means of chemical signals. The detection of an herbivore attack then triggers signal transduction pathways that induce plant defenses.

MEMBRANE SIGNALING The plasma membrane is the part of the plant cell that is in contact with the environment. Within the first minute after an herbivore strikes, changes in the electric potential of the plasma membrane occur in the damaged area. The continuity of the *symplast* (see Concept 25.3) ensures that the signal travels over much of the plant within 10 minutes.

LINK In animals, direct electrical coupling between cells occurs only in specific tissues, such as cardiac muscle; see Concept 36.1

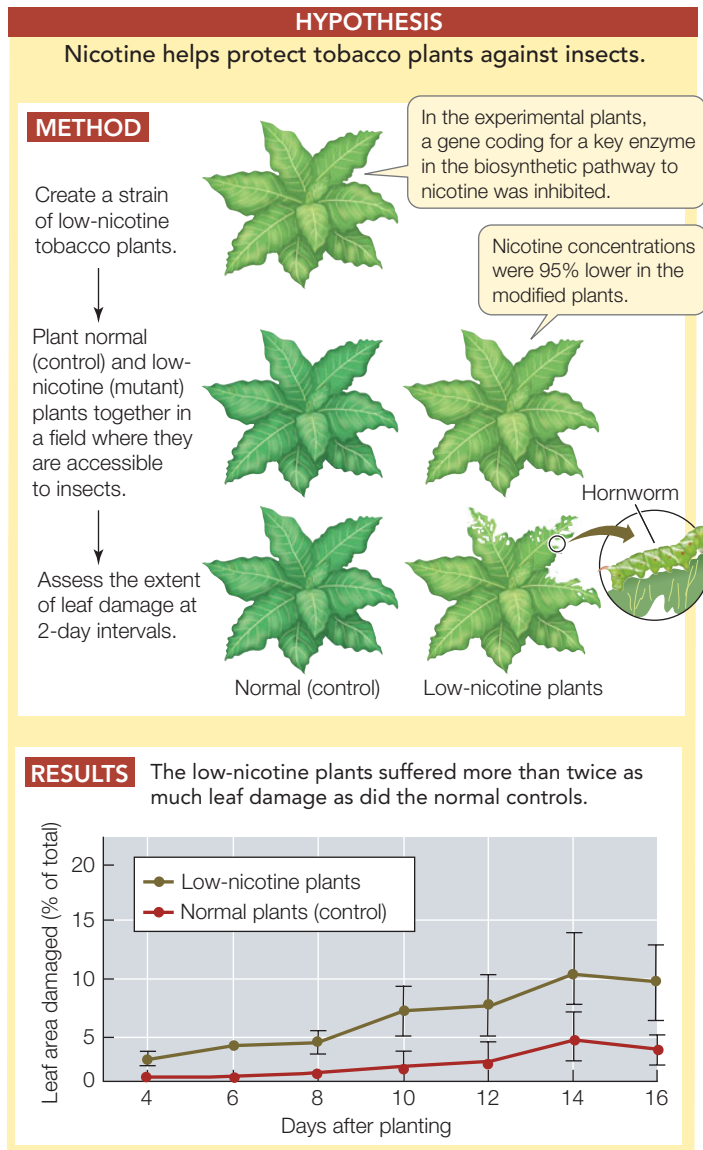

CHEMICAL SIGNALING When some insects (such as caterpillars) chew on a plant, substances in the insect's saliva combine with fatty acids derived from the consumed plant tissue. The resulting compounds act as elicitors to trigger both local and systemic responses to the herbivore. In corn, the elicitor produced by one particular moth larva has been named *volicitin* for its ability to induce production of volatile signals that can travel to other plant parts—and to neighboring corn plants—and simulate their defensive responses.

INVESTIGATION

FIGURE 28.5 Nicotine Is a Defense against Herbivores

The secondary metabolite nicotine, made by tobacco plants, is an insecticide, yet most commercial varieties of tobacco are suscep-

tible to insect attack. Ian Baldwin demonstrated that a tobacco strain with a reduced nicotine concentration was much more susceptible to insect damage.

CONCLUSION

Nicotine provides tobacco plants with at least some protection against insects.

ANALYZE THE DATA

In a separate experiment, Baldwin and his colleagues showed that treatment with jasmonic acid (jasmonate) increased the concentration of nicotine in normal tobacco plants, but not in the low-nicotine plants. The researchers planted a group of normal and low-nicotine plants and treated them with jasmonate seven days after planting. The plants were assessed for herbivore damage every 2 days after being planted. Here are the results:

- Compare these data to those at left for the untreated plants. What was the effect of jasmonate treatment on the resistance of normal plants to herbivore damage? What was the effect on low-nicotine plants?
- What do these data reveal about the role of nicotine in preventing herbivore damage?
- Explain how jasmonate could have had the effect it did on the low-nicotine plants, even though their nicotine levels were still low after jasmonate treatment.
- The error bars at each data point are the standard error of the mean (SEM). What statistical test would you use to determine the possible significance of differences between the jasmonate-treated and untreated plants? At 10 days, the mean damage \pm SEMs for untreated low-nicotine plants was 6.0 ± 1.5 percent ($n = 36$), and for treated low-nicotine plants it was 2.2 ± 0.6 percent ($n = 28$). Run a statistical test comparing the two results, calculate the P -value, and comment on significance.

SIGNAL TRANSDUCTION PATHWAY The perception of damage from herbivory can initiate a signal transduction pathway in the plant that involves the plant hormone *jasmonic acid* (**jasmonate**) (FIGURE 28.6; also see Figure 28.5, Analyze the Data):

When the plant senses a herbivore-produced elicitor, it makes jasmonate, which triggers many plant defenses, including the synthesis of a protease inhibitor. The inhibitor, once in an insect's gut, interferes with the digestion of proteins and thus stunts the insect's growth. Jasmonate also "calls for help" by triggering the formation of volatile compounds that attract insects that prey on the herbivores attacking the plant. Similarly, the volatile compounds induced by volicitin in corn attract wasps that parasitize herbivorous caterpillars, so the "call for help" is a recurrent theme in plant-insect interactions.

FIGURE 28.6 A Signaling Pathway for Induced Defenses against Herbivory The chain of events initiated by herbivory that leads to the production of a defensive chemical can consist of many steps. These steps may include the synthesis of one or two hormones, binding of receptors, gene activation, and finally, synthesis of the defensive chemical.

Why don't plants poison themselves?

Why don't the constitutive defensive chemicals that are so toxic to herbivores and pathogens kill the plants that produce them? Plants that produce toxic defensive chemicals generally use one of several measures to protect themselves.

COMPARTMENTALIZATION Isolation of the toxic substance is the most common means of avoiding exposure. Plants store their toxins in vacuoles if the toxins are water-soluble. If they are hydrophobic, the toxins may be dissolved in latex (a complex mixture of dissolved molecules and suspended particles) and stored in a specialized compartment, or they may be dissolved in waxes on the epidermal surface. Such compartmentalized storage keeps the toxins away from the mitochondria, chloroplasts, and other parts of the plant's metabolic machinery.

STORAGE OF PRECURSORS Some plants store the precursors of toxic substances in one type of tissue, such as the epidermis, and store the enzymes that convert those precursors into the active toxin in another type, such as the mesophyll. When an herbivore chews part of the plant, cells are ruptured, the enzymes come into contact with the precursors, and the toxin is

produced. The only part of the plant that is damaged by the toxin is that which was already damaged by the herbivore. Plants such as sorghum and some legumes, which respond to herbivory by producing cyanide (a potent inhibitor of cellular respiration), are among those that use this type of protective measure.

MODIFIED PROTEINS The plant has modified proteins that do not react with the toxin. As noted above, canavanine resembles arginine and therefore plays havoc with protein synthesis in insect larvae. In plants that make canavanine, the plant enzyme that charges the arginine tRNA discriminates correctly between arginine and canavanine, so canavanine is not incorporated into the plant's proteins.

Plants don't always win the arms race

Milkweeds such as *Asclepias syriaca* store their defensive chemicals in latex in specialized tubes called **laticifers**, which run alongside the veins in the leaves. When damaged, a milkweed releases copious amounts of toxic latex from its laticifers. Field studies have shown that most insects that feed on neighboring plants of other species do not attack laticiferous plants, but there are exceptions. One population of beetles that feeds on *A. syriaca* exhibits a remarkable prefeeding behavior: these beetles cut a few veins in the leaves before settling down to dine. Cutting the veins causes massive latex leakage from the adjacent laticifers and interrupts the latex supply to a downstream

portion of the leaf. The beetles then move to the relatively latex-free portion and eat their fill.

Latex from laticifer

This is just one of many ways that herbivores circumvent plant defenses. A successful plant defense exerts strong selection pressure on herbivores to get around it somehow; a successful herbivore, in turn, exerts strong selection pressure on plants to develop new defensive strategies. One can imagine, for example, that over time, *A. syriaca* might evolve to have thicker walls around the base of its laticifers, such that the beetles can no longer cut them, or to produce a different toxin that does not depend on laticifers.

Do You Understand Concept 28.2?

- Using a plant growing near you as an example, describe anatomical features that help plants avoid herbivores.
- A mutant strain of a plant makes jasmonate constitutively. What would be the phenotype of this plant?
- You have isolated a secondary metabolite from apple tree leaves. What circumstantial and experimental evidence would you use to show that the metabolite prevents the herbivorous larva of the moth *Spilonota ocellana* from damaging apple orchards?

In addition to coping with their biological enemies, plants must survive in their physical environment. Plants have a number of adaptations that allow them to cope with stressful environmental conditions.

concept 28.3 Plants Adapt to Environmental Stresses

In an ever-changing environment, plants face a number of potential stressors: drought, submersion, heat, cold, and high concentrations of salt and heavy metals in the soil. Here we will focus on the overall mechanisms by which plants deal with extremes of climate and soil conditions. You will see that in these cases,

as with defenses against pathogens and herbivores, there are constitutive defenses (adaptations) as well as induced responses.

Some plants have special adaptations to live in very dry conditions

Many plants, especially those living in deserts, must cope with extremely limited water supplies. A variety of anatomical and life-cycle adaptations allow plants to survive under these conditions. Many of these adaptations are ways to avoid or reduce the inevitable water loss through transpiration that occurs during active photosynthesis (see Concept 25.3). Other adaptations help plants tolerate the high levels of light and heat that are often found in deserts.

DROUGHT AVOIDERS Some desert plants have no special structural adaptations for water conservation. Instead, these desert annuals, called *drought avoiders*, simply evade periods of drought. Drought avoiders carry out their entire life cycle—from seed to seed—during a brief period in which rainfall has made the surrounding desert soil sufficiently moist for growth and reproduction (FIGURE 28.7). A different drought

FIGURE 28.7 Desert Annuals Avoid Drought The seeds of many desert annuals lie dormant for long periods, awaiting conditions appropriate for germination. When they do receive enough moisture to germinate, they grow and reproduce rapidly before the short wet season ends. During the long dry spells, only dormant seeds remain alive.

avoidance strategy is seen in deciduous perennial plants, particularly in Africa and South America, that shed their leaves in response to drought as a way to conserve water. These plants remain dormant until conditions are again favorable for growth, much as deciduous trees in temperate climates shed their leaves in fall and are dormant until the following spring.

LEAF STRUCTURES Most desert plants are not drought avoiders, but rather grow in their dry environment year-round. Plants adapted to dry environments are called **xerophytes** (Greek *xeros*, “dry”). Three structural adaptations are found in the leaves of many xerophytes:

- Specialized leaf anatomy that reduces water loss
- A thick cuticle and a profusion of trichomes over the leaf epidermis, which retard water loss
- Trichomes that diffract and diffuse sunlight, thereby decreasing the intensity of light impinging on the leaves and the risk of damage to the photosynthetic apparatus by excess light

In some xerophytes, the stomata are strategically located in sunken cavities below the leaf surface (known as *stomatal crypts*), where they are sheltered from the drying effects of air currents (**FIGURE 28.8**). Trichomes surrounding the stomata slow air currents further. Cacti and similar plants have spines rather than typical leaves, and photosynthesis is confined to the fleshy stems. The spines may help the plants cope with desert conditions by reflecting solar radiation or by dissipating heat. The spines also deter herbivores.

WATER-STORING STRUCTURES Succulence—the possession of fleshy, water-storing leaves or stems—is another adaptation to dry environments (**FIGURE 28.9**). This adaptation allows plants to take up large amounts of water when it is available (such as after a brief thunderstorm) and then draw on the stored water during subsequent dry periods. Other

FIGURE 28.8 Stomatal Crypts Stomata in the leaves of some xerophytes, in this case oleander (*Nerium oleander*), are located in sunken cavities called stomatal crypts. The trichomes (hairs) covering these crypts trap moist air.

FIGURE 28.9 Succulence *Aloe vera* stores water in its fleshy leaves.

adaptations of succulents include a reduced number of stomata and a variant form of photosynthesis, both of which reduce water loss.

ROOT SYSTEMS THAT MAXIMIZE WATER UPTAKE Roots may also be adapted to dry environments. Cacti have shallow but extensive fibrous root systems that effectively intercept water at the soil surface following even light rains. The tamarugo tree (**FIGURE 28.10**) obtains water through taproots that grow to great depths, reaching water supplies far underground, as well as from condensation on its leaves. The Atacama Desert in northern Chile often goes several years without measurable rainfall, but the landscape there has many surprisingly large shrubs.

SOLUTE ACCUMULATION Xerophytes and other plants that must cope with inadequate water supplies may accumulate high concentrations of the amino acid proline or of secondary metabolites in their vacuoles. This solute accumulation lowers the water potential in the plant’s cells below that in the soil, which allows the plant to take up water via osmosis. Plants living in saline environments share this and several other adaptations with xerophytes, as we will see shortly.

LINK Review the principles of water potential and water movement in Concept 25.3

Some plants grow in saturated soils

For some plants, the environmental challenge is the opposite of that faced by xerophytes: too much water. They live in environments so wet that the diffusion of oxygen to their roots is severely limited. These plants have shallow root systems that grow slowly; oxygen levels are likely to be highest near the surface of the soil, and slow growth decreases the roots’ need for oxygen.

The root systems of some plants adapted to swampy environments, such as cypresses and some plants that grow in

FIGURE 28.10 Mining Water with Deep Taproots In the Atacama desert in Chile, the roots of this tamarugo tree (*Prosopis tamarugo*) must grow far beneath the soil surface to reach water.

Plants can respond to drought stress

The adaptations of xerophytes for coping with dry environments are generally constitutive—they are always present—and under normal conditions they prevent the plants from experiencing drought stress. When conditions become so dry that even xerophytes are stressed, however, the plants turn to inducible responses. The same responses are found in many other plants, including those that are not adapted to grow in dry climates.

coastal mangrove habitats, have **pneumatophores**, which are extensions that grow out of the water and up into the air (**FIGURE 28.11A**). Pneumatophores contain *lenticels* (openings) that allow oxygen to diffuse through them, aerating the submerged parts of the root system.

Many submerged or partly submerged aquatic plants have large air spaces in the leaf and stem parenchyma and in the petioles. Tissue containing such air spaces is called **aerenchyma** (**FIGURE 28.11B**). Aerenchyma stores oxygen produced by photosynthesis and permits its ready diffusion to parts of the plant where it is needed for cellular respiration. Aerenchyma also imparts buoyancy. Furthermore, because aerenchyma contains far fewer cells than most other plant tissues, metabolism in aerenchyma proceeds at a lower rate, so the need for oxygen is much reduced.

When the weather is abnormally dry, the water content of the soil is reduced, and less water is available to plants. Water deficits in plant cells have two major biochemical effects: a reduction in membrane integrity as the polar–nonpolar forces that orient the lipid bilayer are reduced, and changes in the three-dimensional structures of proteins. Plant growth is reduced when the structure of plant cells is compromised in these ways. Indeed, inadequate water supply is the single most important factor that limits production of our most important food crops.

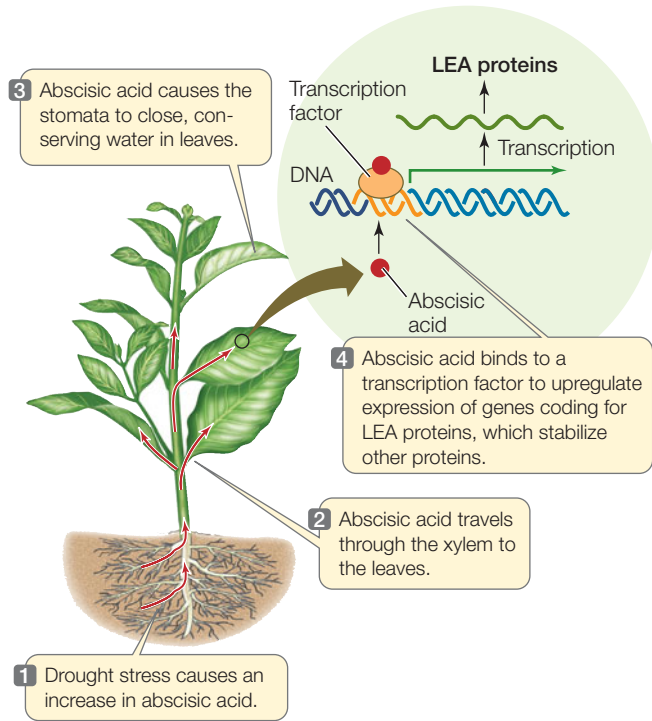

FIGURE 28.11 Plant Adaptations to Saturated Habitats

(A) The submerged roots of mangrove trees obtain oxygen through pneumatophores. (B) This cross section of a petiole of the yellow water lily shows the air-filled channels of aerenchyma tissue.

Pneumatophores are root extensions that grow out of the water, under which the rest of the roots are submerged.

When plants sense a water deficit in their roots, a signaling pathway is set in motion that initiates several measures to conserve water and maintain cellular integrity. This pathway begins with the production of the hormone abscisic acid (see Concept 26.3) in the roots. This hormone travels from the roots to the shoot, where it causes stomatal closure and initiates gene transcription that leads to other physiological events that conserve water and cellular integrity (FIGURE 28.12).

Many plant genes whose expression is altered by drought stress have been identified, largely through research using DNA microarrays, proteomics, and other molecular approaches (see Chapters 12 and 13). One group of proteins whose production is upregulated during drought stress is the *late embryogenesis abundant* (LEA; pronounced “lee-yuh”) proteins.

FIGURE 28.12 A Signaling Pathway in Response to Drought Stress Acclimation to drought stress begins in the root with the production of the hormone abscisic acid.

These hydrophobic proteins also accumulate in maturing seeds as they dry out (hence their name). The LEA proteins bind to membrane proteins and other cellular proteins to stabilize them, preventing their aggregation during desiccation.

Plants can cope with temperature extremes

Temperatures that are too high or too low can stress plants and even kill them. Plant species differ in their sensitivity to heat and cold, but all plants have their limits. Any temperature extreme can damage cellular membranes.

- High temperatures destabilize membranes and denature many proteins, especially some of the enzymes of photosynthesis.
- Low temperatures cause membranes to lose their fluidity and alter their permeabilities to solutes.
- Freezing temperatures may cause ice crystals to form, damaging membranes.

Plants have both constitutive adaptations and inducible responses for coping with temperature extremes.

ANATOMICAL ADAPTATIONS Many plants living in hot environments have constitutive adaptations similar to those of xerophytes. These adaptations include hairs and spines that dissipate heat and leaf forms that intercept less direct sunlight.

HEAT SHOCK RESPONSE The plant inducible response to heat stress is similar to the response to drought stress in that new proteins are made, often under the direction of an abscisic acid–mediated signaling pathway. Within minutes of experimental

APPLY THE CONCEPT

Plants respond to environmental stresses

The *Arabidopsis* gene *cor15a* is under the control of a promoter that responds to environmental conditions. *Arabidopsis* plants were genetically modified with a copy of the *cor15a* promoter fused to a reporter gene that is expressed as an enzyme that is readily detected in leaf extracts. The transgenic plants were transferred to environments kept at two different temperatures (19°C and 2°C), and the enzyme activity in their leaves was measured at different times after the transfer. The results are shown in the table.

1. Plot these data with hours after transfer on the x axis and enzyme activity on the y axis. What can you conclude about the role of *cor15a*?
2. In a separate experiment, plants were kept at 19°C for 36 hours in the presence of abscisic acid, and the

HOURS AFTER TRANSFER	ENZYME ACTIVITY (UNITS/g LEAF PROTEIN)	
	19°C	2°C
12	0.35	3.21
24	0.51	5.66
36	0.45	9.65
48	0.60	10.10
72	0.49	11.33

enzyme activity was 8.99. What can you conclude from this result?

3. How would you investigate the possible role of *cor15a* in the plant’s response to drought? Why would you expect that there might be such a role?

FIGURE 28.13 Salty Soil Accumulation of salt from irrigation water in an area with inadequate drainage has caused this soil in central California (San Joaquin Valley) to become unsuitable for most plant growth.

exposure to raised temperatures (typically a 5°C–10°C increase), plants synthesize several kinds of **heat shock proteins**. Among these proteins are *chaperonins*, which help other proteins maintain their structures and avoid denaturation. Threshold temperatures for the production of heat shock proteins vary, but 39°C is sufficient to induce them in most plants.

COLD-HARDENING Low temperatures above the freezing point can cause *chilling injury* in many plants, including crops such as rice, corn, and cotton as well as tropical plants such as bananas. Many plant species can acclimate to cooler temperatures through a process called **cold-hardening**, which requires repeated exposure to cool temperatures over many days. A key change during the hardening process is an increase in the proportion of unsaturated fatty acids in cell membranes, which allows them to retain their fluidity and function normally at cooler temperatures (see Figure 2.12). Plants have a greater ability to modify the degree of saturation of their membrane lipids than animals do. In addition, low temperatures induce the formation of proteins similar to heat shock proteins, which protect against chilling injury.

If ice crystals form within plant cells, they can kill the cells by puncturing organelles and plasma membranes. Furthermore, the growth of ice crystals outside the cells can draw water from the cells and dehydrate them. Freeze-tolerant plants have a variety of adaptations to cope with these problems, including the production of *antifreeze proteins* that slow the growth of ice crystals.

Some plants can tolerate soils with high salt concentrations

Salty, or *saline*, environments (high in Na⁺, K⁺, Ca²⁺, and Cl⁻) are found in nature in diverse locales, from hot, dry deserts to moist, cool coastal marshes. Much of the land in Australia is naturally saline. In addition, agricultural land can become increasingly saline as a result of irrigation and the application of

chemical fertilizers. This *salinization*, which can eventually make land unsuitable for farming, is an increasing problem worldwide (**FIGURE 28.13**).

Because of its high salt concentration, a saline environment has a very negative water potential. To obtain water from such an environment, a plant must have an even more negative water potential (see Concept 25.3); otherwise water will diffuse out of its cells, and the plant will wilt and die. Plants in saline environments are also challenged by the potential toxicity of sodium ions, which inhibit enzymes and protein

synthesis.

Plants that are adapted for survival in saline soils are called **halophytes**. Most halophytes take up Na⁺, and many take up Cl⁻, into their roots and transport those ions to their leaves, where they accumulate in the central vacuoles of leaf cells, away from more sensitive parts of the cells. The accumulated salts in the tissues of halophytes make their water potential more negative than the soil solution and allow them to take up water from their saline environment.

FRONTIERS Knowledge about the mechanisms by which plants accumulate salt is being applied to plant breeding. Selection of mutant *Arabidopsis* plants that can tolerate high salt concentrations has led to the isolation of a gene for salt tolerance and the creation of transgenic crop plants that can tolerate saline conditions. Agricultural scientists and farmers hope that these transgenic crops will allow farming in regions where salinization has made agriculture unfeasible.

Some halophytes have **salt glands** in their leaves. These glands excrete salt, which collects on the leaf surface until it is removed by rain or wind (**FIGURE 28.14**). This adaptation, which reduces the danger of poisoning by accumulated salt, is found in some desert plants and in some plants growing in mangrove habitats. The negative water potential in the salt-laden leaves also promotes water flow from the roots up through the xylem by *transpiration–cohesion–tension* (see Concept 25.3).

Some plants can tolerate heavy metals

High concentrations of heavy metal ions are toxic to most plants. Some soils are naturally rich in heavy metals as a result of normal geological processes or acid rain. The mining of metallic ores also leaves localized areas with high concentrations of heavy metals and low concentrations of nutrients.

FIGURE 28.14 Excreting Salt This saltwater mangrove plant has specialized glands that excrete salt, which appears here as crystals on the leaves.

Such sites are hostile to most plants, and seeds falling on them generally do not produce adult plants.

Some plants can survive in these environments, however, by accumulating concentrations of heavy metals that would kill most plants. Over 200 plant species have been identified as **hyperaccumulators** that store large quantities of metals such as arsenic (As), cadmium (Cd), nickel (Ni), aluminum (Al), and zinc (Zn).

Perhaps the best-studied hyperaccumulator is alpine pennycress (*Thlaspi caerulescens*). Before the advent of chemical analysis, miners used the presence of this plant as an indicator of mineral-rich deposits. A *Thlaspi* plant may accumulate as much as 30 g/kg Zn (most plants contain 0.1 g/kg) and 1.5 g/kg Cd (most plants contain 0.001 g/kg). Studies of *Thlaspi* and other hyperaccumulators have revealed the presence of several common adaptations:

- Increased ion transport into the roots
- Increased rates of translocation of ions to the leaves
- Accumulation of ions in vacuoles in the shoot
- Resistance to the ions' toxicity

Knowledge of these hyperaccumulation mechanisms and the genes underlying them has led to the emergence of **phytoremediation**, a form of bioremediation (see Chapter 13) that uses plants to clean up environmental pollution in soils. Some phytoremediation projects use natural hyperaccumulators, while others use genes from hyperaccumulators

FIGURE 28.15 Phytoremediation Plants that accumulate heavy metals can be used to clean up contaminated soils. Here, poplars are being used to remove contaminants from an air base.

to create transgenic plants that grow more rapidly in and are better adapted to a particular polluted environment. In either case, the plants are grown in the contaminated soil, where they act as natural “vacuum cleaners” by taking up the contaminants (**FIGURE 28.15**). The plants are then harvested and disposed of to remove the contaminants. Perhaps the most dramatic use of phytoremediation occurred after an accident at the nuclear power plant at Chernobyl, Ukraine (then part of the Soviet Union), in 1986, when sunflower plants were used to remove uranium from the nearby soil. Phytoremediation is now widely used to clean up land after strip mining.

Do You Understand Concept 28.3?

- Compare the constitutive and induced mechanisms that allow plants to cope with drought conditions.
- Describe a mechanism shared by plants that tolerate high concentrations of salts and those that tolerate heavy metals.
- If an inhibitor of abscisic acid synthesis was sprayed on a plant and the plant was exposed to drought conditions, what would happen? Give details.

How can knowledge of plant and fungal biology be used to prevent the spread of wheat rust?

ANSWER Today, *Puccinia graminis* strain Ug99 continues its spread and threatens wheat crops worldwide. In the Green Revolution of the 1960s to 1980s, wheat plants were bred to have the gene complexes *Sr24* and *Sr31*, *R* genes that conferred resistance to existing strains of wheat rust fungus (Concept 28.1). The first strain of Ug99 found in Uganda had *Avr* genes that form elicitor proteins that do not bind to *Sr31* and

therefore overcome part of the plant's resistance. Then, in 2006, a new genetic variant of Ug99 was found in Kenya with additional *Avr* genes that allow the pathogen to overcome the *Sr24* gene resistance as well (FIGURE 28.16).

Because 90 percent of the wheat grown in the world has no resistance to this new strain of Ug99, an intensive search is under way for additional wheat resistance genes. In the regions where Ug99 infections are now raging, occasional wheat plants grow that are resistant. Samples of both wheat plants and fungus are sent to a U.S. government laboratory in Minnesota, where, under high security and sterility, they are tested and examined for *Avr* and *R* genes. In addition, seeds from thousands of varieties of wheat, collected from all over the world, are being grown into seedlings and examined for *R* genes.

FIGURE 28.16 Overcoming Resistance to Pathogens Blotches caused by wheat rust are visible on the stem of a wheat plant. This plant has a gene called *Sr24* that confers resistance to the wheat rust pathogen, but it has been infected by a strain of the pathogen, Ug99, that can overcome that resistance.

28 SUMMARY

concept 28.1 Plants Have Constitutive and Induced Responses to Pathogens

- Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms for attacking plants, and plants have evolved mechanisms for defending themselves against those attacks.
- Some of the responses by which plants fight off pathogens are **constitutive**—always present in the plant—whereas others are **induced**—produced in reaction to the presence of a pathogen. **Review Figure 28.1 and ANIMATED TUTORIAL 28.1**
- Plants use physical barriers to block pathogen entry and seal off infected regions.
- Gene-for-gene resistance** depends on a match between a plant's **resistance (*R*) genes** and a pathogen's **avirulence (*Avr*) genes**. **Review Figure 28.2**
- In the **hypersensitive response** to infection, cells produce **phytoalexins** and **pathogenesis-related (PR) proteins**, and the plant isolates the area of infection by forming necrotic lesions.
- The hypersensitive response may be followed by another defensive reaction, **systemic acquired resistance**, in which salicylic acid activates further synthesis of defensive compounds throughout the plant.

concept 28.2 Plants Have Mechanical and Chemical Defenses against Herbivores

- Physical structures such as spines and thick cell walls deter some herbivores.
- Plants produce **secondary metabolites** as defenses against herbivores. **Review Table 28.1, Figure 28.5, and WORKING WITH DATA 28.1**

- Hormones, including **jasmonate**, participate in signaling pathways leading to the production of defensive compounds. **Review Figure 28.6**
- Plants protect themselves against their own toxic defensive chemicals by compartmentalizing those chemicals, by storing their precursors separately, or through modifications of their own proteins.

concept 28.3 Plants Adapt to Environmental Stresses

- Xerophytes** are plants adapted to dry environments. Their structural adaptations include thickened cuticles, specialized trichomes, **stomatal crypts**, **succulence**, and long taproots.
- Some plants accumulate solutes in their cells, which lowers their water potential so they can more easily take up water.
- Adaptations to water-saturated habitats include **pneumatophores**, extensions of roots that allow oxygen uptake from the air, and **aerenchyma**, tissue in which oxygen can be stored and can diffuse throughout the plant. **Review Figure 28.11**
- A signaling pathway involving abscisic acid initiates a plant's response to drought stress. **Review Figure 28.12**
- Plants respond to high temperatures by producing **heat shock proteins**. Low temperatures can result in **cold-hardening**.
- Plants that are adapted for survival in saline soils are called **halophytes**. Most halophytes accumulate salt. Some have **salt glands** that excrete salt to the leaf surface.
- Some plants living in soils that are rich in heavy metals are **hyperaccumulators** that take up and store large amounts of those metals into their tissues.
- Phytoremediation** is the use of hyperaccumulating plants or their genes to clean up environmental pollution in soils.

See **WEB ACTIVITY 28.1** for a concept review of this chapter.

PART

6

Animal Form and Function

Physiology, Homeostasis, and Temperature Regulation

29

Ground squirrels live in high mountains such as California's Sierra Nevada, where the ground is covered by snow for more than 5 months of the year. How do these animals, which derive all of their food from sources on or near the ground, survive the winter? One strategy is to store enough energy to last through the time of scarcity.

Belding's ground squirrel (*Citellus beldingi*) lives in alpine meadows and, in summer, feeds on grass and other green plants. As fall approaches, these animals store energy in the form of body fat, growing to about three times their lean body mass. An individual that weighed 160 g in the spring may put on over 300 g of fat before snow begins to fall and it retires to its burrow system. In contrast, the golden-mantled ground squirrel (*Citellus lateralis*) lives on forested slopes during the summer, eating plants, berries, seeds, and fungi. Its lean body mass is similar to that of Belding's ground squirrel, but it does not put on nearly as much pre-winter fat. Instead, *C. lateralis* stores energy in the form of food in its burrow. The success of each of these strategies depends on the balance between supply and demand. How much energy is available, and how much is needed to get through the winter?

The resting metabolic rate of a 160-g ground squirrel is about 1.2 Kcal/hr. But to maintain the animal's body temperature in a cold burrow under snow, the metabolic rate rises to about 4.0 Kcal/hr. Over 5 months, this amounts to 14,400 Kcal. Three hundred grams of fat yield

A golden-mantled ground squirrel feeds in the summer forest of the Sierra Nevada.

2,700 Kcal—which would mean a serious shortfall for the Belding's ground squirrel.

How about the food hoarder? If we assume that the golden-mantled ground squirrel stores fir and pine seeds with an average energy content of 5 Kcal/g, an individual would have to store about 3 kg of seeds—an enormous amount. (See Figure 21.16, or better yet, try prying apart one scale of a pine cone and removing the seed; it takes a lot of seeds to make 3 kg.)

The supply side of the winter survival equation does not explain how ground squirrels survive the months they cannot be active above ground. What about the demand side? How can the animal reduce its energetic needs?

What can ground squirrels do to lower the metabolic demands of surviving through the winter?*

*You will find the answer to this question on page 601.

KEY CONCEPTS

- 29.1** Multicellular Animals Require a Stable Internal Environment
- 29.2** Physiological Regulation Achieves Homeostasis of the Internal Environment
- 29.3** Living Systems Are Temperature-Sensitive
- 29.4** Animals Control Body Temperature by Altering Rates of Heat Gain and Loss
- 29.5** A Thermostat in the Brain Regulates Mammalian Body Temperature

concept 29.1 Multicellular Animals Require a Stable Internal Environment

Animal cells must take in nutrients and oxygen from the environment and eliminate carbon dioxide and other waste products of metabolism to the environment. The cells of tiny or thin aquatic animals are so close to the surrounding water that they can meet their needs by diffusional exchange. The cells of larger animals are too far from the outside environment to depend on diffusional exchange of nutrients, oxygen, and wastes.

Multicellular animals have an internal environment of extracellular fluid

The cellular needs of multicellular animals are served by a fluid environment that is internal to the animal. That internal fluid environment mediates the exchange of substances between the cells of the body and the external environment. Much of physiology—the study of how organisms function—involves analyzing exchanges of energy and materials that take place between the cells and the internal environment, and between the internal environment and the external environment.

Animals are mostly water (you, for example, are about 60 percent water). That water is distributed in different body compartments. Most of the water in an animal's body is located within its cells; this is *intracellular fluid*. The rest is the *extracellular fluid*. For all animals with blood circulatory systems, a portion of the extracellular water is the liquid portion of the blood, or *plasma*. The majority of extracellular fluid, however, is found between the cells of the body and is called **interstitial fluid** (FIGURE 29.1). Most cells exchange materials and nutrients with the interstitial fluid that surrounds them.

Maintenance of the internal environment protects the cells of the body from external changes and harsh conditions, making it possible for an animal to occupy habitats that would kill its cells if they were exposed to the environment directly. The constancy of the internal environment is critical, and any change in its composition can threaten the health of cells. The activities of the cells can deplete the nutrients present in the

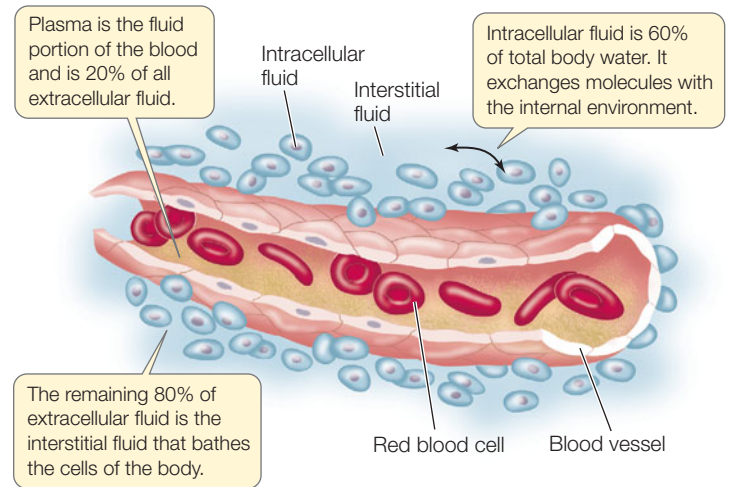

FIGURE 29.1 The Internal Environment Extracellular fluid is the body's internal environment. Its components include the liquid portion of the blood (plasma) and the interstitial fluid that bathes all the cells of the body. By exchanging molecules with the intracellular fluid, the internal environment serves the needs of all the body's cells.

interstitial fluid; furthermore, cells are constantly dumping their waste products into the interstitial fluid and can poison this critical environment.

The physical and chemical nature of an animal's habitat, along with the metabolic activities of its cells, constantly threaten to change the composition of its internal environment. How is the internal environment kept constant?

Homeostasis is the process of maintaining stable conditions in the internal environment

As multicellular organisms evolved, cells became specialized for maintaining specific aspects of the internal environment—among them temperature, pH, ion concentrations, O_2 and CO_2 levels, and levels of fuel molecules such as glucose—within specific limits. The maintenance of such stability is known as **homeostasis**.

APPLY THE CONCEPT

Multicellular animals have an internal environment of extracellular fluid

Different substances injected into the bloodstream will distribute into the body's intracellular and extracellular fluid compartments. Their distribution pattern depends on the chemical properties of the injected substances. In three experiments, 10 ml of 10% solutions of each of three compounds (2H_2O , or heavy water; inulin, a polysaccharide; and Evan's Blue, a dye) are injected into the bloodstream of a 70-kg man. After 1 hour, a blood sample is taken from the subject and the concentrations of the substances are measured. From the results shown and the information in Figure 29.1, what would

SUBSTANCE	CONCENTRATION INJECTED	FINAL CONCENTRATION IN PLASMA
Heavy water	10%	0.0024%
Inulin	10%	0.006%
Evan's Blue	10%	0.03%

you conclude about how these three substances are distributed among the fluid compartments of the body?

The presence of an internal environment facilitated the evolution of specializations of cells, tissues, and organs. When each cell no longer had to carry out all exchanges with the external environment for itself, cells could adapt to contribute a variety of specialized functions to the maintenance of the internal environment, all the while benefitting from that internal environment. Some cells became the boundary between the internal and the external environments, transporting nutrients in, moving wastes out, and maintaining appropriate ion concentrations. Others provided specialized internal functions such as storing energy, processing information, and moving the body. As complexity of animals evolved, these specialized cells evolved into tissues, organs, and ultimately organ systems. These systems function to maintain homeostasis of the internal environment. Examples are the digestive, respiratory, and circulatory systems. Adaptations of these systems made it possible for animals to maintain homeostasis and survive in many different habitats.

Cells, tissues, and organs serve homeostatic needs

Each physiological system is composed of discrete **organs**, such as the liver, heart, lungs, and kidneys, that serve specific functions in the body. These organs are made up of tissues. A **tissue** is an assemblage of cells; however, although there are a multitude of different cell types, there are only four kinds of tissue: *epithelial*, *connective*, *nervous*, and *muscle*.

- **Epithelial tissues** are sheets of densely packed, interconnected *epithelial cells* that cover inner and outer body surfaces. Some epithelial cells secrete substances such as hormones, mucus, digestive enzymes, or sweat. Some, such as the lining of blood vessels, serve as selective barriers. Some serve transport functions, such as absorption of nutrients from the gut. Some, like the lining of the respiratory passages, have cilia that move mucus and detritus over their surfaces. Some epithelial tissues serve sensory functions, including smell, taste, and touch.
- **Connective tissues** are dispersed populations of cells embedded in an *extracellular matrix* that the cells themselves secrete. The composition and properties of the matrix differentiate the types of connective tissues. A matrix of protein fibers (collagen and elastin) provides the structural strength and elasticity that characterizes cartilage (the substance that lines the joints between bones and gives structure to the nose and the external ears). The extracellular matrix of bone is mineralized to give it rigid structural strength. In contrast, the extracellular matrix of blood cells—the plasma—is liquid so blood can flow through vessels. Adipose tissue is a connective tissue of energy-storing fat cells with little extracellular matrix.
- **Nervous tissues** consist of neurons and glial cells. *Neurons* are individual cells that generate and conduct electrical signals, or *nerve impulses*, around the body. They are the foundational units of the *central* and *peripheral nervous systems* that transmit information from both the internal and external environments to the other cells of the body, as we will detail in Chapters 34 and 35. Neurons communicate with each other using chemical signals called *neurotransmitters*. *Glial cells* do

not fire nerve impulses, but they do release chemical signals, and they support the information-processing functions of neurons in various ways.

- **Muscle tissues** account for most of the body mass of vertebrates. They consist of elongated cells that contract to generate forces that result in movement, as we will describe in Chapter 36. *Skeletal muscle* (so named because it is usually attached to bones) is responsible for locomotion and other body movements. The heart is made up of *cardiac muscle* that generates the heartbeat and pumps blood. *Smooth muscle* generates forces in many hollow internal organs, including the gut, bladder, and blood vessels.

Organs include more than one kind of tissue, and most organs include all four (**FIGURE 29.2**). The wall of the stomach or the small intestine is a good example. Its inner surface is lined with a sheet of columnar epithelial cells. Different epithelial cells secrete mucus, enzymes, or stomach acid. Beneath the epithelial lining is connective tissue. Within this connective tissue are blood vessels, neurons, and glands (clusters of secretory epithelial cells). Concentric layers of smooth muscle tissue enable the stomach to contract to mix food with digestive juices. A network of neurons between the muscle layers controls these movements. Surrounding the stomach is a sheath of connective tissue and an epithelial lining.

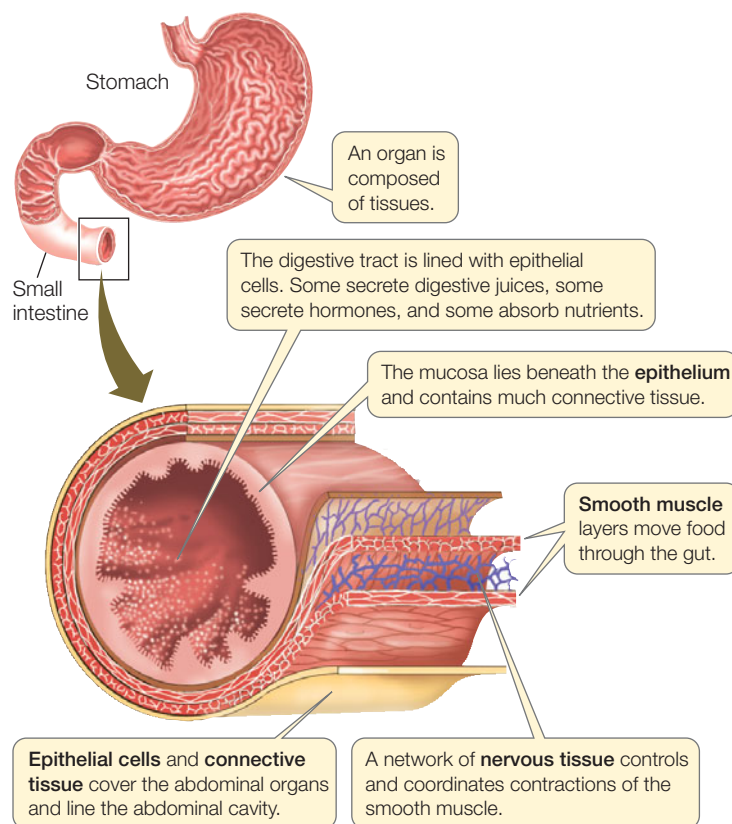

FIGURE 29.2 Tissues Form Organs Most organs contain more than one of the four types of tissue; many organs are made up of all four types.

An individual organ is usually part of an **organ system**—a group of organs that work together to carry out certain functions. The stomach is part of the digestive system. If an organ fails to function properly, homeostasis is compromised and cells may be damaged and die.

Tissues and Cell Types

Do You Understand Concept 29.1?

- What are the roles of the blood plasma and the interstitial fluid in serving the needs of the body, and how do these two extracellular fluids interrelate?
- What are the properties and functions of each of the four tissue types?
- How do organ systems contribute to the maintenance of the internal environment? Describe an example.

To maintain homeostasis, the activities of each organ and organ system must be matched to the demands of the body's cells. This matching requires that physiological systems be controlled and regulated in response to changes in both the external and internal environments.

FIGURE 29.3 Control, Regulation, and Feedback The animal body uses information and control mechanisms to maintain homeostasis, just as a driver uses them to regulate the speed of a car.

concept 29.2

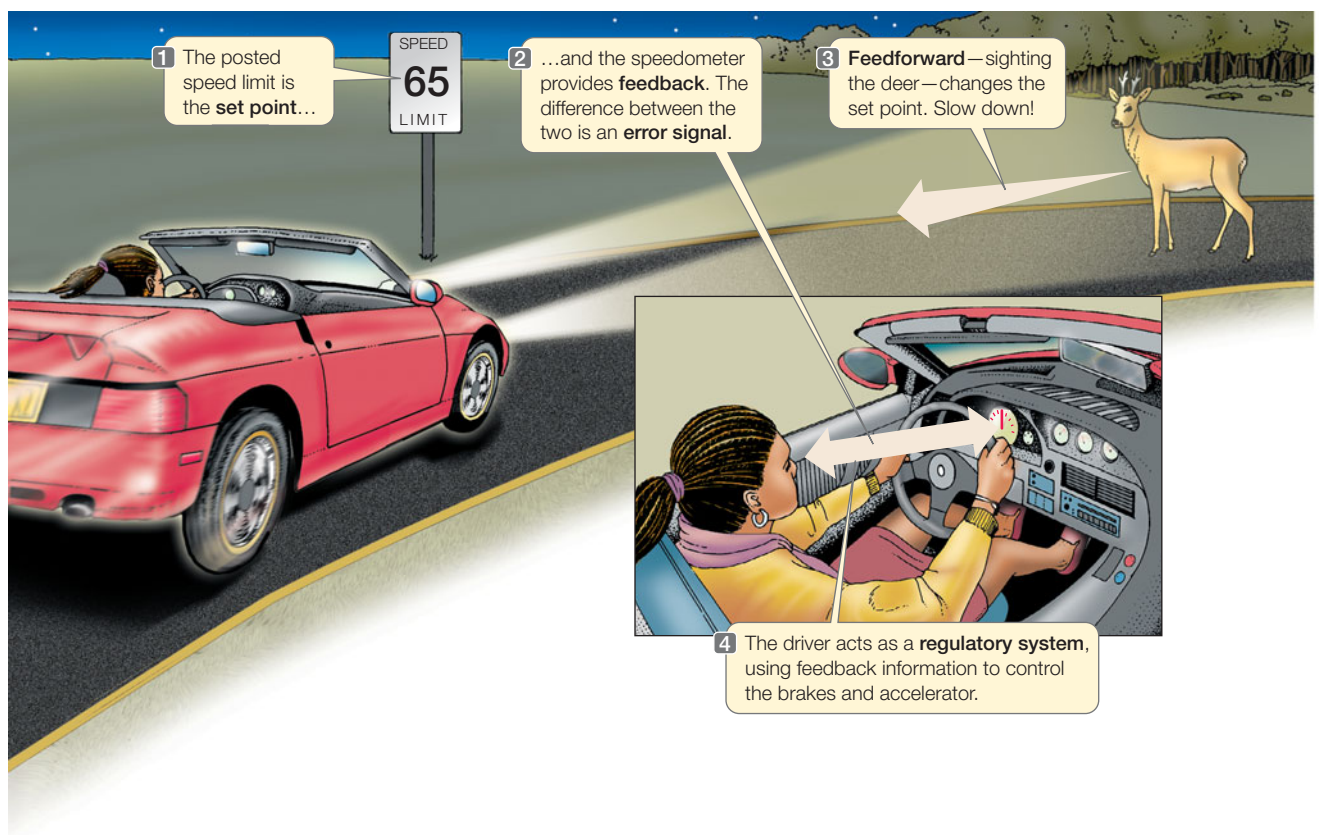

Physiological Regulation Achieves Homeostasis of the Internal Environment

As we will detail in subsequent chapters, the activities of an animal's physiological systems are controlled—speeded up or slowed down—by actions of the nervous and endocrine systems. But to *regulate* the internal environment, information is required.

Regulating physiological systems requires feedback information

Think of control and regulation in the context of driving a car. You *control* the speed of your car with the accelerator and the brakes; but to use the accelerator and the brakes to *regulate* the speed of your car, you have to know both how fast you are going and how fast you want to go. The desired speed is a **set point**; the reading on your speedometer is **feedback information**. When the set point and feedback information are compared, any difference between them is an **error signal**. Error signals suggest corrective actions, which you make by using the accelerator or brake (**FIGURE 29.3**).

Regulatory systems obtain, process, and integrate feedback information and then issue commands. An important component of any regulatory system is a *sensor*, which provides the feedback information that is compared with the set point. (Sensors will be described in Chapter 35.) Once sensory information is processed, the regulatory system issues commands to *effectors*, so named

because they effect changes in the internal—or external—environment. The accelerator and brake act as effectors in your car; muscles and glands are important effectors in the animal body (see Chapter 36). Effectors are **controlled systems** because their activities are controlled by commands from regulatory systems.

Feedback information can be negative or positive

A fundamental way to study a physiological regulatory system is to identify the information to which it responds. What detects the information? How is the information from the sensors used? **Negative feedback** is the most common use of sensory information in regulatory systems. The word “negative” indicates that this feedback information is used to counteract the influence that created an error signal. Whatever force is pushing the system away from its set point is “negated” by negative feedback, resulting in a movement back to the set point. In our car analogy, the recognition that you are going too fast is negative feedback that causes you to slow down. Negative feedback is a stabilizing influence in physiological systems.

Rather than returning a system to a set point, **positive feedback** amplifies a response (i.e., it *increases* the deviation from the set point). Although it is not as common as negative feedback, examples of positive feedback are seen in regulation of the responses that empty body cavities, such as urination and defecation. Another example is sexual behavior, in which a little stimulation increases the behavioral response, which increases stimulation, and so on. Positive feedback responses tend to reach a limit and then terminate rapidly.

The function of **feedforward information** is to change the set point. Seeing a deer ahead on the road when you are driving is an example of feedforward information; this information takes precedence over the posted speed limit, and you change your set point to a slower speed. In physiology, feedforward information is predictive of a change in the internal environment before that change occurs. For example, the climatological signs of oncoming winter (shorter days, dying vegetation, cooler temperatures) are feedforward information that stimulates physiological changes in the ground squirrels mentioned at the start of this chapter.

Do You Understand Concept 29.2?

- A regulatory system you encounter often is the thermostatically controlled heat and air conditioning system that keeps a building’s temperature constant in changing external conditions. Describe such a system in terms of the regulating system, the controlled system, the set points, feedback information, and effector commands.
- A common type of sensor is a nerve cell that increases its activity when it is stretched. Describe a situation where information from stretch-sensitive neurons is used as negative feedback and an example where it is used as positive feedback.

The principles of control and regulation help organize our thinking about physiological systems. Once we understand

how a system works, we can then ask how it is regulated. For each of the various animal organ systems described in the subsequent chapters of this unit, we will consider the challenges imposed by the environment, some of the physiological adaptations that have evolved to meet those challenges, and how those physiological mechanisms are regulated. The remainder of this chapter applies that approach to the regulation of body temperature.

concept 29.3 Living Systems Are Temperature-Sensitive

Temperatures over the face of Earth vary enormously, from the boiling hot springs of Yellowstone National Park to the interior of Antarctica, where temperatures can fall below -80°C . But most eukaryotic cells can function only over a relatively narrow range of temperatures. If cells cool below 0°C , ice crystals can form and damage their structures. Some animals have adaptations (such as “antifreeze molecules” in their blood) that help them resist freezing; others are able to survive freezing. Generally, however, cells must remain above 0°C to stay alive.

The upper temperature limit for survival of most cells is about 45°C , and proteins begin to denature and lose their function as soon as temperatures rise above 40°C . Therefore, normal cellular functions are limited to the range between 0°C and 40°C , which approximates the thermal limits for life of cells. A particular species, however, usually has much narrower limits. Humans face heat exhaustion and other serious heat-induced illness as body temperatures rise above 40°C , and we begin to lose coordination and cognitive capacity when body temperature falls below 35°C . Thus the homeostatic mechanisms of the human thermoregulatory system must maintain the body’s temperature between 35°C and 40°C —no matter what the *ambient* (external environment) temperature may be.

Q_{10} is a measure of temperature sensitivity

Most biochemical reactions and physiological processes are temperature-sensitive, and they usually proceed faster at higher temperatures (see Figure 3.20). The temperature sensitivity of a reaction or process can be described in terms of Q_{10} , a factor calculated by dividing the rate of a process or reaction at a certain temperature, R_T , by the rate of that process or reaction at a temperature 10°C lower, R_{T-10} :

$$Q_{10} = R_T / R_{T-10}$$

Q_{10} can be measured for a simple enzymatic reaction or for a complex physiological process, such as rate of oxygen consumption. If a reaction or process is not temperature-sensitive, it has a Q_{10} of 1. Most biological Q_{10} values are between 2 and 3. A Q_{10} of 2 means that the reaction rate doubles as temperature increases by 10°C , and a Q_{10} of 3 indicates a tripling of the rate (**FIGURE 29.4**).

Changes in body temperature can disrupt an animal’s physiology because not all of the biochemical reactions that comprise

FIGURE 29.4 Q_{10} and Reaction Rate The larger the Q_{10} of a reaction or process, the faster its rate rises in response to an increase in temperature.

the metabolism of an animal have the same Q_{10} . These biochemical reactions are linked together in complex networks in which the products of one reaction are the reactants for other reactions. Because different reactions have different Q_{10} values, changes in tissue temperature will shift the rates of some reactions more than others, disrupting the overall network. To maintain homeostasis, organisms must be able to compensate for or prevent changes in body temperature.

Animals can acclimatize to seasonal temperature changes

The body temperatures of some animals (especially aquatic animals) are tightly coupled to the environmental temperature. The body temperature of a fish in a pond, for example, will always be the same as the water temperature, which might range more than 20°C seasonally. Nevertheless, the fish can maintain similar levels of activity in summer and winter because, over time, it can acclimatize. Important means of acclimatization are to produce more or fewer enzymes or enzymes with different temperature optima. The ability to acclimatize means that metabolic functions are less sensitive to long-term changes in temperature than they are to short-term changes.

Animals can regulate body temperature

The body temperature of a fish, amphibian or reptile depends on the temperature of its environment, so they are called **ectotherms** (“heat from the outside”). In contrast, birds and mammals are referred to as **endotherms** (“heat from the inside”) because they maintain high and rather constant body temperatures over a wide range of ambient temperatures, largely because of their ability to generate internal heat metabolically.

FIGURE 29.5 shows the differences in the effects of ambient temperature on the metabolism of endotherms and ectotherms. In the experiments summarized here, an endotherm (mouse) and an ectotherm (lizard) of the same body size are put in closed chambers. Air is circulated through the chambers,

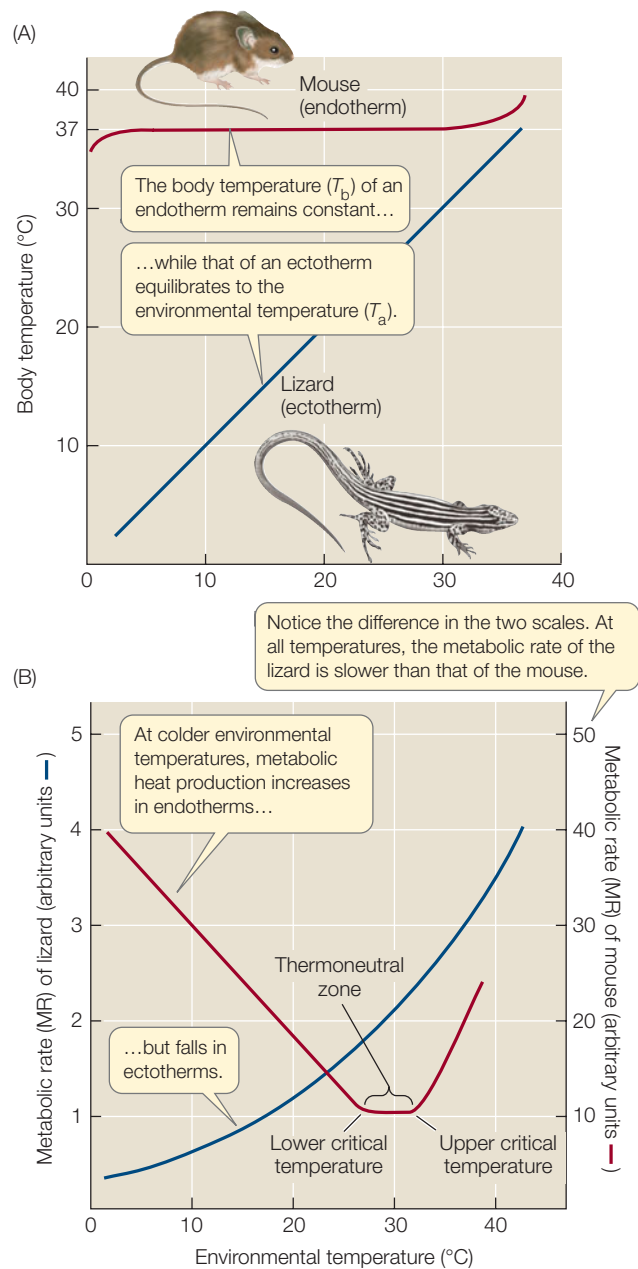

FIGURE 29.5 Ectotherms and Endotherms React Differently to Environmental Temperatures (A) At the same ambient temperature, an ectotherm and an endotherm of approximately the same body size (here, a lizard and a mouse) have different body temperatures. (B) The metabolic rate of the lizard drops as the environmental temperature falls, but below a lower critical temperature the mouse curve rises as ambient temperature falls. The mouse curve turns up again at an upper critical temperature because it takes metabolic energy to actively dissipate heat.

yourBioPortal.com

Go to WEB ACTIVITY 29.2
Thermoregulation in an Endotherm

and the animals’ rates of oxygen consumption (a measure of their metabolic rate, MR) are measured at different ambient temperatures (T_a). The first thing we notice is that the body temperature (T_b) of the mouse remains constant at 37°C over

a broad range of T_a , whereas the T_b of the lizard equilibrates with T_a (see Figure 29.5A).

In the lizard, MR shows a typical biological temperature sensitivity (see Figure 29.5B) while T_b follows a Q_{10} curve. The MR of the mouse responds quite differently; over a range of T_a , the MR of the mouse remains low and constant. We call this range the **thermoneutral zone (TNZ)**. Within the TNZ, MR is at the minimal level compatible with all of the physiological functions essential to maintain homeostasis of the internal environment in the resting animal; this level is known as the **basal metabolic rate**, or **BMR**.

Do You Understand Concept 29.3?

- What are some cellular processes or events that would lead to the survival of cells being limited to an approximately 40°C range of temperatures?
- Explain how a physiological process can be disrupted by changes in its temperature when its component biochemical reactions have different Q_{10} 's.
- Why does MR of a mammal increase as T_a decreases, whereas MR of a reptile decreases as T_a decreases, in the range of T_a 's below 25°C in the example in the figure?"

We have seen how living systems are affected by temperature and how they respond to changes in temperature. Next we examine how the properties and adaptations of animals interact with the thermal environment to determine body temperature.

concept 29.4

Animals Control Body Temperature by Altering Rates of Heat Gain and Loss

An animal's body temperature is the result of the balance between thermal energy flowing into the body from the environment and from metabolism (heat_{in}), and thermal energy leaving the animal (heat_{out}). The two sides of this **heat budget**

equation must be equal if the body temperature of the animal is to remain constant. In other words, unless $\text{heat}_{\text{in}} = \text{heat}_{\text{out}}$, body temperature changes.

If we expand both sides of the heat budget equation to describe all of the pathways of thermal energy exchange between the animal and the environment, we can see all of the possible ways an animal can control its body temperature (**FIGURE 29.6**). All gains and losses of thermal energy that an animal experiences occur by the following mechanisms:

- **Metabolism:** All energy conversions are inefficient and produce heat as a by-product. Thus, the conversion of chemical bond energy in nutrients to the chemical bond energy in ATP, and the use of ATP to do work result in the production of heat in the animal.
- **Radiation:** Heat transfers from warmer objects to cooler ones via the exchange of infrared radiation (e.g., what you feel when you stand in front of a fire). Incoming radiation is that which is absorbed, R_{abs} , and outgoing radiation is that which is emitted, R_{out} .
- **Convection:** Heat transfers to a surrounding medium such as air or water as that medium flows over a surface (the "wind chill" factor).
- **Conduction:** Heat transfers directly when objects of two different temperatures come into contact (think of putting an icepack on a sprained ankle).
- **Evaporation:** Heat transfers away from a surface when water evaporates on that surface (the effect of sweating).

Under most circumstances, heat_{in} for an animal is generated by metabolism and thermal radiation (MR and R_{abs}). The other terms in the above list are mostly avenues of heat loss and are on the right side of the heat budget equation (heat_{out}). "Under most circumstances" is important, because the direction of heat flow through radiation, conduction, and convection depends on the difference between the temperature of the environment and the temperature of the animal's surface. Thus,

$$\underbrace{\text{heat}_{\text{in}}}_{\text{metabolism} + R_{\text{abs}}} = \underbrace{\text{heat}_{\text{out}}}_{R_{\text{out}} + \text{convection} + \text{conduction} + \text{evaporation}}$$

APPLY THE CONCEPT

Living systems are temperature-sensitive

Neurons convey information from one part of the body to another as streams of electrical signals called nerve impulses. Information is coded as the frequency of nerve impulses (impulses/sec). Thus, changes in the temperature of neurons can alter the information they are transmitting. A neurobiologist recorded the impulse frequencies of three different types of neurons in the skin of an animal at different skin temperatures. Use the data in the table to answer the questions at right.

FIRING RATE (IMPULSES/SEC)	SKIN TEMPERATURE (°C)			
	25	30	35	40
Neuron A	1	2	6	18
Neuron B	12	6	3	1
Neuron C	8	7	9	8

1. Calculate the Q_{10} for each of the three neuron types.
2. On the basis of your calculations, what type of information do you think each different neuron might be conveying from the skin to the brain?

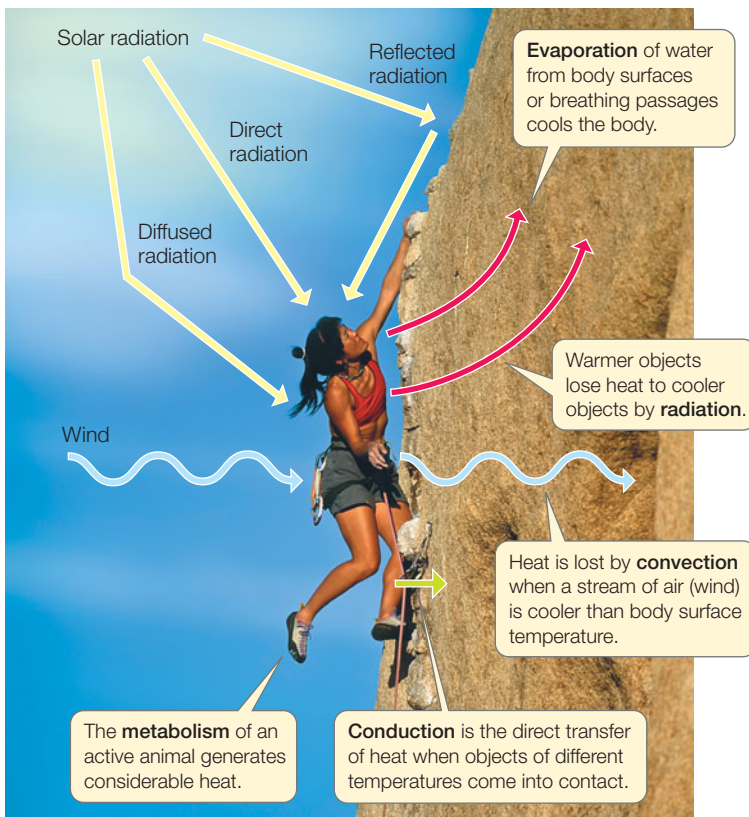

FIGURE 29.6 Animals Exchange Heat with the Environment

An animal's body temperature is determined by the balance between internal heat production—metabolism—and four avenues of heat exchange with the environment.

Any adaptation that serves to regulate an animal's body temperature must influence one or more terms of this equation. Moreover, if we expanded each term on the right side of the equation and looked at them as a physicist would, we would see that recurrent factors are surface temperature and surface area. Thus, an important insight we gain from the heat budget equation is the central importance of *surface temperature* and *surface area* for heat exchange. Those two terms are key determinants of radiative, conductive, and convective heat loss.

Mammals and birds have high rates of metabolic heat production

A close look at Figure 29.5B reveals that even the highest MR of the resting lizard is lower than the BMR of a mouse. Most of the energy a resting endotherm expends goes into pumping ions across membranes. To the extent that cell membranes are permeable to ions, the ions diffuse down their concentration gradients (from high concentration to low). To maintain proper concentrations inside and outside cells, the ions must be transported back “uphill,” which requires an expenditure of energy. While this is true for both ectotherms and endotherms, the cells of endotherms are leakier to ions than those of ectotherms. Thus endotherms must expend more energy (and thus release more heat) to maintain ion concentration gradients. This is akin to running

on a treadmill: the faster the treadmill goes (analogous to leaking ions), the faster you have to run (analogous to pumping ions) to remain in the same position.

LINK Review the mechanisms of ion transport described in Concepts 5.2 and 5.3

When T_a falls below an endotherm's thermoneutral zone—the lower end of which is called the *lower critical temperature*—the animal must increase its metabolic heat production or its T_b will fall. One adaptation that produces metabolic heat in all endotherms is shivering. Skeletal muscles are organized in antagonistic pairs, one of which will flex a joint and the other of which will extend it. If both muscles contract at the same time, they consume energy and produce heat, but they will not produce major movements other than a tremor that is experienced as shivering. Such *shivering thermogenesis* allows a mammal or a bird to increase its MR by about four times above its BMR (see Figure 29.5B).

Some mammals also are capable of *non-shivering thermogenesis*. Tissues other than skeletal muscle can produce metabolic heat by uncoupling oxidative phosphorylation (see Chapter 6, p. 104). These tissues burn fuel without producing ATP, and therefore the animal's metabolic rate is not limited by the buildup of ATP. The major evolutionary adaptation for non-shivering thermogenesis is **brown fat** (FIGURE 29.7). This adipose tissue looks brown because it has a high density of mitochondria and blood vessels. It is found in the newborns of many species of mammals, including humans. For mammals that hibernate, it is an important source of heat as they cycle out of hibernation.

FIGURE 29.7 Brown Fat In many mammals, specialized brown fat tissue produces heat. White fat cells (left) contain large droplets of lipid but have few organelles and limited blood supply. Brown fat cells (right) are packed with mitochondria and richly supplied with blood.

Basal metabolic rates are correlated with body size

As you would expect, the total metabolic expenditure of a resting elephant (its basal metabolic rate) is greater than that of a mouse. After all, the elephant is more than 100,000 times more massive than the mouse. The elephant's BMR, however, is only about 7,000 times greater than that of the mouse. That means that 1 g of mouse tissue uses energy at a rate about 15 times greater than does 1 g of elephant tissue (FIGURE 29.8). Across all endotherms, BMR per gram of tissue increases as animals get smaller.

Why should this disproportionate difference exist? Several reasons have been suggested, but none of these is sufficient by itself. As animals get bigger, they have a smaller ratio of surface area to volume (see Figure 4.2). Because heat production is a function of an animal's volume, or mass, but its capacity to dissipate heat is a function of its surface area, it has been reasoned that larger animals evolved lower metabolic rates to avoid overheating. This explanation is insufficient because the relationship between body mass and metabolic rate also holds for small organisms and for ectotherms, in which overheating is not a problem. Another hypothesis is that larger animals have a greater proportion of support tissues (notably skin and bone) that are not very active metabolically. The real answer is probably a mixture of different factors.

Insulation is the major adaptation of endotherms to cold climates

Endotherms from all climates, tropical to arctic, fall on the same line when it comes to relating their BMRs to their body sizes; thus we can conclude that BMR is not an adaptation to different climates. When we compare the MR versus T_a curves for different endotherms, a decreased response to declines in environmental temperature indicates that an ability to conserve heat is an important adaptation for cold climate endotherms. How do you conserve body heat? You put on more or heavier

FIGURE 29.8 The Mouse-to-Elephant Curve On a weight-specific basis, the basal metabolic rates of small endotherms are much greater than those of larger endotherms. This graph plots O_2 consumption per kg of body weight (a measure of metabolic rate) against a logarithmic plot of body mass.

FIGURE 29.9 Anatomical Adaptations to Climate (A) The desert fox has short fur and limited body insulation. Its large ears and long limbs allow heat to radiate from these extended body surfaces. (B) The Arctic fox has a thick coat of insulating fur. Its small ears, short limbs, and rounded body shape give it a smaller surface-to-volume ratio than its desert-dwelling relative—in other words, there is less surface area over which heat can be lost to the environment.

clothing—that is, you increase your thermal insulation. What you do behaviorally, evolution has provided anatomically for many species (FIGURE 29.9).

How can we measure and compare the thermal insulation of animals? Referring back to Figure 29.5B, the rising portion of the graph that occurs in the mouse when T_a falls below the lower critical temperature is described by the equation

$$MR = K(T_b - T_a)$$

where K is the slope of the curve, or *thermal conductance*—a measure of how readily the animal loses heat. The inverse of thermal conductance is *insulation*, which is a measure of how effectively the animal conserves heat. Note that this equation predicts that when $T_a = T_b$, MR will be 0. But, of course, MR is never 0 because there is always a BMR necessary for maintaining the homeostatic functions of life. Nevertheless, the equation tells us that the

curve describing the effect of low T_a on heat production (i.e., on MR) will intersect with the x axis at T_a equal to T_b .

Above lower critical temperatures, the MR versus T_a curves for endotherms show a region of thermoneutral zones over which MR remains at basal levels. How can the MR be at the BMR level over such a wide range of ambient temperatures? Surely, heat loss continues to be a function of the difference between T_b and T_a within the thermoneutral zone. The answer is that, above the lower critical temperature, the animal can change the value of K . It can smooth or fluff its fur or feathers. It can send more or less blood to skin surfaces that dissipate heat to the environment. And it can change its posture and positioning to expose parts of its body that are not as well insulated with fur or feathers.

Some fish can conserve metabolic heat

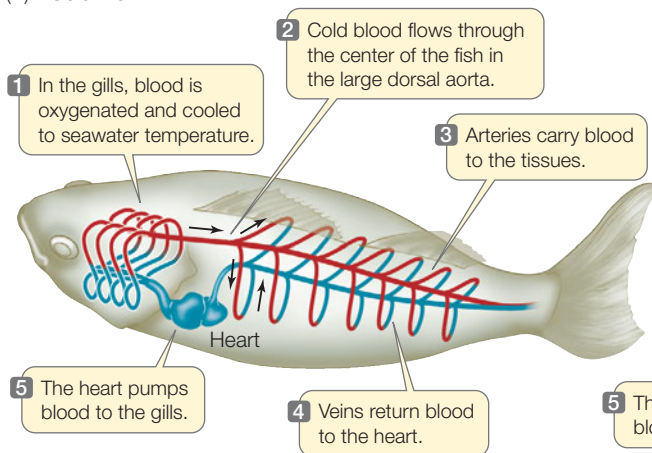

Active fish produce substantial amounts of metabolic heat, but they have difficulty retaining any of that heat. Blood pumped from the fish heart goes directly to the gills for respiratory gas exchange. The gills are thin and have a huge surface area, so the blood comes into thermal equilibrium with the surrounding water. Thus any heat the blood picks up from the metabolically active muscles is lost to the cold water flowing over the gills. But some large, rapidly swimming fishes, such as bluefin tuna and great white sharks, can maintain body temperatures 10°C – 15°C higher than the temperature of the surrounding water. The heat comes from their powerful swimming muscles, and the ability

FRONTIERS Covered with insulation, how can a heavily furred or feathered endotherm dissipate the heat generated by high levels of activity? Such animals have heat-loss portals—body areas that are not furred or feathered, and which are underlain by special blood vessels that bring large volumes of blood close to the skin surface (thereby acting as radiators). These body areas include the palms of the hands, soles of the feet, and parts of the face. Humans inherited these special blood vessels in non-hairy skin from our primate ancestors. Scientists exploited this adaptation with a new technology: a portable device that uses a partial vacuum to increase blood flow through the heat-dissipating vessels and a heat sink to efficiently transfer the heat from the skin surface. Using this technology, scientists found that muscle fatigue is a function of rising muscle temperature, and that extracting that heat could increase an individual's ability to sustain high levels of physical effort, even in hot environments.

of these “hot” fish to conserve that heat is based on the arrangement of their blood vessels.

In the typical (“cold”) fish circulatory system, cold oxygenated blood from the gills travels through the center of the fish in a large artery that distributes blood to all regions of the body (FIGURE 29.10A). “Hot” fish have a smaller central artery, and most of their cold oxygenated blood is transported in large vessels just under the skin (FIGURE 29.10B). Thus, the cold blood from the gills is kept close to the surface of the body. Smaller vessels transporting this cold blood into the muscle mass run

(A) “Cold” fish

(B) “Hot” fish

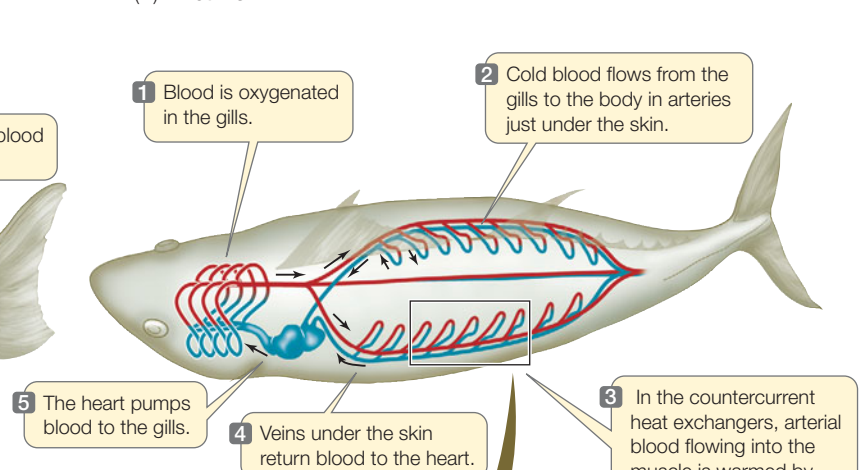

FIGURE 29.10 “Cold” and “Hot” Fish

(A) In most fish species, the circulatory system conducts cool, oxygenated blood from the gills through a large dorsal aorta to the rest of the body. (B) The anatomy of “hot” fish species includes a mechanism that allows heat to pass into cold arterial blood from venous blood that has been warmed by the metabolism of the muscles. (C) The principle of countercurrent exchange allows heat to be transferred with maximum efficiency.

(C)

parallel to vessels transporting warm blood from the muscle mass back toward the heart. Heat flows from the warm to the cold blood and is therefore retained in the muscle mass.

Because heat is exchanged between blood vessels carrying blood in opposite directions, this adaptation is called a **countercurrent heat exchanger** (FIGURE 29.10C). Countercurrent heat exchange enables these fish to have an internal body temperature considerably above the water temperature. Why is this advantageous for the fish? Each 10°C rise in muscle temperature increases the fish's sustainable power output almost threefold, giving it a faster swimming speed that is useful in capturing prey.

LINK The principle of countercurrent exchange is seen in other physiological systems, including oxygen transport (see Concept 37.2) and the ability of the kidney to concentrate urine (see Concept 40.4)

Evaporation is an effective but expensive avenue of heat loss

Blood flow to the skin maximizes passive heat loss only when there is a substantial difference between body temperature and ambient temperature. Therefore, high ambient temperatures as well as high metabolic rates threaten to raise body temperature. Endotherms live close to their upper lethal temperatures, so even small increases in body temperature can be dangerous. Many endotherms counter this increase with evaporative cooling by sweating or panting. You probably have “worked up a sweat” in a hot environment or when exercising.

When a gram of water evaporates, it absorbs about 580 calories of heat. If that evaporation takes place on the skin, much of that 580 calories is removed from the body. Evaporation is therefore an effective means of dissipating heat. During heavy sweating or panting, however, any water that drips off the body's surface does not contribute to heat loss. Combine this with the fact that animals carry little excess water and can die rapidly from dehydration, and it becomes clear that evaporative heat loss is a physiologically expensive and potentially dangerous thermoregulatory adaptation. In addition, sweating is an *active* process that requires the expenditure of metabolic energy. That is why the metabolic rate increases above the upper critical temperature (the rising curve on the right side of Figure 29.5B). A sweating or panting animal is generating heat in the process of dissipating heat.

Some ectotherms elevate their metabolic heat production

Although elevated metabolic heat production is characteristic of endotherms, some ectotherms can also raise their body temperatures in this way. For example, the flight muscles of many insects must reach 35°C–40°C before the insects can fly, and they must maintain these high temperatures during flight. Such insects produce the required heat by contracting their flight muscles in a manner analogous to shivering in mammals.

FIGURE 29.11 Bees Keep Warm in Winter Honey bee colonies survive winter cold because workers generate metabolic heat. In this infrared photograph of the center of an overwintering hive, individual bees are discernible by the heat their bodies produce as they cluster around their queen as she lays eggs.

Honey bees regulate temperature as a group. They live in large colonies consisting mostly of female worker bees that maintain the hive and rear the larval offspring of the queen bee. During winter, worker bees cluster around the brood (eggs and larvae). They adjust their individual metabolic heat production and density of clustering so that the brood temperature remains remarkably constant, at about 34°C, even as the outside air temperature drops below freezing (FIGURE 29.11).

Behavior is a common thermoregulatory adaptation in ectotherms and endotherms

The lizard in a metabolism chamber (see Figure 29.5) can't do much to regulate its body temperature, yet in its natural desert environment it does remarkably well. When it is active during the day, it maintains its body temperature in the 35°C–40°C range. It achieves this by the thermoregulatory behavior described in FIGURE 29.12. In the morning, the lizard maximizes its surface exposure to the sun and absorbs solar radiation. Through the middle of the day, it maintains its body temperature by moving between sun and shade and by climbing rocks and brush to be in convective air streams. Only when the lizard retires to its underground nightly refuge does its body temperature equilibrate with the ambient.

Behavioral thermoregulation is not limited to ectotherms; it is a preferred thermoregulatory strategy of endotherms as well. The elephant sprays itself with water or dust, the lion seeks midday shade, and you would rather put on a sweater than shiver. All of these behavioral strategies alter components of the heat budget equation.

Do You Understand Concept 29.4?

- Compare the two foxes in Figure 29.9 and explain how the differences you observe influence each element of the heat balance equation for these two species.
- Many newborn mammals have brown fat even if brown fat is not seen in adults of that species. Why is brown fat adaptive for newborns?
- For both hot and cold stress, explain how behavioral adaptations can alter heat exchange through all of the components of the heat budget equation.
- If sweating and panting are such costly avenues of cooling (due to water loss and metabolic energy expenditure), why haven't evolutionary mechanisms eliminated them as regulatory mechanisms?

There are many adaptations for altering heat exchange between animals and their environments. Regulation of body temperature, however, requires that these various adaptations be controlled in a way that results in the ability of the animal to regulate its body temperature. We next explore how mammals achieve this feat of homeostatic regulation.

FIGURE 29.12 Ectotherms Can Use Behavior to Regulate Body Temperature The body temperature of a lizard depends on the heat of its environment, but the lizard can regulate its temperature by moving from place to place within that environment. The behavior of a desert species, the spiny lizard *Sceloporus serrifer*, is illustrated here.

concept 29.5 A Thermostat in the Brain Regulates Mammalian Body Temperature

Hormonal and neural mechanisms are responsible for controlling thermoregulatory adaptations, whether these changes involve the involuntary constriction or dilation of blood vessels, changes in shivering or non-shivering thermogenesis, sweating or panting, or changes in behavior. What sets the level of the neural and hormonal regulatory commands to the effector mechanisms? To achieve a constant, optimal body temperature, a regulatory system must be able to receive information about actual body temperature, compare it to a set point, and issue appropriate commands to effector mechanisms. In the case of thermoregulation, we can call such a regulatory system a *thermostat*. We will focus here on the thermostat of mammals.

The mammalian thermostat uses feedback information

In vertebrates, the major integrative center of the thermostat is at the bottom of the brain, in a structure called the **hypothalamus** (see Figure 30.7A). The hypothalamus is a key part of many homeostatic regulatory systems we will discuss in the following chapters.

In many species, the temperature of the hypothalamus itself is the major source of feedback information to the thermostat. Cooling the hypothalamus causes fish and reptiles to seek a warmer environment, and warming the hypothalamus causes them to seek a cooler environment. In mammals, cooling the hypothalamus stimulates constriction of the blood vessels supplying the skin and increases metabolic heat production. Because it activates these thermoregulatory responses, cooling the hypothalamus causes the body temperature to rise. Conversely, mild warming of the hypothalamus stimulates dilation of the blood vessels supplying the skin, while stronger hypothalamic heating stimulates sweating or panting. Consequently, heating the hypothalamus can actually cause the overall body temperature to fall (FIGURE 29.13).

The hypothalamus generates a set point like a setting on a home thermostat. When the temperature of the hypothalamus exceeds or drops below that set point, thermoregulatory responses are activated to reverse the direction of temperature change. Hence, hypothalamic temperature is a negative feedback signal.

The mammalian thermoregulatory system has adjustable set points and integrates sources of information in addition to hypothalamic temperature. For example, temperature sensors in the skin register environmental temperature; change in skin temperature is feedforward information that shifts the hypothalamic set point for thermoregulatory responses. The set point for metabolic heat production is higher when skin is cold and lower when skin is warm.

INVESTIGATION

FIGURE 29.13 The Hypothalamus Regulates Body Temperature

A mammal's hypothalamus was subjected directly to temperature manipulation. The body's responses to the manipulations were as expected if the hypothalamus is the mammalian "thermostat."

HYPOTHESIS

Heating or cooling the mammalian hypothalamus results in corresponding and predictable changes in body temperature.

METHOD

1. Implant a probe into the hypothalamus of a living ground squirrel's brain. Use the probe to heat or cool the hypothalamus directly (i.e., without affecting the ambient temperature).
2. Manipulate the hypothalamic temperature T_H .

3. Measure the animal's metabolic rate and body temperature throughout the period of hypothalamic manipulation.

RESULTS

1 When the hypothalamus was cooled, metabolic heat production increased and the animal's body temperature rose.

2 When the hypothalamus was heated, the squirrel's metabolic rate and body temperature fell.

CONCLUSION

The ground squirrel's hypothalamus acts as a thermostat. When cooled it activates metabolic heat production; when warmed, it suppresses metabolic heat production and favors heat loss.

ANALYZE THE DATA

The data below were recorded from an experiment in which the hypothalamus of a ground squirrel was randomly cooled (T_H) while the animal's metabolic rate (MR) was measured. T_H is given in $^{\circ}\text{C}$, MR is given in calories per gram of body mass per minute.

T_H	MR	T_H	MR	T_H	MR
39.5	0.040	36.5	0.038	37.5	0.041
39.0	0.041	36.0	0.040	37.0	0.039
38.5	0.040	35.5	0.060	34.5	0.110
38.0	0.038	35.0	0.080	34.0	0.140

- A. Plot the data and describe what it tells you about the properties of the hypothalamic thermostat.
- B. What is the threshold temperature for the metabolic heat production response?

The Hypothalamus

The thermostat can be adjusted up and down

Fever is an adaptive response that helps the body fight pathogens. A *fever* is a regulated rise in body temperature caused by a rise in the hypothalamic set point for the metabolic heat production response. As a result, you shiver and crawl under a blanket, and your body temperature rises until it matches a new and higher set point. At the higher body temperature you no longer feel cold, and you may not feel warm, but someone touching your forehead will say that you are "burning up." Taking aspirin lowers your set point to normal.

FRONTIERS Although a fever that raises body temperature above 42°C can cause brain damage and even death, medical evidence also points to the possibility that fever helps fight against bacterial and viral infections. Many pathogenic microbes grow best at normal body temperature, and their growth is inhibited at higher temperatures. In addition, the production of certain white blood cells that fight microbes goes up with a rise in body temperature. Fever also decreases the levels of iron and zinc in the blood, both of which are necessary for the proliferation of the infecting organisms.

The regulated body temperature can also be lowered. This happens every day as the body temperature cycles from a high during the active phase of the daily rhythm to a low during the rest phase of the daily cycle. There is both a daily rhythm of the set point for body temperature and a further lowering of regulated body temperature during sleep. In some temperate-climate animals, lowering body temperature during a portion of the day has evolved into an important energy saving adaptation called *daily torpor*. Body temperature may decline 15°C or more during a bout of torpor. A more extreme adaptation for conserving energy and surviving the cold winter season is *hibernation*, in which bouts of torpor last multiple days and body temperature may be regulated slightly above freezing.

Do You Understand Concept 29.5?

- Draw a diagram of the mammalian thermostat that includes the effectors, the set points, and the negative feedback.
- Explain at least four sources of feedforward information for the mammalian thermostat that can either keep body temperature constant in spite of changes in the environment, or can cause body temperature to change.

What can ground squirrels do to lower the metabolic demands of surviving through the winter?

ANSWER Being mammals, ground squirrels have high basal metabolic rates, and in a cold winter environment (below their lower critical temperatures), the metabolic cost of maintaining a normal mammalian body temperature is much higher. Neither the enormous fat reserves of Belding's ground squirrel nor the food stores of the golden-mantled ground squirrel can fuel this metabolic demand for an average 5 months of underground, snow-shrouded existence.

One possible physical-chemical basis for an adaptation was discussed in Concept 29.3. Lowering the temperature of biological systems lowers their metabolic demand, with a Q_{10} of about 2.5. Because there is a large range of temperatures between normal mammalian body temperature and the lower limit for

cell survival, the range for lowering the temperature of mammalian metabolism extends over more than 30°C . Lowering body temperature to the lowest possible level would result in a greater than 16-fold decrease in metabolic demand. Ground squirrels take advantage of these metabolic savings to stretch their fat or food reserves; they achieve this by hibernating.

Hibernation is a regulated lowering of body temperature over long periods when food is not available (FIGURE 29.14A). Typically a ground squirrel will retire to its burrow when snow falls, and for the rest of the winter it will undergo repeated bouts of hibernation during which its body temperature will drop to a level close to that of the environment. A bout of hibernation will last about a week, and then the squirrel will return to a normal mammalian body temperature for a day or less before entering the next bout (FIGURE 29.14B). The periodic arousals are the major energy expenditure of these animals over the winter, yet we still do not know their function.

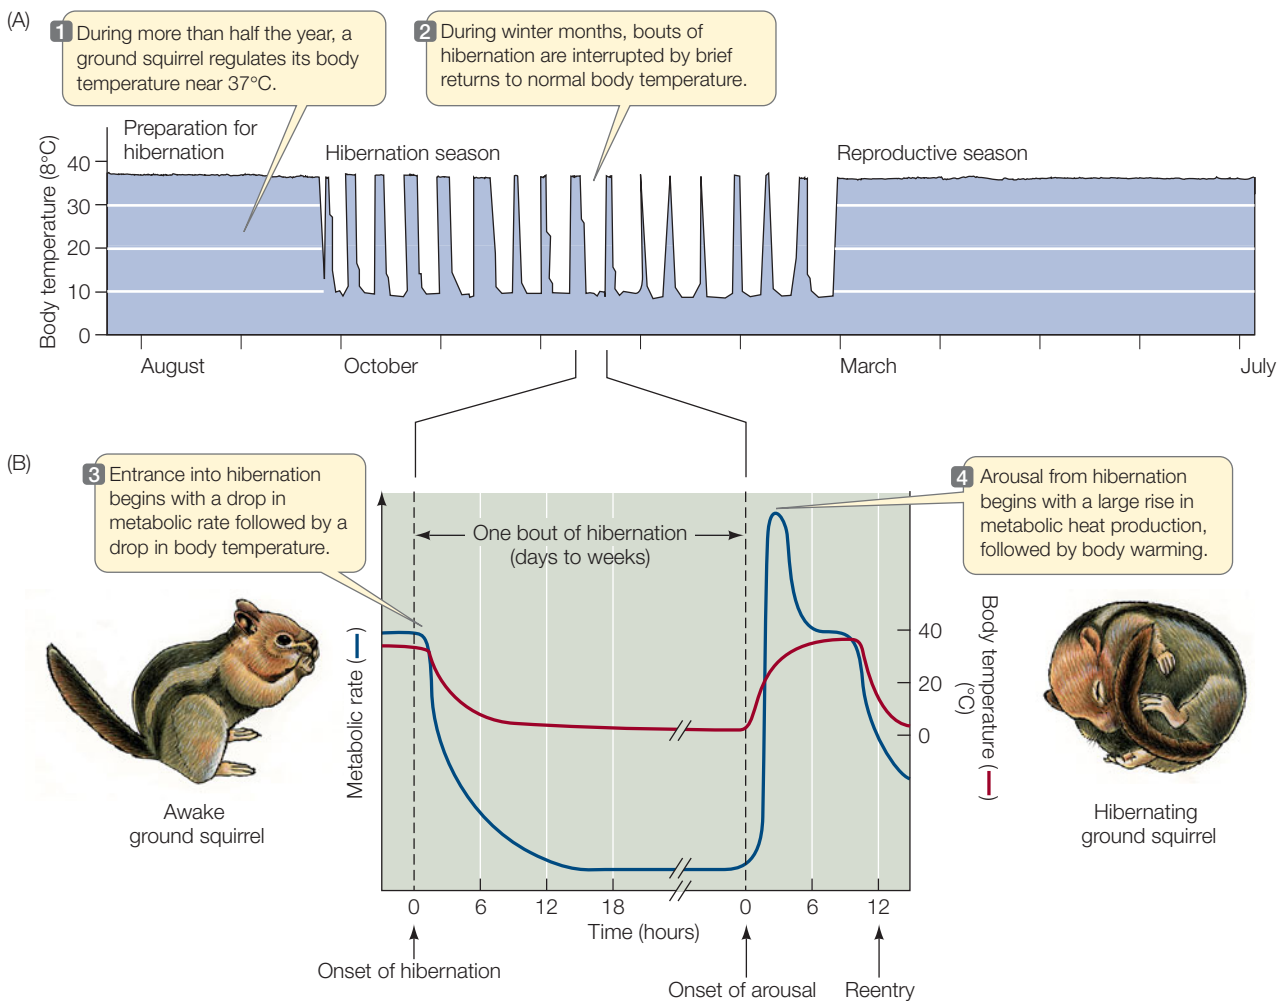

FIGURE 29.14 Hibernation Patterns in a Ground Squirrel
 (A) During most of the year, the ground squirrel regulates its body temperature around 37°C , as other mammals do. But when snow falls and temperatures plunge, these animals retire to underground burrows and spend the winter living off stored fuel, in the form

of either food or fat. (B) The metabolic demands for these stored fuels are decreased by repeated bouts of torpor, during which the regulated body temperature drops close to that of the environment for long periods of time.

SUMMARY

concept 29.1 Multicellular Animals Require a Stable Internal Environment

- Multicellular animals provide for the needs of all of their cells by maintaining a stable internal environment, which consists of the extracellular fluid. **Review Figure 29.1**
- **Tissues** are assemblages of cells. Although there are many cell types, there are only four types of tissues: epithelial, muscle, connective, and nervous. **Review WEB ACTIVITY 29.1**
- **Organs** are made up of tissues; most organs contain all four tissue types. Organs are grouped into **organ systems**. **Review Figure 29.2**

concept 29.2 Physiological Regulation Achieves Homeostasis of the Internal Environment

- Physiological systems are regulated primarily through **negative feedback**, which keeps the system stable by returning it toward a **set point**.
- **Positive feedback** increases the deviation from a set point. **Feedforward information** changes a system's set point. **Review Figure 29.3**

concept 29.3 Living Systems Are Temperature-Sensitive

- Life is sustained within a narrow range of ambient (environmental) temperatures. Q_{10} is a measure of the sensitivity of a life process to temperature. **Review Figure 29.4**
- An animal's **metabolic rate (MR)** is a measure of the energy turnover of its cells. The MR is often measured in terms of the rate of O_2 consumption.
- The body temperature of an ectotherm depends on heat from the environment.
- **Endotherms** regulate body temperature independent of the environment by metabolically producing heat internally.

- The minimal metabolic rate at which an endotherm can maintain homeostasis of its internal environment in a resting state is its **basal metabolic rate (BMR)**. **Review Figure 29.5 and WEB ACTIVITY 29.2**

concept 29.4 Animals Control Body Temperature by Altering Rates of Heat Gain and Loss

- A **heat budget** describes all pathways for heat exchange between an organism and its environment. These avenues of heat exchange are **metabolism, radiation, convection, conduction, and evaporation**. **Review Figure 29.6**
- The BMRs of endothermic animals are higher than the resting metabolic rates of ectotherms when at the same body temperature.
- The basal metabolic rate is a function of body size. **Review Figure 29.8**
- Surface insulation decreases heat loss.
- Adaptations such as **countercurrent heat exchange** can conserve metabolic heat. **Review Figure 29.10**
- Behavioral thermoregulation is the first line of defense against changes in the thermal environment. **Review Figure 29.11**
- Evaporative water loss is an effective but expensive means of heat loss.

concept 29.5 A Thermostat in the Brain Regulates Mammalian Body Temperature

- In mammals, the control of thermoregulatory effectors relies on commands from a regulatory center in the **hypothalamus** of the brain.
- The hypothalamus uses its own temperature as a negative feedback signal and external (skin) temperature as a feedforward signal. **Review Figure 29.13, WORKING WITH DATA 29.1, and ANIMATED TUTORIAL 29.1**
- Fever is a regulated increase in body temperature. Hibernation is a regulated decrease. **Review Figure 29.14**

Animal Hormones

30

In humans, genes on the Y chromosome are essential for development of the male body plan, including the formation of the testes—the primary male sex organs. Early in a male's development, the testes start to produce the *steroid hormone* testosterone. Testosterone and other masculinizing steroid hormones are known as *androgens* (Greek, "male-makers").

Many characteristics of the male phenotype are the direct result of testosterone and other androgens. The changes in these characteristics at puberty are due to a large increase in testosterone production. The hormone enters cells, binds to receptors, and alters gene expression throughout the body, promoting the mature male phenotype: deep voice, facial and body hair, and increased muscle and bone mass.

The bodies of both sexes respond to testosterone, but women normally have lower concentrations of this hormone than men do. The extreme transformative powers of testosterone can be seen in female bodybuilders who take high doses of synthetic androgens, a class of drugs known as anabolic steroids. These women develop male muscle patterns, a deep voice, and body and facial hair. Because male sex steroids inhibit the hormones controlling female reproductive physiology, the women's breast tissue diminishes, menstruation stops, and they become infertile. Analogous negative feedback in males who take steroids also causes infertility. Other dangerous side effects for both men and women are increased risks of cancer and of heart, liver, and kidney diseases.

The transformative power of testosterone is also seen in certain *intersex* conditions in which individuals' physical phenotypes are discordant with their chromosomal sex. In androgen insensitivity

syndrome (AIS), for example, a person's cells do not respond to testosterone. An individual with AIS who is a genetic male (XY) will have internal testes that produce testosterone, but that person develops the external sex organs and secondary sexual characteristics of a female: breasts, widening of hips, and subcutaneous fat deposition.

A rare, inherited intersex condition is "guevedoces," or "testes-at-twelve," first studied in a small community in the Dominican Republic. Children with this particular genetic mutation all appear to be female until puberty. But at puberty, those with the XY genotype suddenly develop the external sex organs of males, and they function as males. Both of these intersex conditions offer insights into the mechanisms of action of *hormones*.

Synthetic androgens known as anabolic steroids mimic the male hormone testosterone. This action can result in enhanced muscle development in both males and females.

How do the transformative effects of testosterone exemplify the way many hormones work?

KEY CONCEPTS

- 30.1** Hormones Are Chemical Messengers

concept
30.1

Hormones Are Chemical Messengers

In any multicellular body, the individual cells must be able to communicate with one another. Most such intercellular communication is by means of chemical signals that are released from one cell and travel to another (the *target cell*). The signal molecules bind to receptors on the target cell, triggering a response in it; these responses can result in profound effects on the organism's physiology, anatomy, and behavior. Although details vary, this general pattern of chemical signaling, which we described in Chapter 5 of this book, is seen in physiological systems across all multicellular phyla. In this chapter we will focus on the *endocrine system*, which consists of those cells that produce and release the chemical signals we call hormones.

Endocrine signals can act locally or at a distance

Cells can secrete substances either into the extracellular fluid (*endocrine secretion*) or into a duct or an internal body cavity that communicates to the external world (*exocrine secretion*). For example, endocrine cells in the digestive tract secrete signaling molecules that diffuse into the blood and are transported to other organs of the digestive system to control their activities. Exocrine cells in the digestive tract secrete enzymes into the digestive tract that break down the complex molecules of food. Other exocrine secretions include saliva, sweat, and pheromones (chemical signals that an animal releases into the environment and that communicate information to other individuals of the same species). You can think of “endocrine” as referring to “into the body” and “exocrine” as referring to “out of the body” or at least into a body cavity lined by epithelial cells.

Cells that secrete endocrine signals are called **endocrine cells**. Some endocrine cells exist as single cells scattered within a larger organ, as is the case with the digestive tract endocrine cells mentioned above. In other cases, endocrine cells are aggregated into secretory organs called **endocrine glands**. The testes and thyroid are examples of endocrine glands.

As noted in Chapter 5 (see Figure 5.10), endocrine signaling molecules have traditionally been classified as paracrine signals, autocrine signals, or hormones, according to the distance over which they operate. While paracrine signals act on nearby cells and autocrine signals stimulate the same cell that produces them, **hormones** are “long-distance” endocrine signals that are released into the bloodstream and circulate through the entire body.

Whether the endocrine signal is a hormone, paracrine, or autocrine, the cell that responds to it is the target cell. **Target cells** have receptor proteins that recognize and bind to a signal (even when that signal is present only at extremely low concentrations, as is usually the case with hormones) and can trigger appropriate responses. The same hormone can influence the activities of a variety of different target cells, all of which are distant from the cells that originally released it.

The dividing lines between hormones, paracrine signals, and autocrine signals have blurred somewhat as researchers have discovered endocrine signals that operate over a variety of distances. In this chapter we will focus on the “classic” hormones that are released into the bloodstream and circulate widely.

Hormones can be divided into three chemical groups

There is enormous diversity in the chemical structure of hormones, but most hormones can be classified into three groups:

- **Peptide and protein hormones** are relatively large molecules (FIGURE 30.1A) that are water-soluble and therefore easily transported in the blood. They are packaged in vesicles within the cells that synthesize them and are released by exocytosis. Since water-soluble molecules cannot cross cell membranes easily, the receptors for peptide hormones must be on the exterior of the target cell. Most hormones are peptides: there are dozens, perhaps hundreds, of such hormones, with diverse structures and effects.
- **Steroid hormones** are synthesized from cholesterol molecules and share a similar structure of four interlinked rings (FIGURE 30.1B). Steroids are lipid-soluble and readily pass through the membranes of the cells that synthesize them, but they do not dissolve well in blood plasma and thus are usually bound to carrier proteins for transport in the blood. Once they reach a target cell they easily pass through its membrane; thus most steroid receptors are found inside target cells.
- **Amine hormones** are small molecules synthesized from single amino acids. For example, *thyroxine* and *epinephrine* are made from tyrosine (FIGURE 30.1C), and melatonin is made from tryptophan. Depending on whether the modified amino acid is polar or nonpolar, an amine hormone may be water-soluble (can't cross membranes) or lipid-soluble (can cross membranes).

Hormonal communication has a long evolutionary history

Intercellular chemical signaling was critical for the evolution of multicellularity. The most primitive of the multicellular animals—the sponges—do not have nervous systems, but they do have intercellular chemical communication. Plants and fungi also use a wide variety of hormones.

LINK The study of plant growth and development has contributed greatly to our knowledge of hormones and how they work; see Chapter 26

Studying the evolution of hormonal signaling reveals an interesting generalization: the signal molecules themselves are highly conserved over evolutionary time, although their functions may change. For example, the hormone prolactin was first shown to be a signal stimulating milk production in the mammary glands of female mammals. Prolactin (but not milk

(A) Protein hormones

FIGURE 30.1 Three Classes of Hormones (A) The largest hormone molecules are peptides or proteins. This class includes insulin and growth hormone. (B) Steroid hormones are modified from cholesterol molecules. They include the corticosteroids produced by the adrenal gland and the sex steroids produced primarily by the gonads. (C) Amine hormones are small molecules synthesized from a single amino acid. Thyroxine and epinephrine are both made from tyrosine, but thyroxine is lipid-soluble and epinephrine is water-soluble; their modes of release, dynamics of transport, and locations of receptor binding differ accordingly.

or mammary glands) has since been found in all the vertebrate phyla. In salmon, prolactin is involved in triggering the animals' migrations from salt water back to their freshwater spawning grounds. In birds, prolactin can stimulate nest building and parental care. Many of prolactin's functions relate to reproduction, but significant differences in the specifics of this hormone's action have evolved in the different vertebrate groups.

The ubiquity and shared evolutionary history of the hormones means we can study their actions in organisms from across the tree of life. An example is the well-documented hormonal control of molting and metamorphosis in arthropods.

Insect studies reveal hormonal control of development

The many arthropod classes, including the insects, are all characterized by having a rigid exoskeleton. Their growth is episodic, punctuated with *molts* (shedding of the exoskeleton). The hormonal mechanisms that control insect molting and metamorphosis are a longstanding area of research.

CONTROL OF MOLTING A classic series of experiments on the bloodsucking bug *Rhodnius prolixus* demonstrated that molting in this insect is controlled by hormones. A juvenile *Rhodnius* bug molts five times before developing into a mature adult; the growth stages between the molts are called *instars*. Each episode of molting is triggered by a blood meal.

Rhodnius is an amazingly hardy experimental animal—it can survive for more than a week after researchers cut off its head. A bug decapitated within an hour after a blood meal never

(B) Steroid hormones

(C) Amine hormones

molts; however, if it is decapitated a week after its blood meal, it *does* molt. The British physiologist Sir Vincent Wigglesworth hypothesized that this time lag meant that some substance that triggers molting diffuses slowly from the head. He tested his hypothesis with the experiment described in **FIGURE 30.2**.

We now know that two diffusible hormones working in sequence regulate molting in arthropods: *prothoracicotropic hormone* (PTTH, a peptide) and *ecdysone* (a steroid related to the vertebrate hormone testosterone). Cells in the brain produce PTTH, which is why it is sometimes called “brain hormone.” PTTH is transported to and stored in paired structures—the *corpora cardiaca*—attached to the brain. After appropriate

INVESTIGATION

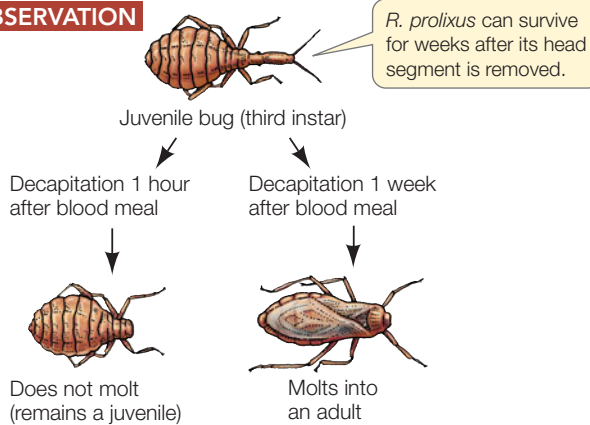

FIGURE 30.2 A Diffusible Substance Triggers Molting

The bloodsucking bug *Rhodnius prolixus* develops from hatching to adult in a series of five molts (instars) that are triggered by ingesting blood. Sir Vincent Wigglesworth's experiments demonstrated that a blood meal stimulates production of some molt-inducing substance in the insect's head.

HYPOTHESIS

The substance that controls molting in *R. prolixus* is produced in the head segment and diffuses slowly through the body.

OBSERVATION

METHOD

1. Decapitate third-instar juveniles at different times after blood meal.

RESULTS

CONCLUSION

A blood meal stimulates production of some substance within the insect's head that then diffuses slowly through the body, triggering a molt.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

prothoracic gland to release ecdysone, which in turn diffuses to target tissues and stimulates molting.

The control of molting by PTTH and ecdysone exemplifies not only Wigglesworth's "diffusible substance," but also how the endocrine system works with the nervous system to integrate diverse information and induce long-term effects. The nervous system of an arthropod receives many types of information about the animal's environment (such as day length, temperature, social cues, and nutrition) that help determine the optimal timing for the stages of growth and development. When conditions are right, the brain (nervous system) signals the prothoracic gland (endocrine system), which produces ecdysone, which in turn orchestrates the processes of development and molting. Later in this chapter we will see similar links between the nervous system and endocrine glands in vertebrates.

JUVENILE HORMONE AND METAMORPHOSIS PTTH and ecdysone determine whether an insect will molt. But what determines whether the molting insect becomes just a slightly larger juvenile or a dramatically different adult? A third hormone, **juvenile hormone (JH)**, determines the final outcome of the molt. In immature insects, JH is produced continuously from the *corpora allata* (structures attached to the corpora cardiaca). Further experiments with *Rhodnius* demonstrated that if JH is present in high concentration during a molt, the molting bug becomes a slightly larger juvenile; if JH levels are low, the bug becomes an adult.

Some insects, such as butterflies, undergo a particularly dramatic developmental change called *complete metamorphosis*. A fertilized egg hatches into a *larva*, which feeds and molts several times, becoming bigger each time. After a fixed number of molts, it enters an inactive stage called *pupation*. The pupa undergoes major body reorganization and finally emerges as an adult. Studies in silkworm moths have shown that larvae will molt into larger larvae as long as juvenile hormone is present in high concentrations. It is only when the level of JH falls that the larvae spin cocoons, pupate, and metamorphose into adults (FIGURE 30.3).

Complete Metamorphosis

Do You Understand Concept 30.1?

- How do hormone and paracrine signals differ?
- Compare the different methods by which peptide hormones and steroid hormones are released, travel through the blood, and reach their receptors. What is the underlying chemical reason for these differences?
- Suppose a newly hatched butterfly larva (i.e., a first-instar caterpillar) has a mutation such that its corpora allata cannot produce any hormones. Will this caterpillar ever molt? If it does, what will happen?

stimulation (which for *Rhodnius* bugs is a blood meal), PTTH is released and diffuses through the extracellular fluid to an endocrine gland, the prothoracic gland. PTTH stimulates the

FIGURE 30.3 Hormonal Control of Metamorphosis Three hormones control molting and metamorphosis in the silkworm moth *Hyalophora cecropia*.

Dozens of hormone molecules are circulating in your blood right now, conveying messages to virtually every organ in your body. But each hormone molecule is only a message. To have a physiological effect, the messages must be “read” and acted upon, which involves receptor molecules.

concept 30.2 Hormones Act by Binding to Receptors

A hormone can affect only those cells with the appropriate receptor proteins that bind to the specific hormone and trigger specific responses in the target cell. A hormone released into the blood circulates throughout the body. If and when it contacts a cell that has the right receptor, the hormone binds (usually temporarily) to that receptor; the receptor then does the rest. If the cell does not have a receptor protein for a given hormone, that hormone will have no effect on that cell.

LINK Review the mechanisms of receptor protein actions in Concepts 5.5 and 5.6

Hormone receptors can be membrane-bound or intracellular

Peptide and some amine hormones, being water-soluble, cannot pass readily through plasma membranes, so they must bind to receptors on the surfaces of target cells. Peptide receptors are large transmembrane complexes with three domains: a *binding domain* that projects outside the plasma membrane; a *transmembrane domain* that anchors the receptor in the membrane; and a *cytoplasmic domain* that extends into the cytoplasm of the cell. When a hormone binds, it changes the conformation of the receptor, and the cytoplasmic domain initiates the target cell's response, often through a second messenger cascade that eventually activates protein kinases or protein phosphatases (see Figure 5.17). In most cases, these kinases and phosphatases activate or inactivate enzymes in the cytoplasm, which leads to the cell's response.

Steroid and some amine hormones are lipid-soluble and thus can diffuse through plasma membranes; their receptors are usually in the target cell's cytoplasm. When the steroid binds to its receptor in the cytoplasm, the hormone-receptor complex usually moves to the target nucleus, where it alters gene expression. For example, when testosterone binds to androgen receptors in the cytoplasm of skeletal muscle cells, testosterone-receptor complexes move into the nuclei and activate several genes, including genes for the proteins that form contractile filaments (see Concept 36.1). Thus, one effect of testosterone is an increase in muscle mass.

Hormone action depends on the nature of the target cell and its receptors

The same hormone can cause very different responses in different types of cells, depending on which receptors are present in those cells and which cellular responses are triggered by the receptors. For example, the amine hormone epinephrine is involved in the rapid physiological response to sudden danger or highly stressful situations known as the **fight-or-flight response** (FIGURE 30.4). Suppose you are hiking and almost

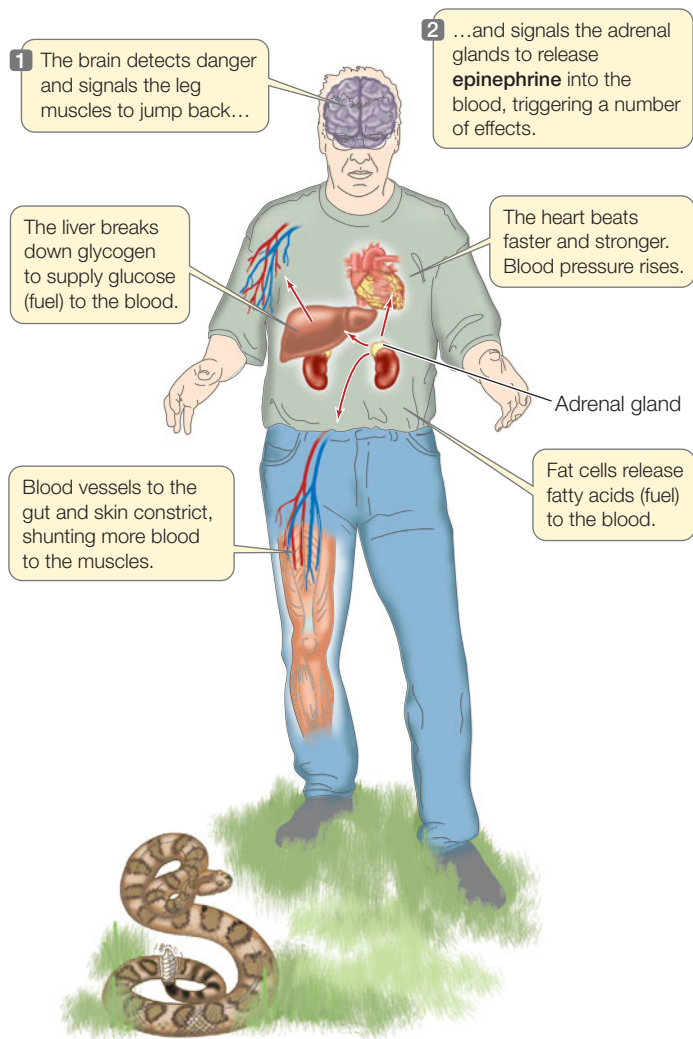

FIGURE 30.4 The Fight-or-Flight Response When a person is suddenly faced with a threatening situation, the brain sends a signal to the adrenal glands, which almost instantaneously release epinephrine. Epinephrine circulating through the body induces the different components of the fight-or-flight response.

step on a rattlesnake. You jump back, and your heart starts to thump. Both these actions are driven by your nervous system, which reacts very quickly. Simultaneously, your nervous system stimulates endocrine cells in the *adrenal glands* located just above your kidneys (see Figures 30.6 and 30.12) to secrete **epinephrine** and a related hormone, **norepinephrine**. Within seconds, these hormones are circulating through your body to activate the many components of the fight-or-flight response.

Epinephrine and norepinephrine (sometimes known as *adrenaline* and *noradrenaline*) bind to a set of **adrenergic receptors**. We know of at least five types of these receptors, all of which are G protein-linked receptors (see Concept 5.5). They are grouped into two basic categories— α -adrenergic and β -adrenergic—with different affinities for epinephrine and norepinephrine (**FIGURE 30.5**). Stimulation of one type of β -adrenergic receptor in heart cells causes a faster and

stronger heartbeat (thus pumping more blood). Stimulation of α -adrenergic receptors in skin causes you to sweat. These same receptors in the digestive system shut off the secretion of digestive enzymes and decrease blood flow through your gut (digesting lunch can wait). Meanwhile, β receptors cause arterioles in skeletal muscle to dilate (enlarge), so increased blood flow is diverted from your gut to your skeletal muscles (which you need to run). In the liver β receptors cause the breakdown of glycogen into glucose for a quick energy supply (see Chapter 39), while in fatty tissue β receptors stimulate the breakdown of fats to yield fatty acids—another source of energy.

These diverse actions are triggered by the same two hormones. The variation in cellular responses arises because, first, cells of different tissues can have different receptors; and second, even when different types of cells have the same receptor, they may respond very differently to activation of that receptor. Pharmacologists have exploited this diversity in the adrenergic system by developing drugs called “beta blockers” that selectively inhibit the activation of β -adrenergic receptors, thereby taking the edge off anxiety reactions.

FRONTIERS The genes for hormone receptors frequently have similar sequences and can be grouped into gene families. Armed with this information, investigators have scanned the human genome sequence looking for homologies to known receptor gene sequences. This method has resulted in the discovery of many “orphan” hormone receptors—receptors that do not appear to bind any known hormone. The existence of orphan receptors raises the possibility that there may be many as-yet undiscovered human hormones, and that determining the effects of these hormones could have profound implications for health.

Hormone receptors are regulated

Like the hormones themselves, hormone receptors are subject to feedback control. In some cases, continuous high concentrations of a hormone can cause a decrease in the number of its receptors in the target cell's cytoplasm or nucleus, a process known as *downregulation*. Downregulation makes the cells less sensitive to the hormone, in essence causing the cells to ignore the excess hormone. An example of downregulation occurs in type II diabetes mellitus, in which chronically high levels of the hormone insulin (usually caused by excessive carbohydrate intake) downregulate production of insulin receptors throughout the body. The result is that cells become less sensitive to insulin.

LINK The crucial role of insulin in regulating glucose metabolism is detailed in Concept 39.4

Conversely, *upregulation* of receptors can occur if hormone secretion is chronically low. Cells often respond to low signal levels by making more receptors for that hormone. An example of upregulation is seen in people who have been on a regular dose of the beta blocker medications mentioned in the previous section. If the activity of β -adrenergic receptors is blocked

β -Adrenergic receptors **α -Adrenergic receptors**

FIGURE 30.5 Adrenergic Receptors Receptors that respond to epinephrine and norepinephrine are G protein-linked (see Figure 5.14) and fall into two broad categories. Epinephrine acts on both α - and β -adrenergic receptors, whereas norepinephrine acts mostly on α -adrenergic receptors. The effect produced when the hormone binds depends on the type of cell.

for some length of time, more receptors are produced. If the person then goes off the medication suddenly, the effects of the receptors are amplified, resulting in heightened anxiety and blood pressure. This explains why changes in dosage for medications that cause up- or downregulation of receptors are usually gradual and carefully supervised.

Do You Understand Concept 30.2?

- Growth hormone is a large, water-soluble peptide. Given these characteristics, how would you expect this hormone to act on its target cells?
- What do you think might be the cause of androgen insensitivity syndrome, one of the intersex conditions described on page 603?
- When you are suddenly alarmed, your adrenal glands release epinephrine, norepinephrine, and the steroid hormone cortisol. The effects of epinephrine and norepinephrine are seen within seconds and decrease within minutes; cortisol's effects are not seen for many minutes and last for hours. Explain some reasons for these differences in time course of action.

Hundreds of animal and plant hormones are known, and more are being discovered each year. The rest of this chapter will focus primarily on the human endocrine system (FIGURE 30.6), but the same hormonal systems are acting in other species. We look first at the hormones involved in coordinating the endocrine system with the nervous system.

concept 30.3 The Pituitary Gland Links the Nervous and Endocrine Systems

The nervous and endocrine systems represent two means of communication using molecular signals. Whereas the nervous system communicates via molecules called *neurotransmitters* that are released at the junction between nerve cells (see Concept 34.3), the endocrine system communicates by releasing molecular signals into the blood, which carries them to target cells throughout the body. These two methods of communication complement each other, with nerve cells often mediating rapid, highly specific responses and hormones mediating longer-term, more broadly distributed responses.

In addition to complementing each other, the nervous and endocrine systems also interact. The nervous system directly or indirectly controls the activity of many endocrine glands—for example, the production of sex steroids by the gonads. Some neurons even secrete hormones directly; hormones secreted by neurons are known as *neurohormones*. Conversely, hormones

FIGURE 30.6 The Human Endocrine System Cells that produce and secrete hormones may be organized into discrete endocrine glands, or they may be embedded in the tissues of other organs, such as the digestive tract or kidneys. Although the hypothalamus is part of the brain, it includes cells that secrete neurohormones into the extracellular fluid.

yourBioPortal.com

Go to WEB ACTIVITY 30.1
The Human Endocrine Glands

can influence the activity of the nervous system, as when exposure of the brain to sex steroid hormones stimulates the development and expression of sexual behavior.

The key meeting point for these two communication networks is the **pituitary**, an endocrine gland that serves as an interface between the nervous and endocrine systems and is involved in the hormonal control of many physiological processes.

Go to ANIMATED TUTORIAL 30.2
The Hypothalamus–Pituitary–Endocrine Axis

The pituitary gland has two parts

The pituitary sits in a depression at the bottom of the skull, just over the back of the roof of the mouth (**FIGURE 30.7A**). It is attached by a stalk to a region of the brain called the **hypothalamus**, which is itself involved in many physiological regulatory systems. The pituitary has two parts with different developmental origins: the **anterior pituitary** (derived from gut epithelium) and the **posterior pituitary** (derived from neural tissue).

THE POSTERIOR PITUITARY Long processes of hypothalamic neurons extend into the posterior pituitary. The ends (terminals)

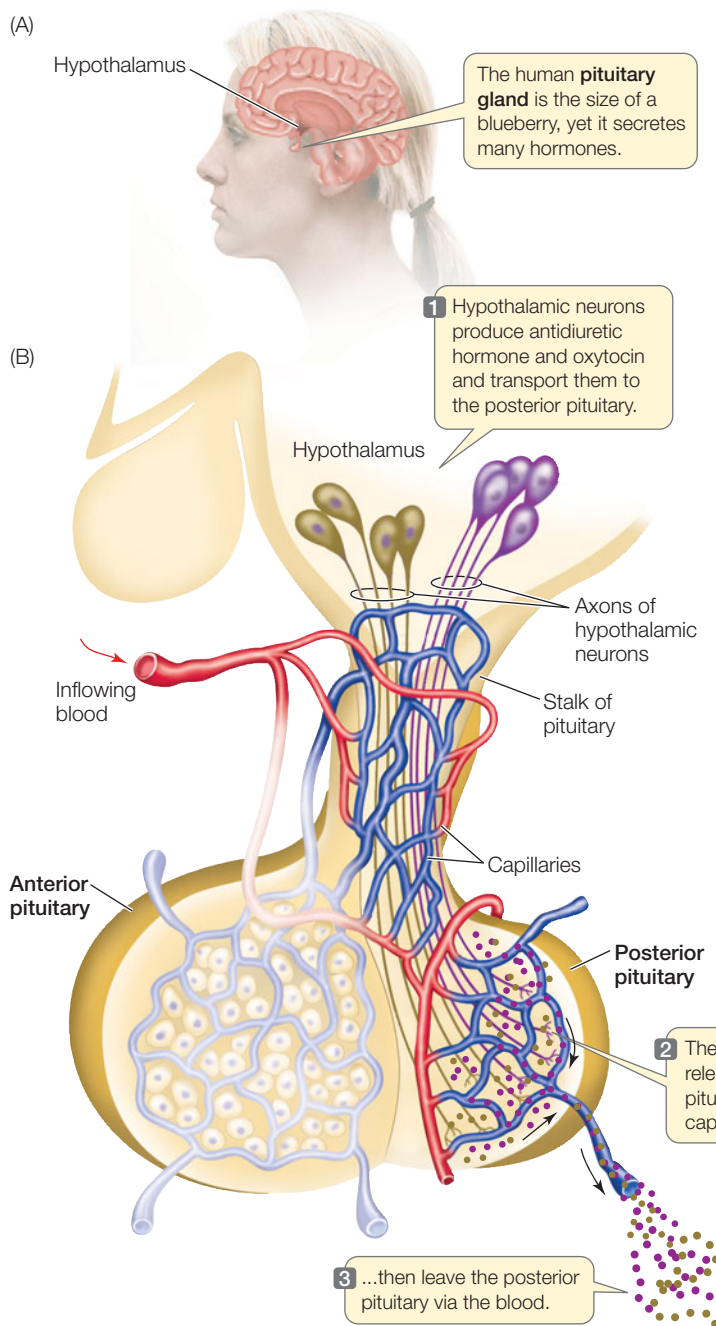

FIGURE 30.7 The Posterior Pituitary Neurons in the hypothalamus produce two peptide neurohormones, which are stored and released by the posterior pituitary.

of those axons release two neurohormones produced by the hypothalamus, antidiuretic hormone (also called *vasopressin*) and oxytocin (FIGURE 30.7B).

- The main action of **antidiuretic hormone (ADH)** in mammals and birds is to increase the amount of water conserved by the kidneys. When ADH secretion is high, the kidneys produce only a small volume of highly concentrated urine. When ADH secretion is low, the kidneys produce a large volume

of dilute urine. The posterior pituitary increases its release of ADH when blood pressure falls or if the blood becomes too salty.

- **Oxytocin** is produced in both sexes but is best known for its role in female reproduction, in which it stimulates uterine contractions during birth and also stimulates the flow of milk from the mother's breasts. In both sexes, oxytocin promotes pair bonding and trust. In humans and in some other mammals, oxytocin secretion rises with intimate sexual contact and orgasm and has thus been called the "cuddle hormone."

Oxytocin provides an excellent example of how hormones influence the nervous system. After birth, the baby's suckling stimulates neurons in the mother's brain that cause further secretion of oxytocin and release of breast milk. Even the sight and sound of a baby can cause a nursing mother to release breast milk, an example of the sensory nervous system integrating information to affect hormone release. If oxytocin release is experimentally blocked, mammalian mothers from rats to sheep will reject their newborn offspring; conversely, if a virgin rat is given oxytocin, she will adopt strange pups as if they were her own.

THE ANTERIOR PITUITARY The anterior pituitary releases four **tropic hormones**, which are hormones that direct and control the activities of other endocrine glands (FIGURE 30.8). These four hormones are *thyroid-stimulating hormone (TSH)*, *luteinizing hormone (LH)*, *follicle-stimulating hormone (FSH)*, and *adrenocorticotropic hormone (ACTH)*. Each tropic hormone is produced by a different type of pituitary cell. We will say more about the tropic hormones later in this chapter when we describe their target glands (thyroid, testes, ovaries, and adrenal cortex, respectively).

The anterior pituitary also produces several other peptide hormones, including prolactin (see pp. 604–605) and growth hormone. **Growth hormone (GH)** (see Figure 30.1A) acts on a wide variety of tissues to promote growth. One of its important effects is to stimulate cells to take up the amino acids needed for protein synthesis. Growth hormone also stimulates the liver to produce chemical signals called *somatomedins*, or *insulin-like growth factors (IGFs)*, which stimulate the growth of bone and cartilage. Overproduction of growth hormone causes *gigantism*, in which affected individuals may grow to nearly 8 feet tall. Underproduction causes *pituitary dwarfism*, in which individuals fail to reach normal adult height.

The neurohormones of the anterior pituitary are produced in minute amounts

Whereas the posterior pituitary secretes neurohormones produced by the hypothalamus, the anterior pituitary makes and secretes its own hormones—but its production of hormones is under the *control* of hypothalamic neurohormones. The hypothalamus receives information about conditions in the body

FIGURE 30.8 The Anterior Pituitary Cells of the anterior pituitary produce four tropic hormones that control other endocrine glands, as well as several other peptide hormones. These cells are controlled by neurohormones produced in the hypothalamus and delivered through portal blood vessels that run between the hypothalamus and the anterior pituitary through the pituitary stalk.

and the external environment, and it communicates that information to the anterior pituitary by secreting neurohormones.

FRONTIERS In the 1960s, some children with severe growth hormone deficiencies were treated with GH extracted from the pituitaries of cadavers. The treatments were successful in stimulating growth, but the availability of human pituitaries was a limiting factor. In 1981, the biotechnology pioneer Genentech used recombinant DNA technology to produce bacteria that synthesized human growth hormone. Today GH treatment for pituitary dwarfism is common, but its wider availability has engendered controversy. Is it valid, for example, to administer the hormone to children merely because they are shorter than average? The use of GH as a performance-enhancing drug is also under scrutiny.

The hypothalamic neurohormones that control the anterior pituitary are carried in a special type of blood vessel, the *portal blood vessels*. Portal blood vessels begin in capillaries in the hypothalamus and then run down the pituitary stalk, ending in capillaries within the anterior pituitary (see Figure 30.8). Because the portal vessels deliver molecules directly to the anterior pituitary and not into the general circulation, neurohormones can be produced and secreted in extremely small quantities.

In the 1960s, two teams of scientists, one led by Roger Guillemin and the other by Andrew Schally, began to search for hypothalamic neurohormones, but because these hormones are produced in such minute amounts, they were very difficult to isolate. Massive numbers of hypothalami from pigs and sheep were collected from slaughterhouses and shipped to laboratories in refrigerated trucks. In one extraction effort, the hypothalami from 270,000 sheep yielded only 1 milligram of purified **thyrotropin-releasing hormone (TRH)**, the first *releasing hormone* (that is, release-stimulating hormone) to be isolated and characterized. TRH turned out to be a small peptide of only three amino acids that, when secreted by the hypothalamus, causes certain anterior pituitary cells to release **thyroid-stimulating hormone (TSH)**. TSH then stimulates the thyroid gland to release a third hormone, thyroxine (see p. 614).

Frequently in science, giant steps forward are made possible by the invention of a new technique. Research on the hypothalamic hormones was largely dependent on Rosalyn Yalow's invention of the *immunoassay*, a technique that allowed accurate measurement of extremely low concentrations of biochemical substances, including antibodies (see Chapter 31) as well as hormones and other signaling molecules. In 1977, Yalow shared the Nobel Prize in Medicine with Guillemin and Schally. Many other hypothalamic neurohormones, including both releasing and release-inhibiting hormones, are now known. In most cases they are involved in stimulating or inhibiting signaling cascades like that for TRH → TSH → thyroxine.

Negative feedback loops also regulate the pituitary hormones

As well as being controlled by hypothalamic hormones, the endocrine cells of the anterior pituitary are under negative feedback control by the hormones of the target glands they stimulate (FIGURE 30.9). As an example, consider the cortisol cascade, in which corticotropin-releasing hormone (CRH) from the hypothalamus stimulates release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which in turn stimulates release of the hormone cortisol from the adrenal glands. Once cortisol is released, it circulates throughout the body—including back to the hypothalamus and pituitary

APPLY THE CONCEPT

The pituitary gland links the nervous and endocrine systems

Once released from the adrenal gland into the bloodstream, cortisol diffuses from blood plasma into saliva, enabling the collection of measurable amounts of hormone from saliva samples. The table gives cortisol concentrations in saliva samples taken from two female Asian elephants over a 6-day period during which the animals were introduced to each other at a Berlin zoo. Given that (a) baseline salivary cortisol in elephants is 4–5 nanomoles per liter and (b) elephant 1 received an immunization shot on day 1, graph the data in the table and answer the following questions.

1. Do the data indicate that the elephants experienced an adrenal stress response on meeting each other?
2. What physiological effects would elevated cortisol levels cause in the elephants?
3. Do these data indicate communication between the nervous and endocrine systems? Explain your answer.

DAY	CORTISOL CONCENTRATION (NMOL/L)	
	ELEPHANT 1	ELEPHANT 2
1	10	4
2	6	5
3*	21	4
4	33	22
5	5	4
6	4	5

*Elephants were introduced to each other on day 3. The cortisol sample from elephant 1 was taken after the introduction; that from elephant 2 was taken before the introduction.

gland, where it directly inhibits further release of both CRH and ACTH, thereby helping to maintain a constant level of cortisol secretion.

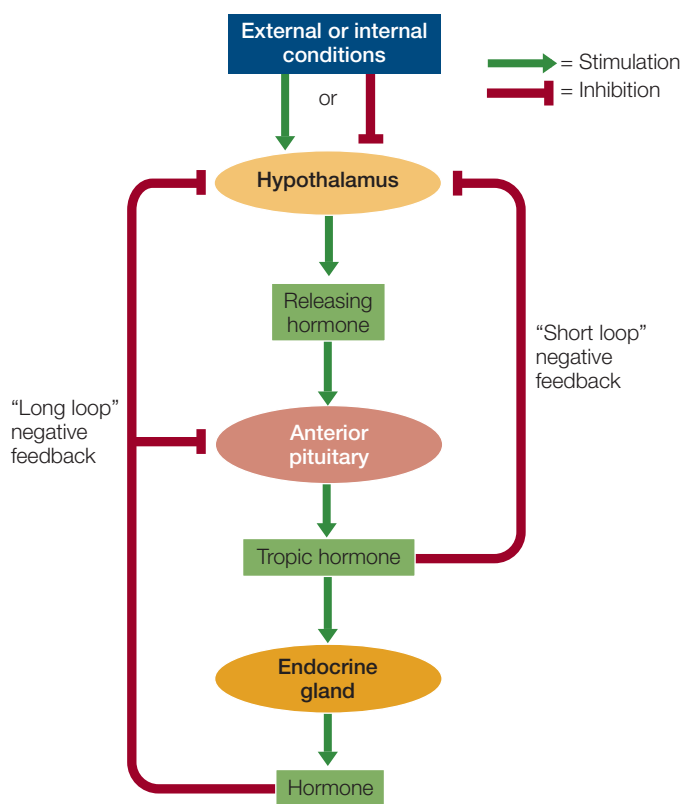

FIGURE 30.9 Multiple Feedback Loops Control Hormone Secretion Multiple negative feedback loops regulate the chain of command from hypothalamus to anterior pituitary to endocrine glands.

Do You Understand Concept 30.3?

- What are the developmental, anatomical, and functional relationships between the brain and the pituitary gland?
- Why are so many anterior pituitary hormones called tropic hormones?
- The hypothalamus and the pituitary gland both have cortisol receptors. If they lose their cortisol receptors, these glands will immediately begin secreting unusually large amounts of CRH and ACTH. Why?

The hypothalamus and pituitary control the secretion of hormones from several other endocrine glands. What hormones do these other glands release, and what are their functions?

concept 30.4 Hormones Regulate Mammalian Physiological Systems

Hormones are involved in regulating most mammalian physiological systems. Some regulatory systems are controlled by pituitary hormones, and all are controlled by feedback information from the physiological functions they regulate. We will examine a few examples of important mammalian hormones, but you should be aware that subsequent chapters will describe many additional examples of regulatory hormones.

Thyroxine helps regulate metabolic rate and body temperature

The **thyroid gland** wraps around the front of the windpipe (*trachea*) and expands into a lobe on either side (see Figure 30.6). Two different cell types in the thyroid gland produce two different hormones, thyroxine and *calcitonin*. In addition, embedded in or near the thyroid gland (depending on the species) are the **parathyroid glands**, which produce *parathyroid hormone*. Calcitonin and parathyroid hormone are involved in calcium regulation and will be discussed in the next section. Here we focus on thyroxine.

Thyroxine is an amine hormone that is synthesized from the amino acid tyrosine. A single thyroxine molecule consists of two tyrosine residues with four iodine atoms covalently attached (two to each tyrosine residue). Thyroxine is also known as T_4 , the subscript signifying that it carries the full complement of four iodine atoms:

The thyroid also releases a nearly identical hormone, T_3 , that has only three iodine atoms:

The thyroid usually releases about four times as much T_4 as T_3 ; however, T_3 is more active in the cells of the body. Circulating T_4 can be converted to T_3 by an enzyme within target cells. Each target cell can set its own sensitivity to thyroid hormones by controlling the conversion of T_4 to the more active T_3 . Although we use the general term thyroxine in this discussion, keep in mind that most of the hormonal activity is due to T_3 .

ACTION AND CONTROL OF THYROXINE In birds and mammals, thyroxine raises metabolic rate. Thyroxine is lipid-soluble and binds to an intracellular receptor that stimulates transcription of numerous genes. These different genes encode proteins involved in energy pathways as well as transport and structural proteins—all of which leads to a general increase in cell metabolism. Thyroxine is especially crucial during development and growth, as it promotes amino acid uptake and protein synthesis. Insufficient thyroxine in a human fetus or growing child greatly retards physical and mental development, resulting in a condition known as cretinism.

As described in Concept 30.3, thyroxine levels are controlled by the hypothalamus and the anterior pituitary. The hypothalamus releases thyrotropin-releasing hormone (TRH), which stimulates the anterior pituitary to release thyroid-stimulating

hormone (TSH). TSH stimulates the thyroid gland to produce and release thyroxine. This sequence of steps is regulated by a negative feedback loop like the one described earlier for cortisol (see Figure 30.9).

GOITERS A *goiter* is an enlarged thyroid gland (**FIGURE 30.10**) that can be associated with either *hyperthyroidism* (excess production of thyroxine) or *hypothyroidism* (thyroxine deficiency). The negative feedback loop whereby thyroxine controls TSH release explains how two very different conditions can result in the same symptom.

The most common cause of hyperthyroid goiter is an autoimmune condition involving an antibody that binds to and activates TSH receptors, causing uncontrolled production and release of thyroxine. Blood levels of TSH are low because of negative feedback from high levels of thyroxine, but the thyroid gland itself remains maximally stimulated and grows bigger. People with hyperthyroidism have a high metabolic rate, tend to be nervous and “jumpy,” usually feel hot, and may develop a buildup of fat behind the eyeballs that causes the eyes to bulge.

Hypothyroid goiter results when there is not enough circulating thyroxine to turn off TSH production. The most common cause of this condition is too little iodine in the diet; without dietary iodine, the thyroid gland cannot make functional thyroxine. Without sufficient thyroxine, TSH levels remain high, stimulating the thyroid to become bigger. The symptoms of hypothyroidism are low metabolism, intolerance of cold, and general physical and mental sluggishness. The occurrence of hypothyroid goiter has been greatly reduced by the widespread use of iodized table salt.

FIGURE 30.10 Goiter Iodine deficiency can result in hypothyroid goiter. In this condition, a lack of functional thyroxine results in enlargement of the thyroid gland.

Hormonal regulation of calcium concentration is vital

Calcium ions (Ca^{2+}) must be maintained at a precise concentration in the blood plasma because Ca^{2+} flow across cell membranes is the trigger for several critical physiological processes. Neurons use calcium to trigger neurotransmitter release, and muscles use calcium to trigger muscle contraction. Shifts in blood calcium concentration above or below a certain narrow range can cause serious problems. Concentrations that are too low can cause muscle spasms and even seizures; excessively high levels of Ca^{2+} can cause the entire nervous system to become depressed, and muscles—including the heart—to weaken or even to stop completely.

Almost 99 percent of the calcium in the human body is located in our bones. About 1 percent is found in cells, and only about 0.1 percent Ca^{2+} is in the extracellular fluid. It is essential that this tiny pool of circulating Ca^{2+} be maintained at precise concentrations. Because the circulating Ca^{2+} pool can be affected greatly by relatively small shifts in the much larger pools in the cells and bones, and because maintaining blood calcium concentration within narrow limits is vital, the body has multiple mechanisms for adjusting and regulating Ca^{2+} levels. These mechanisms include:

- Deposition or resorption of bone
- Excretion or retention of calcium by the kidneys
- Absorption of calcium from the digestive tract

These mechanisms are controlled by the hormones **calcitonin**, **calcitriol** (a hormone synthesized from vitamin D), and **parathyroid hormone (PTH)**.

CALCITONIN Calcitonin is released by the thyroid gland and lowers the concentration of calcium in the blood, mainly by regulating bone turnover (**FIGURE 30.11**). Bone is continuously remodeled through a dynamic process that involves both resorption of old bone and synthesis of new bone (see Concept 36.3). Cells called *osteoclasts* break down bone and release calcium into the blood, whereas cells called *osteoblasts* take up calcium from the blood and deposit it in new bone. Calcitonin decreases the activity of osteoclasts and thereby favors removal of calcium from the blood and its deposition in bone by osteoblasts. The turnover of bone in adult humans is not high, so calcitonin probably does not play a major role in calcium homeostasis in adults. It is likely to be considerably more important in young individuals whose bones are actively growing.

VITAMIN D AND CALCITRIOL As we will discuss in Chapter 39, a *vitamin* is a substance that the body requires in small quantities but cannot synthesize and must therefore obtain from the diet. By this definition, vitamin D (also known as *calciferol*) is not a vitamin, because the

body can and does synthesize it—assuming the skin gets adequate exposure to sunlight. The ultraviolet wavelengths in sunlight convert cholesterol present in the skin cells into vitamin D. If sun exposure is inadequate (as in high-latitude regions during winter months), vitamin D must be obtained from the diet or from supplements. Once present in the body, vitamin D is converted by the liver and kidneys into calcitriol, a hormone whose actions include stimulating the cells of the digestive tract to absorb calcium from ingested food.

Go to ANIMATED TUTORIAL 30.3
Hormonal Regulation of Calcium

PARATHYROID HORMONE The single most important hormone in the regulation of blood calcium levels is parathyroid hormone (PTH), whose synthesis is triggered when blood calcium levels fall below a set point. PTH increases the concentration of calcium in the blood by three different mechanisms:

FIGURE 30.11 Hormonal Regulation of Calcium Calcitonin, parathyroid hormone (PTH), and vitamin D regulate calcium levels in the blood.

APPLY THE CONCEPT

Hormones regulate mammalian physiological systems

The time courses of action for different hormones vary widely. Some hormones are released rapidly, establish their effects almost immediately, and then are cleared from the bloodstream within minutes. Others are released slowly and remain in the blood for many hours or even days.

One way of characterizing the time course of a hormone is to measure its *half-life* in the blood: the length of time it takes for the blood level of a given hormone to fall to half of the baseline (maximum) following its release (or injection). The table gives blood concentrations of thyroxine (T_4) following a 600- μg injection. Plot these data.

TIME (HRS)	CONCENTRATION ($\mu\text{g}/\text{DECILITER}$)
0	7.5
6	13.7
12	12.3
24	11.1
36	10.7
48	10.3
60	9.9
72	9.5
84	9.3
96	9.1

1. Before assessing your graph, consider what you know about the functioning of T_4 . Would you expect this hormone to have a short or a long half-life? Why?
2. Use the data in the table to estimate the actual half-life of 600 μg of T_4 in the bloodstream. (Time 0 is the baseline.)

3. If you were trying to correct a hormonal deficit by administering hormone therapy and needed to maintain a relatively constant hormone level in the blood (i.e., minimizing peaks and troughs), how would your dosing differ for hormones with different half-lives?

- It stimulates the bone-turnover activities of osteoclasts and osteoblasts.
- It stimulates the kidneys to reabsorb calcium.
- It increases the body's absorption of calcium from food by activating the synthesis of calcitriol from vitamin D.

Circulating calcium activates receptors in the plasma membrane of the parathyroid cells, inhibiting the synthesis and release of PTH. A fall in blood calcium removes this inhibition so that PTH can be synthesized and released.

The two segments of the adrenal gland coordinate the stress response

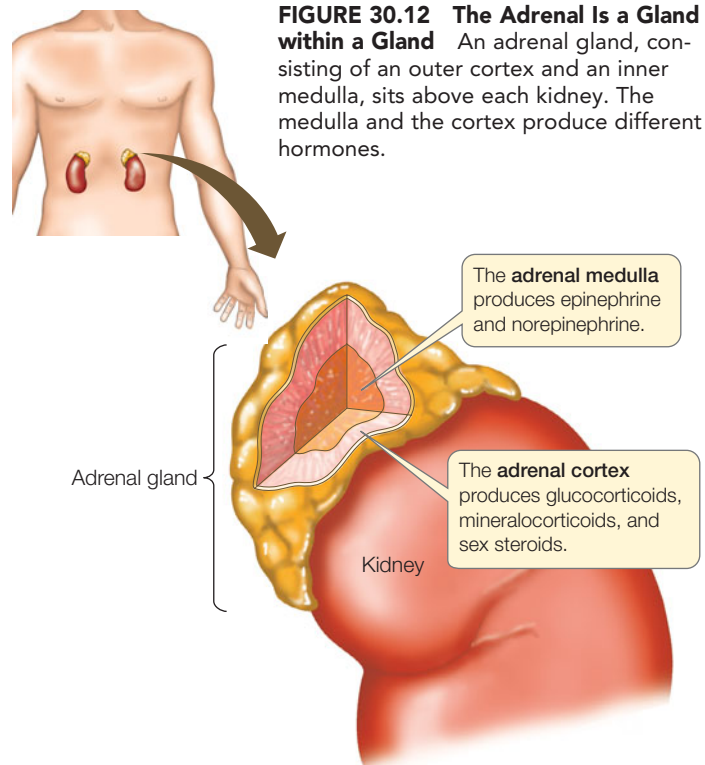

The **adrenal glands** sit above the kidneys, just below the middle of the back (see Figure 30.6). Each of the two adrenal glands is a gland within a gland (**FIGURE 30.12**). The core, or **adrenal medulla**, produces the neurohormones epinephrine and norepinephrine. The medulla's release of these two neurohormones is under the control of the nervous system and is very rapid in response to stressful situations, arousing the body to action as detailed in Concept 30.2. Epinephrine and (to a lesser degree) norepinephrine increase heart rate and blood pressure and divert blood flow to active muscles and away from the gut and skin. They also cause fat and liver cells to release metabolic fuels (see Figure 30.4).

Surrounding the adrenal medulla is the **adrenal cortex**. Under the control of the hypothalamus and anterior pituitary, the adrenal cortex produces a few sex steroids and, importantly, two classes of *corticosteroid hormones*:

- The **mineralocorticoids** influence salt and water balance of the extracellular fluid. The mineralocorticoid *aldosterone*

stimulates the kidneys to conserve sodium and excrete potassium (see Concept 40.5).

- The **glucocorticoids** increase blood glucose concentrations and affect many other aspects of fat, protein, and carbohydrate metabolism. The primary glucocorticoid in most vertebrates is *corticosterone*; in humans and a few other mammals it is **cortisol**.

Corticosterone and cortisol are critical for mediating long-term (hours to days) metabolic responses to stress. Within minutes of a stressful stimulus, blood cortisol levels begin to rise. Cells not critical for fight-or-flight responses are stimulated by cortisol to decrease their use of blood glucose and to shift instead to using fats and proteins for energy. This is no time to feel sick, have allergic reactions, or heal wounds, so cortisol also blocks immune system reactions—which is why cortisol and drugs that mimic its action are useful for reducing inflammation and allergic responses. If glucocorticoids remain elevated for too long, however, they increase the risk of several stress-related conditions, including cardiovascular disorders, gastrointestinal problems, infertility, and lowered immune responses.

Sex steroids from the gonads control reproduction

The gonads—the testes of the male and the ovaries of the female—produce hormones as well as the gametes (sperm and ova). The male steroids are collectively called **androgens**, and the dominant one in humans is *testosterone*. The female sex steroids are **estrogens** and **progesterone**. It is important to note that both sexes make and use androgens and estrogens; however, the relative levels vary in the two sexes.

In embryonic life, the sex steroids determine whether a human embryo develops into a phenotypic female or male. At puberty, they trigger maturation of the reproductive organs and the development of *secondary sexual characteristics*, such as breasts and facial hair. They continue to play essential roles in reproductive cycles and sexual functioning throughout adulthood, as described in Chapter 32.

SEXUAL DIFFERENTIATION IN EMBRYOS If a Y chromosome is present, the undifferentiated embryonic gonads begin producing testosterone in the seventh week of development, along with a peptide hormone called *MIS* (*Müllerian-inhibiting substance*). Testosterone causes testes and the male reproductive ducts to develop, and MIS induces apoptosis of the cells making up the female reproductive (Müllerian) ducts, so they disappear. If no androgens or MIS are produced, female reproductive structures develop (FIGURE 30.13). In other words, androgens are required to trigger male development in humans, and in their absence the fetus develops as a female.

PUBERTY Sex steroids are produced at extremely low levels by the juvenile gonads, but their production increases rapidly at **puberty**—a time of sexual maturation and dramatic physical transformation that occurs around the age of 12 or 13. What triggers this sudden increase?

The production of sex steroids by the gonads is controlled by the anterior pituitary hormones **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, which together are called the **gonadotropins**. Gonadotropin production is in turn under the control of the hypothalamic neurohormone **gonadotropin-releasing hormone (GnRH)**. Before puberty, the hypothalamus produces only very low levels of GnRH. Puberty is initiated by a reduction in the sensitivity of hypothalamic

FIGURE 30.13 Sex Steroids Direct the Development of Human Sex Organs The sex organs of early human embryos are undifferentiated. Androgens promote the development of male sex organs. In the absence of androgens, female sex organs form.

GnRH-producing cells to negative feedback from the sex steroids and gonadotropins. This reduced sensitivity overcomes the negative feedback, so GnRH release increases, stimulating increased production of gonadotropins and hence increased production of sex steroids.

In females, increased levels of LH stimulate the ovaries to increase estrogen production. Increased circulating levels of estrogen initiate development of the traits of a sexually mature woman: enlarged breasts, vagina, and uterus; broadened hips; increased subcutaneous fat; pubic hair; and the menstrual cycle. In males, increasing LH stimulates cells in the testes to produce testosterone, which initiates the physiological, anatomical, and psychological changes associated with male adolescence. The voice deepens, hair begins to

grow on the face and body, muscle mass increases, and the testes and penis grow larger. At this time the anterior pituitary also increases FSH production; in females this stimulates the maturation of ovarian follicles, and in males it stimulates the production of sperm.

Do You Understand Concept 30.4?

- Explain how both hyperthyroidism and hypothyroidism can cause goiter. Refer to the roles of the hypothalamus and the pituitary in your answer.
- How does the hypothalamus affect the endocrine activity of the gonads and the adrenal cortex? What is similar about the way the gonads and the adrenal cortex are regulated?

We have discussed just a few of the glands and their hormones in this chapter—enough to give an overview of how hormones act and the types of physiological functions they regulate. Many more hormones exist, and new hormones are discovered almost every year. As we discuss the organ systems of the body in the chapters that follow, we will see many other examples of hormones regulating other physiological processes.

FIGURE 30.14 Real People, Real Lives This photo shows a group of women with AIS and similar intersex conditions at a support group meeting.

How do the transformative effects of testosterone exemplify the way many hormones work?

ANSWER The effects of testosterone start when this lipid-soluble hormone binds to its receptor in the target cell cytoplasm (Concept 30.1). The hormone–receptor complex then moves into the target cell nucleus, where it stimulates the expression of different genes in different cells; its actions differ depending on the type of target cell it binds to (Concept 30.2). In muscle cells, for example, testosterone induces expression of the genes for the contractile proteins, so muscle mass increases. In hair cells, the genes for the protein keratin are activated.

Androgen insensitivity syndrome (AIS) demonstrates the essential role of hormone receptors, since its cause is not a lack of testosterone but a lack of functional testosterone receptors. Without these receptors, testosterone cannot stimulate development of the male reproductive ducts, male genitalia, or male secondary sexual characteristics. However, the peptide hormone MIS is produced normally and inhibits the development of internal female reproductive ducts. The result is a genetically XY individual whose body appears female on the outside but lacks internal female sex organs (**FIGURE 30.14**).

The rare condition “testes-at-twelve” exemplifies another aspect of hormonal control. It turns out that, like the T_3 and T_4 forms of thyroid hormone (Concept 30.4), testosterone can be modified into an even more potent form known as dihydrotestosterone, or DHT. Guevedoces lack the gene for the enzyme that converts testosterone to DHT, and DHT is required to masculinize the external genitalia during early development. If DHT is not present, the penis and scrotum do not form in the infant, and the young child is perceived to be female. When much higher levels of testosterone are triggered by puberty, however, testosterone stimulates formation of the penis and scrotum, and thus at puberty XY individuals are revealed to be male.

30

SUMMARY

concept 30.1 Hormones Are Chemical Messengers

- **Endocrine cells** secrete chemical signals that induce responses in other cells—called **target cells**—that have receptors for those molecules. In some cases endocrine cells are aggregated into **endocrine glands**. See **WEB ACTIVITY 30.1**
- **Hormones** are endocrine signals that are secreted from a cell, circulate in the blood, and bind to target cells distant from the secreting cell.
- Most hormones are either **peptide hormones**, **steroid hormones**, or **amine hormones**. Peptides and some amines are water-soluble; steroids and some amines are lipid-soluble. **Review Figure 30.1**
- Two hormones, PTTH and ecdysone, control molting in arthropods. A third hormone, **juvenile hormone (JH)**, prevents maturation. When an insect stops producing juvenile hormone, it molts into an adult. **Review Figure 30.3 and ANIMATED TUTORIAL 30.1**

concept 30.2 Hormones Act by Binding to Receptors

- Receptors for water-soluble hormones are located on the cell surface. Receptors for most lipid-soluble hormones are inside the cell.
- Hormones cause different responses in different target cells. **Review Figure 30.5**
- The sensitivity of a cell to hormones can be altered by down-regulation or upregulation of the receptors in that cell.

concept 30.3 The Pituitary Gland Links the Nervous and Endocrine Systems

- The **pituitary gland** is the interface between the nervous and endocrine systems.

- The posterior pituitary secretes two peptide neurohormones: **antidiuretic hormone (ADH)** and **oxytocin**. **Review Figure 30.7**
- The anterior pituitary is controlled by neurohormones produced by cells in the **hypothalamus**. The anterior pituitary secretes four **tropic hormones** as well as **growth hormone**, prolactin, and a few other hormones. **Review Figure 30.8 and ANIMATED TUTORIAL 30.2**
- Hormone release is controlled by negative feedback loops. **Review Figure 30.9**

concept 30.4 Hormones Regulate Mammalian Physiological Systems

- The **thyroid gland** is controlled by **thyroid-stimulating hormone (TSH)** and secretes **thyroxine**, which controls cell metabolism.
- **Calcitonin** from the thyroid lowers blood calcium by promoting bone deposition. **Parathyroid hormone (PTH)** raises blood calcium by promoting bone turnover and decreasing calcium excretion. **Calcitriol**, synthesized from vitamin D, promotes calcium absorption from the digestive tract. **Review Figure 30.11 and ANIMATED TUTORIAL 30.3**
- The **adrenal gland** has two parts. The inner **adrenal medulla** releases **epinephrine** and **norepinephrine** in a rapid response to stress. The **adrenal cortex** produces steroids, including sex steroids, **glucocorticoids**, and **mineralocorticoids**. **Review Figure 30.12**
- Sex steroids (**androgens** in males, **estrogens** and **progesterone** in females) are produced by the gonads in response to tropic hormones. Sex steroids control sexual development, secondary sexual characteristics, and reproductive functions. **Review Figure 30.13**

See **WEB ACTIVITY 30.2** for a concept review of this chapter

Immunology: Animal Defense Systems

31

As a rule, however, there was no ostensible cause; but people in good health were all of a sudden attacked by violent heats in the head, and redness and inflammation in the eyes, the inward parts, such as the throat or tongue, becoming bloody and emitting an unnatural and fetid breath.

The Athenian historian Thucydides wrote these words in 430 B.C.E. He was describing a rapidly spreading infectious disease, or plague, that was sweeping the city of Athens in ancient Greece, and would ultimately kill about one-third of its inhabitants.

One year earlier, in 431 B.C.E., the Spartans had surrounded Athens. Sparta was a rival state with a highly disciplined army, while Athens was near a port and had a powerful navy. The Athenian leader Pericles decided to take advantage of his naval supremacy. He instructed his soldiers to abandon the countryside to the Spartans, relying on the navy to keep the enemies out of the city and to keep the Athenians supplied with food. People living in the countryside poured into Athens.

As Athens became more crowded, deteriorating sanitation and close living conditions resulted in the city becoming an incubator for infectious diseases. In his famous *History of the Peloponnesian War*, Thucydides speculated that this disease came to Athens from Africa. His precise clinical description has provoked great debate among medical historians regarding its nature. In 1994, a burial ground was found near Athens that apparently contained the remains of several dozen people who died of the disease. Samples of dental pulp from the skeletons were examined using the polymerase chain reaction (PCR), and the results revealed the

presence of DNA sequences from the bacterium that causes typhoid fever. Based on these results, it was proposed that the disease that killed so many Athenians was typhoid fever. Others disagree, using arguments based on a clinical description of typhoid fever today.

Whatever the cause, another passage from Thucydides (who was one of the few lucky survivors of the disease) is an interesting observation about immunity—the subject of this chapter:

Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what it was from experience and now had no fear for themselves; for the same man was never attacked twice, never at least fatally.

The siege of Athens by Sparta and its Peloponnesian allies made the city crowded and vulnerable to the spread of an infectious disease.

31.1

Animals Use Innate and Adaptive Mechanisms to Defend Themselves against Pathogens

Animals have a number of ways of defending themselves against **pathogens**—harmful organisms and viruses that can cause disease. There are two general types of defense mechanisms that can provide **immunity**—the ability to avoid disease when invaded by a pathogen:

- **Innate immunity** is nonspecific in that it is deployed against a wide variety of invasive organisms. Innate immunity systems include barriers such as the skin and molecules that are toxic to or destroy invaders; these provide the first line of defense for the body. A second line of innate defense includes phagocytic cells (*phagocytes*), which ingest foreign cells and other particles. These defenses may be present all the time, or they may be activated in response to an injury or invasion by a pathogen. Such inducible innate defenses are typically activated very rapidly. Most animals have innate immunity.

LINK You may review the description of phagocytosis in Concept 4.3 (see Figure 4.9)

- **Adaptive immunity** is specific. It distinguishes between substances that are made by the organism (*self*) and substances that are not part of the organism (*nonself*). Adaptive immunity involves antibody proteins and other proteins that recognize, bind to, and aid in the destruction of specific viruses and bacteria. Adaptive immunity is typically slow to develop and long lasting, and it is found only in vertebrate animals.

TABLE 31.1

Innate and Adaptive Immune Responses to an Infection

RESPONSE (TIME AFTER INFECTION BY A PATHOGEN)	SYSTEM	MECHANISMS
Early (0–4 hr)	Innate, nonspecific (first line)	Barrier (skin and lining of organs)
		Dryness, low pH
		Mucus
Middle (4–96 hr)	Innate, nonspecific (second line)	Lysozyme, defensins
		Inflammation
		Phagocytosis
		Natural killer cells
		Complement system
Late (>96 hr)	Adaptive, specific	Interferons
		Humoral immunity (B cells, antibodies)
		Cellular immunity (T cells)

Mammals have both innate and adaptive immunity and are the focus of this chapter. In mammals and other vertebrates, these nonspecific and specific mechanisms operate together as a *coordinated* defense system, usually in sequence. **TABLE 31.1** gives an overview of these processes during the course of an infection. Innate immunity is the body's first line of defense; adaptive immunity often requires days or even weeks to become effective.

The major players in immunity are specific cells and proteins. These are produced in the blood and lymphoid tissues (see Concept 38.4) and are circulated throughout the body where they interact with almost all of its other tissues and organs. We will describe these cells and proteins briefly here and then in more detail later in the chapter.

White blood cells play many roles in immunity

One milliliter of human blood typically contains about *5 billion* red blood cells and *7 million* white blood cells. While the main function of red blood cells is to carry oxygen throughout the body, **white blood cells** are specialized for various functions in the immune system. Examine **FIGURE 31.1** and you will see that there are two major kinds of white blood cells (also called *leukocytes*): phagocytes and lymphocytes. **Phagocytes** (such as *macrophages*) are large cells that engulf pathogens and other substances by phagocytosis. They are involved in both innate and adaptive immunity. **Lymphocytes**, which include *B cells* and *T cells*, are involved in adaptive immunity.

Go to ANIMATED TUTORIAL 31.1
Cells of the Immune System

Immune system proteins bind pathogens or signal other cells

The cells of the adaptive immune system work together, interacting with one another and with the cells of invading pathogens. These cell–cell interactions depend on a variety of key proteins, including receptors, other cell surface proteins, and signaling molecules. Four of the major players are listed here and will be discussed in more detail later:

- **Antibodies** are proteins that bind specifically to substances identified by the immune system as nonself. This binding can inactivate and destroy microorganisms and toxins, and it can act as a tag on nonself cells, making them easier for the immune system cells to attack. Antibodies are produced by B cells.
- **Major histocompatibility complex (MHC)** proteins are found in two classes (I and II). MHC I proteins are found on the surfaces of most cells in the mammalian body. MHC II proteins are found on most immune system cells. MHC proteins are important self-identifying labels and play a major role in coordinating interactions between lymphocytes and macrophages.
- **T cell receptors** are integral membrane proteins on the surfaces of T cells. They recognize and bind to nonself substances presented by MHC proteins on the surfaces of other cells.

	TYPE OF CELL	FUNCTION
	Basophils (I, A)	Release histamine; may promote development of T cells
	Eosinophils (A)	Kill antibody-coated parasites
	Neutrophils (I)	Stimulate inflammation; engulf and digest microorganisms
	Mast cells (I)	Release histamine when damaged
	Monocytes (I, A)	Develop into macrophages and dendritic cells
	Macrophages (I, A)	Engulf and digest microorganisms; activate T cells
	Dendritic cells (A)	Present antigens to T cells
	B lymphocytes (A)	Differentiate to form antibody-producing cells and memory cells
	T lymphocytes (A)	Kill virus-infected cells; regulate activities of other white blood cells
	Natural killer cells (I)	Attack and lyse virus-infected or cancerous body cells

FIGURE 31.1 White Blood Cells White blood cells have key roles in both innate (I) and adaptive (A) immunity. The lymphocytes are the B cells and T cells; the other cell types are phagocytes.

- **Cytokines** are soluble signaling proteins released by many cell types. They bind to cell surface receptors and alter the behavior of their target cells. Various cytokines activate or inactivate B cells, macrophages, and T cells.

Do You Understand Concept 31.1?

- List the differences between innate and adaptive immunity.
- Rarely, a person is born with a genetic disease and has no lymphocytes. What would be the consequences of this situation for the immune system? Explain why such a person would have to be very careful about going outdoors.

Now that we've seen a brief overview of innate and adaptive immunity, let's look at some of the innate defenses that animals have against invading organisms.

concept 31.2 Innate Defenses Are Nonspecific

Innate, nonspecific defenses are general protection mechanisms that attempt to either stop pathogens from invading the body or quickly eliminate pathogens that do manage to invade. They are genetically programmed (innate) and “ready to go,” in contrast to adaptive, specific immunity, which takes time to develop after a pathogen or toxin has been recognized as non-self. In mammals, innate defenses include physical barriers as well as cellular and chemical defenses (**FIGURE 31.2**).

Barriers and local agents defend the body against invaders

The first line of innate defense is encountered by a potential pathogen as soon as it lands on the surface of the animal. Consider a pathogenic bacterium that lands on human skin. The challenges faced by the bacterium just to reach its target are formidable:

- **The physical barrier of the skin:** Bacteria rarely penetrate intact skin (which explains why broken skin increases the risk of infection).
- **The saltiness of the skin:** This condition is usually not hospitable to the growth of the bacterium.
- **The presence of normal flora:** Bacteria and fungi that normally live in great numbers on body surfaces without causing disease will compete with potential pathogens for space and nutrients.

If a pathogen lands inside the nose or another internal organ, it faces other innate defenses:

- **Mucus** is a slippery secretion produced by *mucous membranes*, which line various body cavities that are exposed to the

FIGURE 31.2 Innate Immunity Physical barriers, cells, and proteins (complement and interferons) provide nonspecific defenses against invading pathogens.

external environment. Mucus traps microorganisms so they can be removed by the beating of *cilia* (see Concept 4.4, p. 70), which continuously move the mucus and its trapped debris away.

- **Lysozyme**, an enzyme made by mucous membranes, cleaves bonds in the cell walls of many bacteria, causing them to *lyse* (burst open).
- **Defensins**, also made by mucous membranes, are peptides of 18–45 amino acids. They contain hydrophobic domains and are toxic to a wide range of pathogens, including bacteria, microbial eukaryotes, and enveloped (membrane-enclosed) viruses. Defensins insert themselves into the plasma membranes of these organisms and make the membranes freely permeable to water and all solutes, thus killing the invaders:

Defensins are also produced inside phagocytes, where they kill pathogens trapped by phagocytosis. Plants also produce defensins in response to pathogens (see Concept 28.1).

- Harsh conditions in the internal environment can kill pathogens. For example, the gastric juice in the stomach is a deadly environment for many bacteria because of the hydrochloric acid and proteases that are secreted into it.

Other innate defenses include specialized proteins and cellular processes

Pathogens that penetrate the body's outer and inner surfaces encounter a second line of innate defenses. These include the activation of defensive cells such as phagocytes and natural killer cells, and the secretion of various defensive proteins such as *complement* and *interferon* proteins.

PHAGOCYTES Pathogenic cells, viruses, or fragments of these invaders can be recognized by phagocytes, which then ingest them by phagocytosis:

Once inside the phagocyte, the invader is killed either by hydrolysis within the lysosomes (see Figure 4.9) or by defensins.

NATURAL KILLER CELLS One class of lymphocytes, known as **natural killer cells**, can distinguish between healthy body cells and those that are infected by viruses or have become cancerous. In the latter cases they initiate apoptosis (programmed cell death; see Concept 7.5) in the target cells. In addition to this nonspecific action, natural killer cells interact with the adaptive defense mechanisms by lysing antibody-labeled target cells.

COMPLEMENT PROTEINS Vertebrate blood contains more than 20 different proteins that make up the antimicrobial **complement system**. Once this system has been activated, the proteins function in a characteristic sequence, or cascade, with each protein activating the next:

1. One complement protein binds to components on the surface of an invading cell. This binding helps phagocytes recognize and destroy the invading cell.
2. Another protein activates the inflammation response (see below) and attracts phagocytes to the site of infection.
3. Finally, other proteins lyse the invading cell.

The complement system can be activated by various mechanisms, including innate (nonspecific) and adaptive (specific) immune responses. In the latter case, the complement cascade is initiated by the binding of a complement protein to an antibody bound to the surface of the invading cell.

INTERFERONS When a cell is infected by a viral pathogen, the cell produces small amounts of signaling proteins called **interferons** that help increase the resistance of neighboring cells to infection. Interferons are a class of cytokines and are found in many vertebrates. Various molecules induce the production of interferons. One such inducer is double-stranded viral RNA; thus interferons are particularly important in defense against viruses. Interferons bind to receptors on the plasma membranes of uninfected cells, stimulating a signaling pathway that inhibits viral reproduction if the cells are subsequently infected. In addition, interferons stimulate the cells to hydrolyze bacterial or viral proteins to peptides, an initial step in adaptive immunity.

Inflammation is a coordinated response to infection or injury

When a tissue is damaged because of infection or injury, the body responds with **inflammation**: redness, swelling, and heat near the damaged site, which can become painful. This response can happen almost anywhere in the body, internally as well as on the outer surface. Inflammation is an important phenomenon: it isolates the area to stop the spread of the damage; it recruits cells and molecules to the damaged location to kill any pathogens that might be present; and it promotes healing.

Among the first responders to tissue damage are **mast cells**, which adhere to the skin and the linings of organs and release numerous chemical signals, including:

- **tumor necrosis factor**, a cytokine protein that kills target cells and activates immune cells.
- **prostaglandins**, fatty acid derivatives that play roles in various responses, including the initiation of inflammation in nearby tissues.
- **histamine**, an amino acid derivative that increases the permeability of blood vessels to white blood cells and molecules so they can act in nearby tissues.

The redness and heat of inflammation result from the dilation of blood vessels in the infected or injured area (**FIGURE 31.3**). Phagocytes enter the inflamed area, where they engulf pathogens and dead tissue cells. Phagocytes and neutrophils are responsible for most of the healing associated with inflammation. They produce several cytokines, which (among other functions) can signal the brain to produce a fever. This rise in body temperature accelerates lymphocyte production and phagocytosis, thereby speeding the immune response. In some cases pathogens are temperature-sensitive, and their growth is inhibited by the fever. The pain of inflammation results from increased pressure due to swelling,

the action of leaked enzymes on nerve endings, and the action of prostaglandins, which increase the sensitivity of the nerve endings to pain. (Recall that in Chapter 3, we describe aspirin and how it alleviates pain by blocking the synthesis of prostaglandins.)

Following inflammation, pus may accumulate. *Pus* is a mixture of leaked fluid and dead cells: bacteria, white blood cells, and damaged body cells. Pus is a normal result of the body's fighting a disease and/or inflammation and is gradually removed by macrophages. If there is a wound, *platelets*—small, irregularly shaped cell fragments that are present in the blood—aggregate at the wound site. The platelets produce growth factors that stimulate nearby skin cells to divide and heal the wound.

Inflammation can cause medical problems

While inflammation is generally a good thing, sometimes the inflammatory response is inappropriately strong:

- In an **allergic** reaction, a nonself molecule that is normally harmless binds to mast cells, causing the release of histamine and subsequent inflammation (along with itchy, watery eyes, and rashes in some cases). The nonself molecule may come from food or from the environment—for example, on the

surface of a plant pollen grain (as in hay fever) or a particle in dust.

- In **autoimmune diseases** such as rheumatoid arthritis, the immune system fails to distinguish between self and non-self, and attacks tissues in the organism's own body. In these cases the inflammation is somewhat more general, affecting tissues throughout the body.
- In **sepsis**, the inflammation due to a bacterial infection does not remain local. Instead it extends throughout the body, with the dilation of blood vessels throughout the body. The resulting drop in blood pressure is a medical emergency and can be lethal.

FRONTIERS Anti-inflammatory drugs are among the most popular medications. Many of the commonly used ones block prostaglandins and have side effects because of their inhibition of prostaglandin-related processes elsewhere in the body. Knowledge of the role of tumor necrosis factor is leading to the development of more specific agents to block inflammation in rheumatoid arthritis.

Do You Understand Concept 31.2?

- Outline the sequence of innate defenses encountered by a pathogenic bacterial cell if it is ingested in food. Similarly, outline the defenses encountered by a bacterial cell that lands in the nose.
- Antihistamines are used to treat the symptom of sneezing due to inflammation caused by irritants in the airways. How do you think antihistamines might work?
- A massive inflammation due to a food allergy can be treated with an injection of epinephrine. Refer to the description of epinephrine's effects in Concept 30.2. How do you think this hormone relieves the inflammation symptoms?

In most instances innate immunity is sufficient to block a pathogen from affecting the body. But many pathogens are present in huge numbers (think of a viral infection), and some may escape the innate responses and begin to proliferate in the body. In these cases, adaptive immunity takes over.

concept 31.3 The Adaptive Immune Response Is Specific

Long before the twentieth century, scientists had suspected that blood was somehow involved in immunity against pathogens, but they did not have definitive experimental evidence to support their suspicions. Over a century ago, Emil von Behring and Shibasaburo Kitasato at the University of Marburg in Germany performed a key experiment that pointed to blood as an important factor in adaptive immunity (**FIGURE 31.4**).

They showed that guinea pigs injected with a sublethal dose of diphtheria toxin developed in their blood serum (the non-cellular fluid that remains after blood is clotted) a factor that when injected into other guinea pigs was able to protect them from a lethal dose of the same toxin. In other words, the serum recipients had somehow acquired immunity. The response of the donor guinea pigs to the diphtheria toxin is an example of *adaptive immunity*: after exposure to the toxin, they made a protective factor that was not present before their exposure. Moreover, the immunity was specific: the factor made by the first guinea pig protected the others only against the specific toxin produced by the strain of bacteria with which the first guinea pigs had been injected.

Based on the animal model, Behring realized that serum protection might work for human diseases as well. It did, and he won the Nobel Prize for his efforts in protecting children against diphtheria. Later, the agent of this immunity was identified as an antibody protein, and the process of acquiring immunity from antibodies received from another individual was called *passive immunity*.

LINK Many bacteria produce toxins of various types; see Concept 19.3

Adaptive immunity has four key features

As we explore adaptive immunity in more detail in this chapter, it is important to keep in mind the key features of the adaptive immune system that enable it to protect the body:

- It is *specific*, which allows it to focus its responses on pathogens that are actually present.
- It is *diverse*, which enables it to respond to novel pathogens.
- It *distinguishes self from nonself*, which prevents it from destroying self cells.
- It has *immunological memory*, which allows it to respond more effectively in later exposures to the same pathogen.

SPECIFICITY B and T lymphocytes are crucial for the specificity of adaptive immune responses. T cell receptors and the antibodies produced by B cells recognize and bind to specific nonself substances called **antigens**, and this interaction initiates a specific immune response. Each T cell and each antibody-producing B cell is specific for a single antigen.

The sites on antigens that the immune system recognizes are called **antigenic determinants** or *epitopes*:

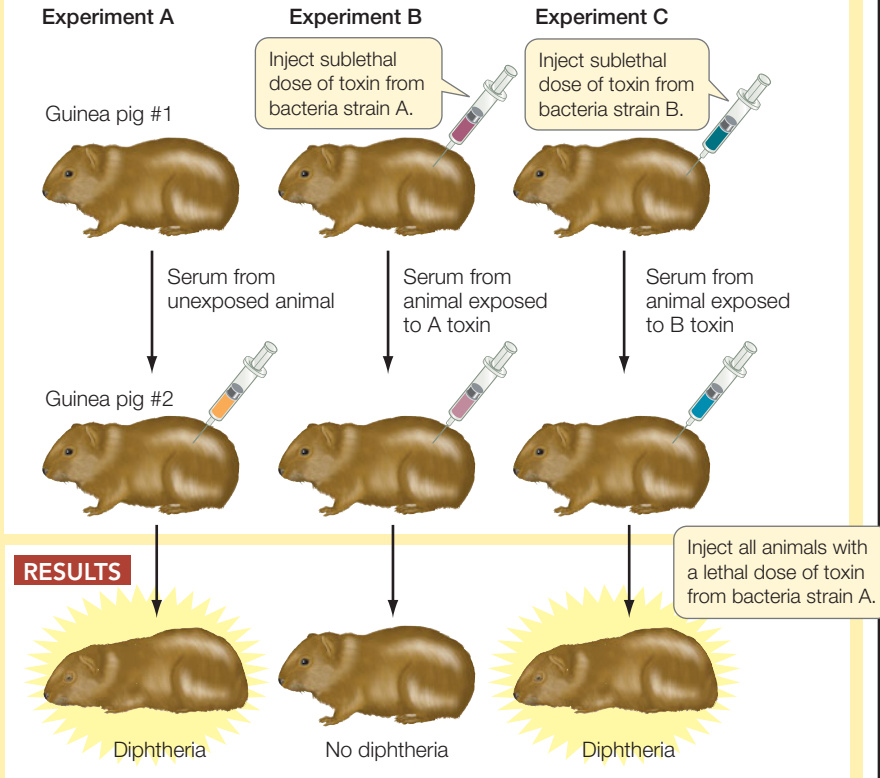

INVESTIGATION

FIGURE 31.4 The Discovery of Specific Immunity Until the twentieth century, most people did not survive an attack of diphtheria, but a few did. Emil von Behring and Shibasaburo Kitasato performed a key experiment using an animal model. They demonstrated that the factor(s) responsible for immunity against diphtheria was in the blood serum.

HYPOTHESIS

Serum from guinea pigs injected with a sublethal dose of diphtheria toxin protects other guinea pigs that are exposed to a lethal dose of the same toxin.

METHOD

RESULTS

CONCLUSION

Serum of toxin-exposed guinea pigs is protective against later exposure to a lethal dose of toxin from the same genetic strain of bacteria, but not a different strain.

ANALYZE THE DATA

In their experiments, Behring and Kitasato used different doses of toxin to test the immunity of guinea pig #2 in each experiment. These are the results:

Experiment	Symptoms	
	0.5 ml dose	10 ml dose
A	Diphtheria	Diphtheria
B	No diphtheria	No diphtheria
C	Diphtheria	Diphtheria

- Explain these data in terms of the level of protection afforded by the serum.
- These experiments could be performed with either intact bacteria that cause diphtheria, or a bacteria-free filtrate of a 10-day-old culture of the bacteria. Explain.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

Antigens are usually proteins or polysaccharides, and there can be multiple antigens on a single invading bacterium. An antigenic determinant is a specific portion of an antigen, such as a certain sequence of amino acids that may be present in a protein. A single antigenic molecule can have multiple different antigenic determinants. For the remainder of the chapter, we will refer to antigenic determinants simply as “antigens.”

DIVERSITY Pathogens take many forms: viruses, bacteria, protists, fungi, and multicellular parasites, and toxins made by these organisms. Furthermore, each pathogenic species usually exists as many subtly different genetic strains, and each strain possesses multiple surface features. Estimates vary, but a reasonable guess is that humans can respond specifically to 10 million different antigens. Upon recognizing an antigen, the immune system responds by activating lymphocytes of the appropriate specificity.

To have the ability to respond to the large number of potential pathogens, the body needs to generate a vast diversity of lymphocytes that are specific for different antigens. These lymphocytes represent a pool from which specific cells are selected when needed.

- Diversity is generated primarily by DNA changes*—chromosomal rearrangements and other mutations—that occur just after the B and T cells are formed in the bone marrow. Each B cell is able to produce only one kind of antibody; thus there are millions of different B cells. Similarly, there are millions of different T cells with specific T cell receptors. The adaptive immune system is “predeveloped”—all of the machinery available to respond to an immense diversity of antigens is already there, even before the antigens are encountered.

- Antigen binding “selects” a particular B or T cell for proliferation.* For example, when an antigen fits the surface receptor on a B cell and binds to it, that B cell is *activated*. It divides to form a clone of cells (a genetically identical group derived from a single cell), all of which produce and/or secrete antibodies with the same specificity as the receptor (**FIGURE 31.5**). Binding, activation, and proliferation also apply to T lymphocytes. A particular lymphocyte is selected via binding and activation, and then it proliferates to generate a clone—hence the name **clonal selection** for this mechanism of producing an immune response.

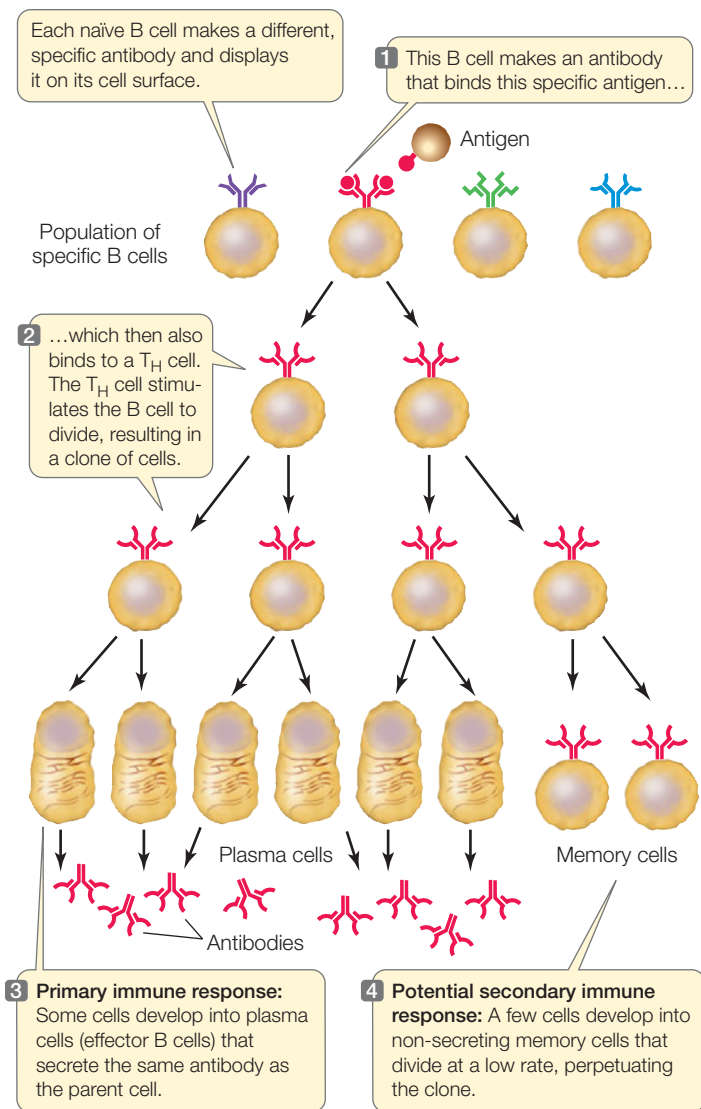

FIGURE 31.5 Clonal Selection in B Cells The binding of an antigen to a specific receptor on the surface of a B cell stimulates that cell to divide, producing a clone of genetically identical cells to fight that invader.

DISTINGUISHING SELF FROM NONSELF The human body contains tens of thousands of different molecules, each with a specific three-dimensional structure capable of generating immune responses. Thus every cell in the body bears a tremendous number of antigens. A crucial requirement of an individual's immune system is that it recognize the body's own antigens and not attack them.

Normally, the body is *tolerant* of its own molecules—the same molecules that would generate an immune response in another individual. This occurs primarily during the early differentiation of T and B cells, when they encounter self antigens. Any immature B or T cell that shows the potential to mount a strong immune response against self-antigens undergoes apoptosis within a short time. This process is called **clonal deletion**.

A failure of clonal deletion leads to an immune response within an individual to self-antigens, or **autoimmunity**. Autoimmunity does not always result in disease, but a number of autoimmune diseases are common:

- People with *systemic lupus erythematosus* (SLE) have antibodies to many cellular components. These antibodies can cause serious damage when they bind to normal tissue antigens and form large circulating antigen–antibody complexes. These can become stuck in tissues and provoke inflammation.
- *Hashimoto's thyroiditis* is the most common autoimmune disease in women over age 50. Immune cells attack thyroid tissue, resulting in fatigue, depression, weight gain, and other symptoms associated with impaired thyroid function.

FRONTIERS One possible mechanism for inducing autoimmunity is *molecular mimicry*, in which exposure to an antigen similar to a self antigen provokes an immune response that cross-reacts with the self antigen. There is a search underway for antigens that cause this response, which can lead to autoimmune diseases. The antigens may be in the environment, foods, or microbes.

IMMUNOLOGICAL MEMORY After responding to a particular type of pathogen once, the immune system “remembers” that pathogen and can usually respond more rapidly and powerfully to the same threat in the future. This **immunological memory** usually saves us from repeats of childhood infectious diseases.

The first time a vertebrate animal is exposed to a particular antigen, it takes several days before the adaptive immune system produces antibodies and T cells specific for the antigen. This is the **primary immune response**. Immunological memory arises from the fact that activated lymphocytes divide and differentiate to produce *two types* of daughter cells: effector cells and memory cells (see Figure 31.5).

- **Effector cells** carry out the attack on the antigen. Effector B cells, called **plasma cells**, secrete antibodies. Effector T cells release cytokines and other molecules that initiate reactions that destroy nonself or altered cells. Effector cells live for only a few days.
- **Memory cells** are long-lived cells that retain the ability to start dividing on short notice to produce more effector and more memory cells. Memory B and T cells may survive in the body for decades, rarely dividing.

After a primary immune response to a particular antigen, subsequent encounters with the same antigen will trigger a much more rapid and powerful **secondary immune response**. The memory cells that bind with that antigen proliferate, launching a huge army of plasma cells and effector T cells. The principle behind vaccination is to trigger a primary immune response that prepares the body to mount a stronger, quicker secondary response if it encounters the actual pathogen again.

FRONTIERS How long does immunological memory last? People currently over age 20 did not receive the now-widespread childhood vaccine against chicken pox, an infection that can be harmful in adults. Most of these people contracted chicken pox as children. Are their memory cells still there in sufficient quantities to prevent new infections by the chicken pox virus, or should they be inoculated? Immunologists are experimenting with cells isolated from inoculated people to answer this question.

Two types of adaptive immune responses interact

The adaptive immune response involves three phases (FIGURE 31.6):

- *Recognition phase.* The organism discriminates between self and nonself to detect a pathogen.
- *Activation phase.* The recognition event leads to a mobilization of cells and molecules to fight the invader.
- *Effector phase.* The mobilized cells and molecules destroy the invader.

Depending on the tissue and antigen, these three phases can occur in either of two types of responses: the *humoral immune response* and the *cellular immune response*.

B cells that make antibodies are the workhorses of the **humoral immune response**, and **cytotoxic T (T_C) cells** are the workhorses of the **cellular immune response**. A key event early in these two processes is the exposure or *presentation* of the antigen to the immune system, where recognition can occur. In humoral immunity, this primarily occurs when an antigen binds to a B cell that has on its surface an antibody that is specific for that antigen. In cellular immunity, an antigen is inserted into the plasma membrane of an

antigen-presenting cell, with the unique epitope structure protruding from the cell membrane. This antigen is recognized by a **T-helper cell (T_H cell)** bearing a T cell receptor protein that is specific for that antigen. In both cases, binding is highly specific and initiates the activation phase.

Antigen binding readies a B cell for division. Some antigen is internalized by the B cell after binding and digested into fragments. When an antigenic fragment binds to the B cell MHC protein and is presented on the B cell surface, a T_H cell whose receptor is specific for that antigen binds to the B cell. The binding of the T cell stimulates the B cell to divide and

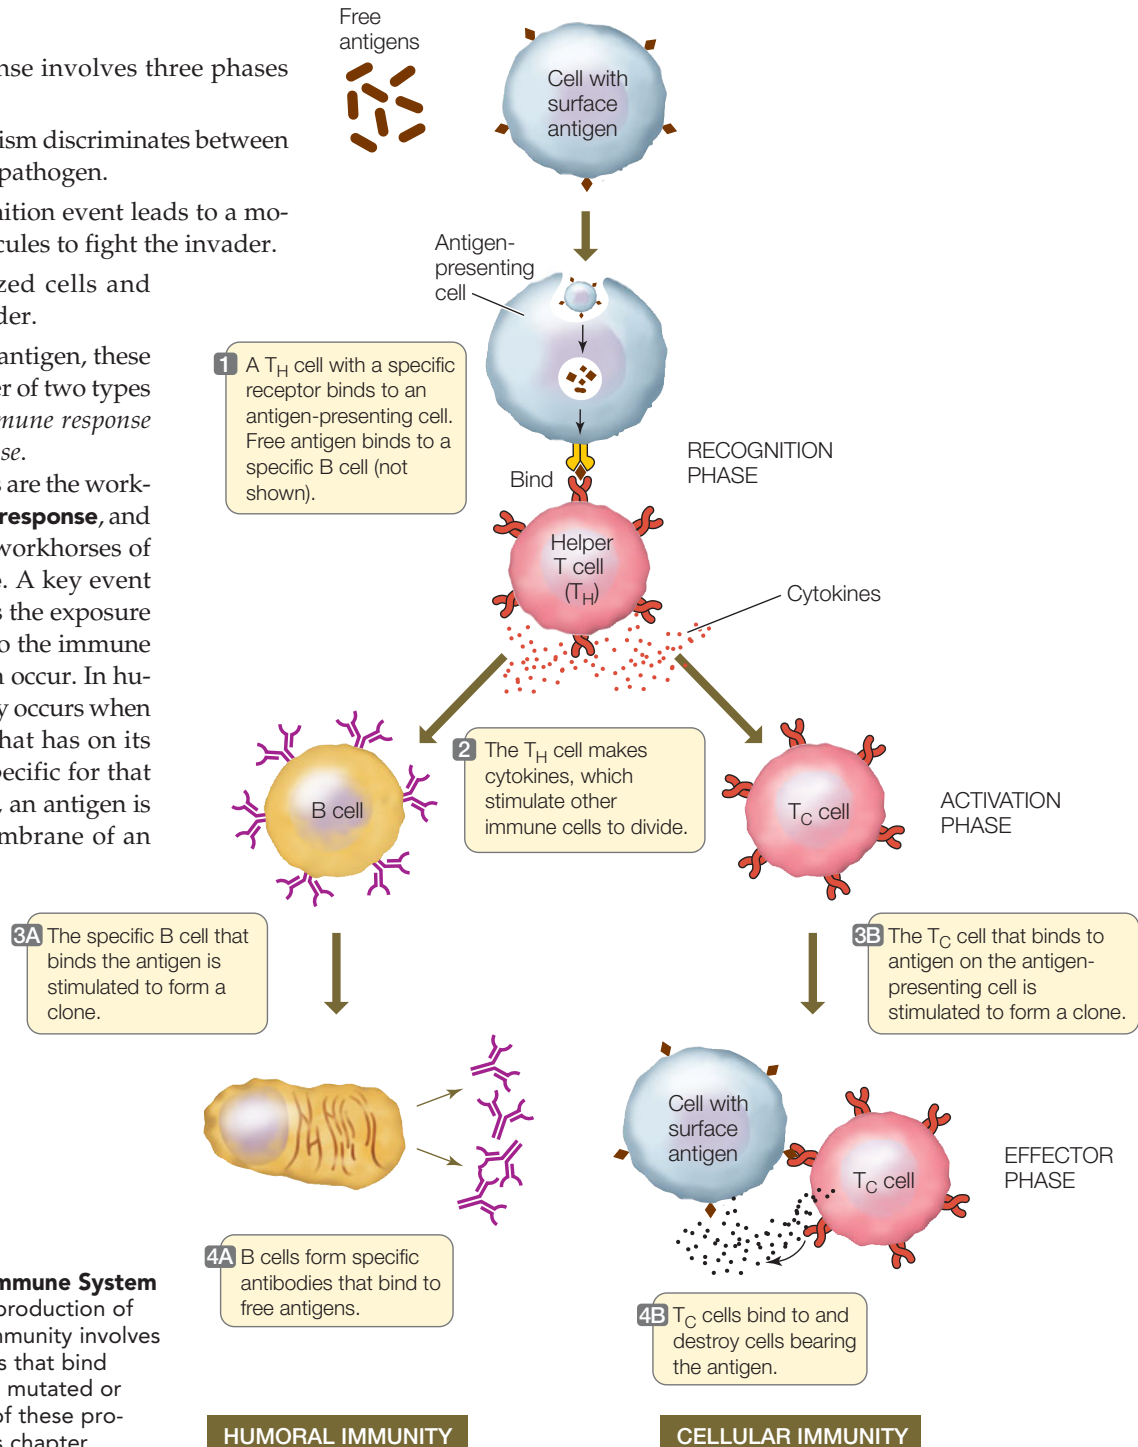

FIGURE 31.6 The Adaptive Immune System Humoral immunity involves the production of antibodies by B cells. Cellular immunity involves the activation of cytotoxic T cells that bind to and destroy self cells that are mutated or infected by pathogens. Details of these processes are described later in this chapter.

APPLY THE CONCEPT

The adaptive immune response is specific

In humans, the dominant gene *D* codes for the RhD (Rhesus) protein on the surfaces of red blood cells. The recessive allele *d* does not encode a cell surface protein. If cells from an individual who is *DD* or *Dd* (Rh^+) enter the bloodstream of an individual who is *dd* (Rh^-), the Rh^- individual makes antibodies that react with the Rh^+ cells. During development, the blood vessels of a mother and her fetus are near to each other but do not mix. However, antibodies can pass through capillary walls between the two blood supplies.

1. Hemolytic disease of the newborn (sometimes resulting in stillbirth) can occur when antibodies from the mother pass into the fetal circulatory system. Fill in the table, which predicts RhD incompatibility.
2. During birth there is mixing of the blood supplies of mother and fetus. In a situation of RhD incompatibility,

MOTHER		FETUS		RESULT
GENOTYPE	Rh PHENOTYPE	GENOTYPE	Rh PHENOTYPE	
<i>Dd</i>		<i>Dd</i>		
<i>dd</i>		<i>Dd</i>		

the first birth does not result in a clinical problem. But a second RhD incompatible birth with this mother results in a hemolytic disease. Explain how this can happen (hint: immunological memory).

3. Today, RhD incompatibility does not result in stillbirths. The mother is treated with serum containing anti-RhD antibodies late in the first and subsequent pregnancies. How can this prevent the immunological reactions?

form a clone. In the cellular immune response, binding of the T_H cell to the antigen-presenting cell causes the T_H cell to release cytokines that stimulate T_C cells bearing the same T cell receptor to divide. So the result of activation is the formation of two clones of cells:

- A clone of B cells that can produce antibodies specific for the antigen
- A clone of T_C cells that express a T cell receptor that can bind to any cell expressing the antigen on its surface

Once formed, the two clones perform their roles in the effector phase. Cells of the B clone produce antibodies that bind to free antigen in the bloodstream. Such binding results in inactivation and destruction of the antigen. Cells of the T_C clone bind to cells bearing the antigen and destroy them.

Do You Understand Concept 31.3?

- Make a table describing the four key features of the adaptive immune system.
- In 2009, the H1N1 strain of influenza was a worldwide epidemic. Notably, very old people, who had been alive during the 1918 flu outbreak, had low rates of H1N1 infection. Explain this in terms of immunological memory.
- Insulin-dependent diabetes (Type 1) results from a destruction of the cells in the pancreas that make the hormone insulin (see Concept 39.4). One hypothesis for this disease is that it is caused by an autoimmune reaction. Explain how this might happen and how you would investigate your hypothesis.

With this overview of the basic characteristics of adaptive immunity and the events of the immune response, we will now turn to some of the cellular and molecular details of how these events occur.

concept 31.4 The Adaptive Humoral Immune Response Involves Specific Antibodies

Every day in the human body, billions of B cells survive the test of clonal deletion and are released from the bone marrow into the circulatory system. B cells are the basis for the humoral immune response.

yourBioPortal.com

Go to ANIMATED TUTORIAL 31.2
Humoral Immune Response

Plasma cells produce antibodies

A B cell begins life as a “naïve” B cell with a receptor protein on its cell surface that is specific for a particular antigen. The cell is activated by antigen binding to this receptor, and, after stimulation by a T_H cell, it produces a clone of plasma cells that make antibodies as well as memory cells (see Figure 31.5). In addition to this stimulation by antigen binding, a B cell can be stimulated to divide by a T_H cell binding to the exposed antigen on the B cell surface. The specific T_H cell may come from a clone that was activated by the cellular immune response (see Concept 31.5). This type of interaction between B cells and T_H cells provides a connection between the cellular and humoral

systems. The T_H cell bound to the B cell secretes cytokines that stimulate the B cell to divide.

All the plasma cells arising from a given B cell produce antibodies that are specific for the antigen that originally bound to the parent B cell. Thus antibody specificity is maintained as B cells proliferate.

Antibodies share a common overall structure

There are several classes of antibodies (also called **immunoglobulins**), but all contain a tetramer with four polypeptide chains (**FIGURE 31.7**). In each immunoglobulin molecule, two of the polypeptides are identical *light chains*, and two are identical

FIGURE 31.7 The Structure of an Immunoglobulin Four polypeptide chains (two light, two heavy) make up an immunoglobulin molecule. Here we show both diagrammatic (A) and space-filling (B) representations of an immunoglobulin.

yourBioPortal.com

Go to **WEB ACTIVITY 31.2**
Immunoglobulin Structure

heavy chains. Disulfide bonds hold the chains together. Each polypeptide chain has a constant region and a variable region:

- The amino acid sequence of the **constant region** determines the general structure and function (the *class*) of an immunoglobulin. All immunoglobulins in a particular class have a similar constant region. When an antibody acts as a B cell receptor, the constant region inserts into the plasma membrane.
- The amino acid sequence of the **variable region** is different for each specific immunoglobulin. The variable region's three-dimensional antigen-binding site is determined by its secondary structure, and is responsible for antibody specificity.

The two antigen-binding sites on each immunoglobulin molecule are identical, making the antibody *bivalent* (*bi*, "two"; *valent*, "binding"). This ability to bind two antigen molecules at once, along with the existence of multiple epitopes on each antigen, permits antibodies to form large complexes with the antigens. For example, one antibody might bind two molecules of an antigen. Another antibody might bind the same antigen at a different epitope. It may bind one of the antigen molecules that is already bound to the first antibody, along with a third antigen molecule:

This binding of multiple antigens and multiple antibodies can result in large complexes that are easy targets for ingestion and breakdown by phagocytes.

There are five classes of immunoglobulins (Ig), and they differ in function and in the type of heavy chain:

- IgG is secreted by B cells and constitutes about 80 percent of circulating antibodies.
- IgD is the cell surface receptor on a B cell.
- IgM is the initial surface and circulating antibody released by a B cell.
- IgA protects mucosa on epithelia exposed to the environment.
- IgE binds to mast cells and is involved with inflammation.

We will focus on IgG antibodies in this chapter.

Antibody diversity results from DNA rearrangements and other mutations

Each mature B cell makes one—and only one—specific antibody targeted to a single antigen. And there are millions of possible antigens to which a human can be exposed. How can

the genome encode enough different antibodies to protect the body against all the possible pathogens? With millions of possible amino acid sequences in immunoglobulins, one explanation might be that there are millions of genes, each one encoding one antibody molecule. A simple calculation using approximate numbers shows that this is impossible:

one IgG heavy chain = 500 amino acids coded for by 1,500 bp of DNA

one IgG light chain = 200 amino acids coded for by 600 bp of DNA

Therefore,

one antibody (two identical heavy and two identical light chains) is encoded by 2,100 bp of DNA

10 million different antibodies = 21 billion bp of DNA

This is 6.5 times the size of the entire human genome! There must be another way to generate antibody diversity.

It turns out that instead of a single gene encoding each complete immunoglobulin, the genome of the differentiating B cell has a number of different coding regions for each domain of the protein, and that diversity is generated by putting together different combinations of these regions. Shuffling of this genetic deck generates the enormous immunological diversity that characterizes each individual mammal.

Each gene encoding an immunoglobulin chain is in reality a “supergene” assembled by means of genetic recombination from several clusters of smaller genes scattered along part of a chromosome (FIGURE 31.8). Every cell in the body has

hundreds of immunoglobulin genes located in separate clusters that are potentially capable of participating in the synthesis of both the variable and constant regions of immunoglobulin chains. In most body cells and tissues, these genes remain intact and separated from one another. But during B cell development, these genes are cut out, rearranged, and joined together in DNA recombination events. One gene from each cluster is chosen randomly for joining, and the others are deleted. In the case of one multigene set, the J genes, the extra sequences are removed in RNA splicing (FIGURE 31.9).

In this manner, a unique immunoglobulin supergene is assembled from randomly selected “parts.” Each B cell precursor assembles two supergenes, one for a specific heavy chain and the other, assembled independently, for a specific light chain. This remarkable example of irreversible cell differentiation generates an enormous diversity of immunoglobulins from the same genome. It is a major exception to the generalization that all somatic cells derived from the fertilized egg have identical DNA.

In both humans and mice, the gene clusters encoding immunoglobulin heavy chains are on one pair of chromosomes and those for the light chains are on two other pairs. Three families of genes (*V*, *D*, and *J*) encode the variable region of the heavy chain. There are two classes of light chain, and the variable regions in both classes are made up of two domains, encoded by two gene families (*V* and *J*).

Figure 31.8 illustrates the gene families that encode the constant and variable regions of the heavy chain in mice. There are multiple genes that encode each of the three parts of the variable region: 100 *V*, 30 *D*, and 6 *J* genes. Each B cell randomly selects one gene from each of these clusters to make the final

FIGURE 31.8 Heavy-Chain Genes Mouse immunoglobulin heavy chains have four domains, each of which is coded for by a gene selected from a cluster of similar genes. The immunoglobulin protein has one domain from each cluster; one example of many is shown.

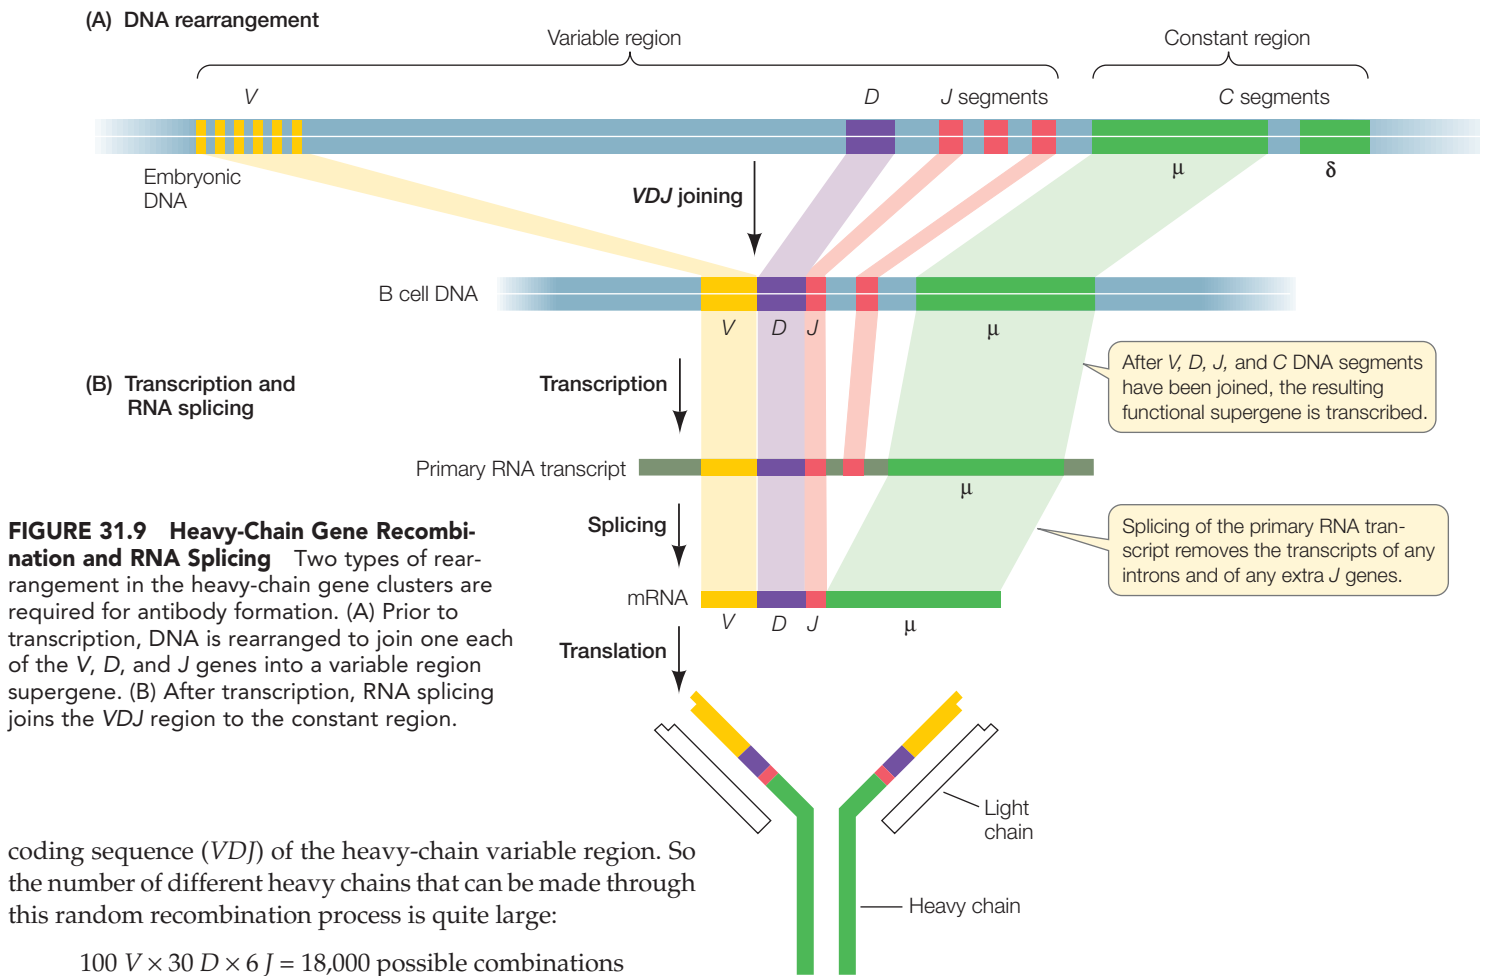

FIGURE 31.9 Heavy-Chain Gene Recombination and RNA Splicing Two types of rearrangement in the heavy-chain gene clusters are required for antibody formation. (A) Prior to transcription, DNA is rearranged to join one each of the V, D, and J genes into a variable region supergene. (B) After transcription, RNA splicing joins the VDJ region to the constant region.

coding sequence (VDJ) of the heavy-chain variable region. So the number of different heavy chains that can be made through this random recombination process is quite large:

$$100 V \times 30 D \times 6 J = 18,000 \text{ possible combinations}$$

Now consider that the light chains are similarly constructed, with a similar amount of diversity made possible by random recombination. If we assume that the degree of potential light-chain diversity is the same as that for heavy-chain diversity, the number of possible combinations of light- and heavy-chain variable regions is:

$$18,000 \text{ different light chains} \times 18,000 \text{ different heavy chains} = 324 \text{ million possibilities!}$$

Other mechanisms generate even more diversity:

- When the DNA sequences that encode the V, D, and J regions are rearranged so that they are next to one another, the recombination event is not precise, and errors occur at the junctions. This *imprecise recombination* can create frameshift mutations, generating new codons at the junctions, with resulting amino acid changes.
- After the DNA sequences are cut and before they are re-joined, the enzyme *terminal transferase* often adds some

APPLY THE CONCEPT

The adaptive humoral immune response involves specific antibodies

Mammals have two kinds of light chains: the kappa (κ) and lambda (λ) chains, and each variable region consists of a V domain and a J domain. Imagine a strain of mouse that has a family of 350 genes encoding the κ V domain and 10 encoding the κ J domain, while the λ variable regions are encoded by 300 V and 5 J genes. The IgG heavy chain is encoded by 350 V, 8 J, and 5 D genes.

1. How many different types of antibodies can be made from these genes by recombination?
2. What are two other ways to generate antibody diversity from these genes?

nucleotides to the free ends of the DNA pieces. These additional bases create insertion mutations.

- There is a relatively high *spontaneous mutation rate* in immunoglobulin genes. Once again, this process creates many new alleles and adds to antibody diversity.

When we include these possibilities with the millions of combinations that can be made by random DNA rearrangements, it is not surprising that the immune system can mount a response to almost any natural or artificial substance.

Once the DNA rearrangements are completed, each supergene is transcribed and then translated to produce an immunoglobulin light chain or heavy chain. These chains combine to form an active immunoglobulin protein.

A B Cell Builds an Antibody

Antibodies bind to pathogens on cells or in the bloodstream

Recall that antibodies have two roles in B cells after they undergo DNA rearrangements and RNA splicing. First, by being expressed on the cell surface, a unique antibody can act as a receptor for an antigen in the recognition phase of the humoral response. Second, in the effector phase of the humoral response, specific antibodies are produced in large amounts by a clone of B cells. These antibodies are secreted from the B cells and enter the bloodstream where they act in either of two ways:

- Some antibodies bind to the antigen that is expressed on the surface of a pathogen. This can stimulate macrophages to ingest, or natural killer cells to destroy, the pathogen.
- If the antigen is free in the bloodstream, antibodies may bind to it using their cross-linking function (see p. 630) to form large, insoluble antibody–antigen complexes. These are ingested and destroyed by phagocytic cells.

Do You Understand Concept 31.4?

- Sketch an IgG antibody, identifying the variable and constant regions, light and heavy chains, and antigen-binding sites.
- The bacterium that causes diphtheria (see Figure 31.4) synthesizes a toxic protein. You have probably not been exposed to this bacterium or its toxin. At the present time, are you making B cells and antibodies that bind specifically to diphtheria toxin? Explain your answer.
- When an antigenic protein such as diphtheria toxin (see above) enters the bloodstream, numerous clones of B cells are activated. Explain.

The humoral immune response works in concert with the cellular immune response in adaptive immunity. Now let's turn to a closer examination of the cellular response.

concept 31.5

The Adaptive Cellular Immune Response Involves T Cells and Their Receptors

Two types of effector T cells (T-helper cells and cytotoxic T cells) are involved in the cellular immune response, along with proteins of the major histocompatibility complex (MHC proteins), which underlie the immune system's tolerance for the body's own cells.

Go to ANIMATED TUTORIAL 31.4
Cellular Immune Response

T cell receptors specifically bind to antigens on cell surfaces

Like B cells, T cells possess specific membrane receptors. The T cell receptor is not an immunoglobulin, however, but a glycoprotein with a molecular weight of about half that of an IgG. It is made up of two polypeptide chains, each encoded by a separate gene (FIGURE 31.10). The two chains have distinct regions with constant and variable amino acid sequences. As in the immunoglobulins, the variable regions provide the site for specific binding to antigens. T cell receptors typically bind to a piece of an antigen, such as a peptide from a protein, displayed

FIGURE 31.10 A T Cell Receptor The receptors on T lymphocytes are smaller than those on B lymphocytes, but their two polypeptides contain both variable and constant regions. As with the B cell receptors, the constant regions fix the receptor in the plasma membrane, while the variable regions establish the specificity for binding to antigen.

FIGURE 31.11 Macrophages Are Antigen-Presenting Cells

A fragment of an antigen is displayed by MHC II on the surface of a macrophage. T cell receptors on a specific T-helper cell can then bind to and interact further with the antigen–MHC II complex.

on the surface of an antigen-presenting cell in the presence of an MHC protein.

MHC proteins present antigen to T cells and result in recognition

Recall that so far we have described two types of T cells: T_H and T_C cells. Both cell types express T cell receptors that bind to antigen on the cell surface. But the response of each cell type to binding is quite different. T_H binding results in activation of the adaptive immune response, whereas T_C binding results in death of the cell carrying the antigen in the adaptive response. The MHC proteins form complexes with antigens on cell surfaces and assist with recognition by the T cells, so that the appropriate type of T cell binds.

The MHC proteins are plasma membrane glycoproteins. Two types of MHC proteins function to present antigens to the two different types of T lymphocytes:

- **Class I MHC** proteins are present on the surface of every nucleated cell in the mammalian body. They present antigens to T_C cells. These antigens can be fragments of virus proteins in virus-infected cells or abnormal proteins made by cancer cells as a result of somatic mutations.
- **Class II MHC** proteins are on the surfaces of macrophages, B cells, and dendritic cells. They present antigens to T_H cells. The three cell types ingest antigens and break them down; one of the fragments then binds to MHC II for presentation (**FIGURE 31.11**).

In humans, there are three genetic loci for class I MHC proteins and three for class II MHC proteins. Each of these six loci has as many as 100 different alleles. With so many possible allele combinations, it is not surprising that different people are very likely to have different MHC genotypes. MHC proteins are “self” markers. To accomplish its role in antigen presentation, an MHC protein has an antigen-binding site that can hold a peptide of about 10–20 amino acids. The T cell receptor recognizes not just the antigenic fragment but also the class I or II MHC molecule to which the fragment is bound.

Information on MHC proteins, the cellular origins of antigens, and T lymphocytes is summarized in **TABLE 31.2**.

Activation of the cellular response results in death of the targeted cell

Activation of a T_H cell results in the stimulation of B cells to propagate and produce antibodies against that antigen. In the case of binding of a T_C cell, activation results in the production of a clone of T_C cells with the specific T cell receptor. These T_C cells bind to cells carrying the antigen–MHC I protein complex (e.g., virus-infected cells). When bound, the T_C cells do two things to eliminate the antigen-carrying cell:

- They produce *perforin*, which lyses the bound target cell.
- They stimulate apoptosis in the target cell.

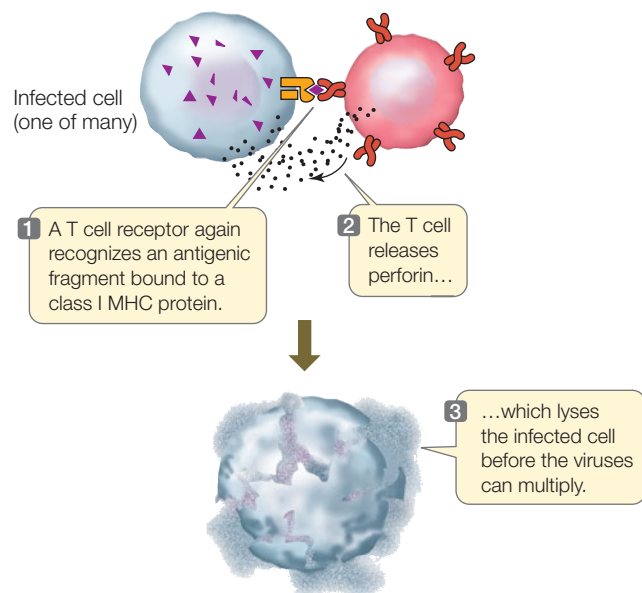

TABLE 31.2 The Interaction between T Cells and Antigen-Presenting Cells

PRESENTING CELL TYPE	ANTIGEN PRESENTED	MHC CLASS	T CELL TYPE
Any cell	Intracellular protein fragment	Class I	Cytotoxic T cell (T_C)
Macrophages and B cells	Fragments from extracellular proteins	Class II	Helper T cell (T_H)

FRONTIERS Cancer cells express specific molecules on their surfaces. When an antibody binds to such a molecule, the targeted cell dies by a mechanism that is not well understood. Nevertheless, several antibodies to cancer cell membrane proteins are in widespread clinical use for breast and colon cancer.

Regulatory T cells suppress the humoral and cellular immune responses

A third class of T cells called **regulatory T cells (Tregs)** ensures that the immune response does not spiral out of control. Like T_H and T_C cells, Tregs are made in the thymus gland, express the T cell receptor, and become activated if they bind to antigen–MHC complexes. But Tregs are different in one important way: the antigens that Tregs recognize are *self antigens*. The activation of Tregs causes them to secrete the cytokine *interleukin-10*, which blocks T cell activation and leads to apoptosis of the T_C and T_H cells that are bound to the same antigen-presenting cell (FIGURE 31.12).

The important role of Tregs is to mediate tolerance to self antigens. Thus they constitute one of the mechanisms for distinguishing self from nonself. There are two lines of experimental evidence for the role of Tregs:

- If Tregs are experimentally destroyed during development in the thymus of a mouse, the mouse grows up with an out-of-control immune system, mounting strong immune responses to self antigens—autoimmunity.
- In humans, a rare X-linked inherited disease occurs when a gene critical to Treg function is mutated. An infant with this disease, called IPEX (*immune dysregulation, polyendocrinopathy and enteropathy, X-linked*), mounts an immune response that attacks the pancreas, thyroid, and intestine. Most affected individuals die within the first few years of life.

AIDS is an immune deficiency disorder

There are a number of inherited and acquired *immune deficiency disorders*. In some individuals, T or B cells never form; in others, B cells lose the ability to give rise to plasma cells. In either case, the affected individual is unable to mount an immune response and thus lacks a major line of defense against pathogens. A

FIGURE 31.12 Tregs and Tolerance A special class of T cells called regulatory T cells (Tregs) inhibits the activation of the immune system in response to self antigens.

more common disease that was first detected in the early 1980s is **acquired immune deficiency syndrome (AIDS)**, which results from infection by **human immunodeficiency virus (HIV)**.

The course of HIV infection provides a good review of adaptive immunity (see Figure 31.6). HIV is transmitted from person to person in blood, semen, vaginal fluid, or breast milk; the recipient tissue is either blood (by transfusion or injection) or a mucous membrane lining an organ. HIV initially infects macrophages, T_H cells, and antigen-presenting dendritic cells (another type of white blood cell) in the blood and tissues. At first there is an immune response to the viral infection, and some T_H cells are activated. But because HIV infects the T_H cells, they are killed both by HIV itself and by T_C cells that lyse infected T_H cells. Consequently, T_H cell numbers decline after the first month or so of infection. Meanwhile, the extensive production of HIV by infected cells activates the humoral immune system. Antibodies bind to HIV and the complexes are removed by phagocytes. The HIV level in blood goes down. There is still a low level of

FIGURE 31.13 The Course of an HIV Infection

An HIV infection may be carried, unsuspected, for many years before the onset of symptoms.

infection, however, because of the depletion of T_H cells (FIGURE 31.13).

During this dormant period, people carrying HIV generally feel fine, and their T_H cell levels are adequate for them to mount immune responses against other infections. Eventually, however, the virus destroys the T_H cells, and their numbers fall to the point where the infected person is susceptible to infections that the T_H cells would normally eliminate. These infections result in conditions such as Kaposi's sarcoma, a skin tumor caused by a herpesvirus; pneumonia caused by the fungus *Pneumocystis jirovecii*; and lymphoma tumors caused by the Epstein–Barr virus. These conditions result from *opportunistic infections* because the pathogens take advantage of the crippled immune system of the host. In addition, HIV infection somehow stimulates Treg cells, and these also downregulate the immune response. The combination of infections and a weakened immune response can lead to death within a year or two.

The molecular biology of HIV and its life cycle have been intensively studied. Drug treatments are focused on inhibiting processes necessary for viral entry, assembly, and replication, such as *reverse transcriptase* that makes cDNA from the viral RNA, and *viral protease* that cuts the large precursor viral protein into its final active proteins. Combinations of such drugs result in long-term survival. Unfortunately, like many medical treatments, HIV drugs are not available to all who need them—particularly in poor regions of the world where AIDS is prevalent. As a result, there are about 2 million deaths per year worldwide from AIDS.

LINK For more on the life cycle of HIV, see Concept 11.1

Do You Understand Concept 31.5?

- Compare the T cell receptor and B cell receptor in terms of structure, diversity, and function.
- What are the similarities and differences in function between class I and II MHC proteins?
- What are the roles of T_H cells in cellular and humoral immunity?
- Since MHC proteins are highly variable and almost always differ between unrelated people, an organ transplant between such people will generally provoke a cellular immune response, and the organ will be rejected. Patients receiving organ transplants are treated with cyclosporin, a drug that inhibits T cell development. How do you think cyclosporin prevents rejection? What side effects might you expect in treated people?

How can a person survive an infection and be resistant to further infection?

ANSWER Almost 2,500 years after Thucydides's observations, we have some answers to this question. During the Athenian plague, innate immunity (Concept 31.2) kept most of the disease agent out of the body. Any agent that penetrated the innate defenses was attacked by the adaptive immune system (Concepts 31.3 and 31.4). The agent was engulfed by macrophages, which broke it up and presented fragments on their cell surfaces, in a complex with class II MHC proteins. These complexes bound to T_H cells with the appropriate T cell receptors. A clone of these T cells ensued, which bound to B cells expressing the appropriate receptor. The B cells then formed clones and made antibodies that bound to the agent; the antibody-bound agent was then destroyed by phagocytes. Meanwhile, if cells were infected by the agent, a parallel series of events occurred in the cellular immune response, resulting in a clone of T_C cells that killed the infected cells (Concept 31.5). These two systems allowed Thucydides to survive the infection that killed so many of his fellow Athenians.

The T and B cells activated by the two adaptive immune responses also formed smaller clones of memory cells. When Thucydides took care of others in Athens who had the disease, the re-entry of the pathogen into his body provoked a rapid, massive T and B cell response. This response prevented the pathogen from proliferating and making him sick again.

An important application of immunological memory is the use of **vaccines**. Exposure to an antigen in a form that does not cause disease can still initiate a primary immune response, generating memory cells without making the person ill. Later, if a pathogen carrying the same antigen attacks, specific memory cells already exist. They recognize the antigen and quickly overwhelm the invaders with a massive production of lymphocytes and antibodies (FIGURE 31.14).

Because the antigens used for immunization or vaccination are produced by pathogenic organisms, they must be altered so they cannot cause disease. This is achieved in a variety of

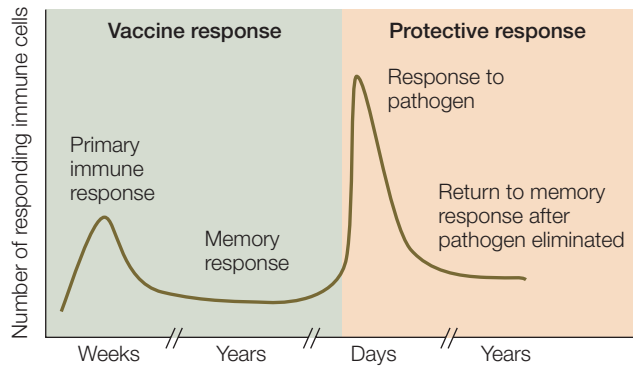

FIGURE 31.14 Vaccination Immunological memory from exposure to an antigen that does not cause disease can result in a massive response to the disease agent when it appears later.

ways, including inactivation of the pathogen by chemicals or heat, mutations that render the pathogen inactive, or recombinant DNA technology to make nonharmful peptides derived from the pathogen. The use of vaccines, especially in children, has been a great success in public health. In industrialized countries, widespread vaccination has completely or almost completely wiped out some deadly diseases, including smallpox, diphtheria, and polio.

SUMMARY

concept 31.1 Animals Use Innate and Adaptive Mechanisms to Defend Themselves against Pathogens

- Animal defenses against **pathogens** are based on the body's ability to distinguish between self and nonself.
- **Innate immunity** is a set of nonspecific, inherited mechanisms that protect the body from many kinds of pathogens. These defenses typically act rapidly.
- **Adaptive immunity** is a set of specific mechanisms that respond to specific pathogens. These defenses develop more slowly than nonspecific defenses but are long lasting.
- Many of these defenses are implemented by cells and proteins carried in the circulatory and lymphatic systems. **Review Figure 31.1 and ANIMATED TUTORIAL 31.1**

concept 31.2 Innate Defenses Are Nonspecific

- Innate defenses include physical barriers such as the skin, mucous membranes, and competing resident microorganisms. **Review Figure 31.2**
- Circulating defensive cells, such as **phagocytes** and **natural killer cells**, work to eliminate invaders.
- The **complement system** consists of more than 20 different antimicrobial proteins that act to alter membrane permeability and kill targeted cells.
- The **inflammation** response activates several types of cells and proteins that act against invading pathogens. **Mast cells** release **histamine**, which increases the permeability of blood vessels to aid in inflammation. **Review Figure 31.3 and WEB ACTIVITY 31.1**

concept 31.3 The Adaptive Immune Response Is Specific

- The adaptive immune system recognizes specific **antigens**, responds to an enormous diversity of **antigenic determinants** (also called epitopes), distinguishes self from nonself, and remembers the antigens it has encountered.
- **Clonal selection** accounts for the specificity and diversity of the immune response and for **immunological memory**. **Review Figure 31.5**
- Adaptive immunity includes the **humoral immune response**, which involves antibody production by B cells, and the **cellular immune response**, mediated by T cells. Both require specific receptors to bind to each antigen. **Review Figure 31.6**

concept 31.4 The Adaptive Humoral Immune Response Involves Specific Antibodies

Go to **ANIMATED TUTORIAL 31.2**

- Naïve B cells are activated by binding of the antigen and by stimulation from T_H cells with the same specificity, and then form **plasma cells**. These cells synthesize and secrete specific antibodies.
- The basic unit of an **immunoglobulin** is a tetramer of four polypeptides: two identical light chains and two identical heavy chains, each consisting of a **constant region** and a **variable region**. The variable regions determine the specificity of an immunoglobulin, and the constant regions of the heavy chain determine its class. **Review Figure 31.7 and WEB ACTIVITY 31.2**
- There are five classes of immunoglobulins, differing in function and in the type of heavy chain.
- B cell genomes undergo recombination events in which the genes that encode specific domains of the immunoglobulin variable regions are randomly selected from large clusters of genes. This DNA rearrangement yields millions of different immunoglobulin proteins. **Review Figures 31.8 and 31.9 and ANIMATED TUTORIAL 31.3**

concept 31.5 The Adaptive Cellular Immune Response Involves T Cells and Their Receptors

- T cell receptors are somewhat similar in structure to the immunoglobulins, having variable and constant regions. **Review Figure 31.10**
- There are several types of T cells. **Cytotoxic T cells (T_C)** recognize and kill virus-infected cells or mutated cells. **T-helper cells (T_H)** direct both the cellular and humoral immune responses.
- The genes of the major histocompatibility complex (MHC) encode membrane proteins that bind antigenic fragments and present them to T cells. **Review Figure 31.11**
- **Regulatory T cells (Tregs)** inhibit the other T cells from mounting an immune response to self antigens. **Review Figure 31.12**
- **Acquired immune deficiency syndrome (AIDS)** arises from depletion of the T_H cells as a result of infection with **human immunodeficiency virus (HIV)**. **Review Figure 31.13**

Animal Reproduction

32

In 1839 Charles Goodyear discovered a method of curing rubber that made it stronger and more elastic. Soon thereafter, this improved material was used to make condoms. The spread of these contraceptive devices led to fears about licentiousness in American society, and in 1873 Congress passed the Comstock Law outlawing contraceptive devices and the dissemination of information for preventing pregnancy as obscene and immoral. Ignorance of reproductive biology and the lack of birth control technologies at the time were at the root of widespread venereal disease and high rates of infant and maternal mortality.

Margaret Higgins Sanger was born 1879, the middle of her mother's 11 children from 18 pregnancies. Margaret cared for her mother as she was dying from tuberculosis, cervical cancer, and physical exhaustion. Later, as a nurse, Margaret worked among the poor in New York City. Witnessing the misery of so many women and children and the deaths from self-induced and illegal abortions led her to write a newspaper column called "What Every Girl Should Know." She also coined the term "birth control" in her monthly newsletter, "The Woman Rebel." For her efforts, she was indicted under the Comstock Law. Undeterred, in 1916 Margaret opened the first U.S. family planning and birth control clinic, located in Brooklyn; within days she was jailed. An appeal of her sentence, however, led to a landmark ruling that allowed physicians to prescribe contraceptive devices. Margaret's movement for reproductive education and rights grew steadily (and she was arrested seven more times).

Among Margaret's friends was Katherine McCormick, heiress to a considerable fortune. With Margaret's zeal and Katherine's money, they convinced reproductive biologist Gregory Pincus to undertake development of a birth control pill. Pincus showed that high doses of the hormone progesterone prevented ovulation in rabbits, but the hormone had to be isolated from animals and was costly. The creation of synthetic progestins by chemists dramatically lowered the costs, and in 1957 "the pill" was released to treat "gynecological disorders." In 1960 it gained FDA approval for use as an oral contraceptive. However, the Comstock Law was not overturned until 1965, when the U.S. Supreme Court ruled that it violated the individual's right to privacy.

Condoms and "the pill" are widely used means of preventing unwanted pregnancies. See Table 32.1.

KEY CONCEPTS

- 32.1** Reproduction Can Be Sexual or Asexual
- 32.2** Gametogenesis Produces Haploid Gametes
- 32.3** Fertilization Is the Union of Sperm and Ovum
- 32.4** Human Reproduction Is Hormonally Controlled
- 32.5** Humans Use a Variety of Methods to Control Fertility

How does "the pill" prevent conception?

concept 32.1 Reproduction Can Be Sexual or Asexual

Sexual reproduction is a nearly universal trait in animals. However, a variety of animals, mostly invertebrates, also reproduce asexually, and some species only reproduce asexually. Asexual reproduction is efficient because it does not require a mate, and because all members of a population can reproduce (not just the females). Because offspring produced asexually are genetically identical to the parent that produced them, asexual reproduction is likely to be observed in relatively constant environments where genetic diversity is not critical for species success. In fact, asexual reproduction is a good way to preserve a genotype that is successful in a particular environment—a good strategy as long as that environment does not change.

Three common modes of asexual reproduction are *budding*, *regeneration*, and *parthenogenesis*.

Budding and regeneration produce new individuals by mitosis

Some simple animals produce offspring by **budding**, where new individuals simply form as outgrowths, or buds, from the bodies of mature animals. A bud grows by mitotic cell division and eventually breaks away from the parent (FIGURE 32.1A). The bud may grow as large as the parent before it becomes independent.

Some species can reproduce by **regeneration**, the development of a complete individual from a piece of an organism. Echinoderms (sea stars), for example, have remarkable abilities to regenerate. If sea stars are cut into pieces, each piece that includes an arm and a portion of the central disc can grow into a new animal (FIGURE 32.1B). In the early 1900s, oyster fishermen in Rhode Island's Narragansett Bay tried to eliminate the sea stars that were preying on their oysters. Whenever they encountered

a sea star, they chopped it up and threw it back into the water. As a result, the sea star population increased explosively.

Parthenogenesis is the development of unfertilized eggs

Offspring can sometimes develop from unfertilized eggs, a mode of asexual reproduction known as **parthenogenesis**. Parthenogenesis is common in arthropods and also occurs in some species of fish, amphibians, and reptiles.

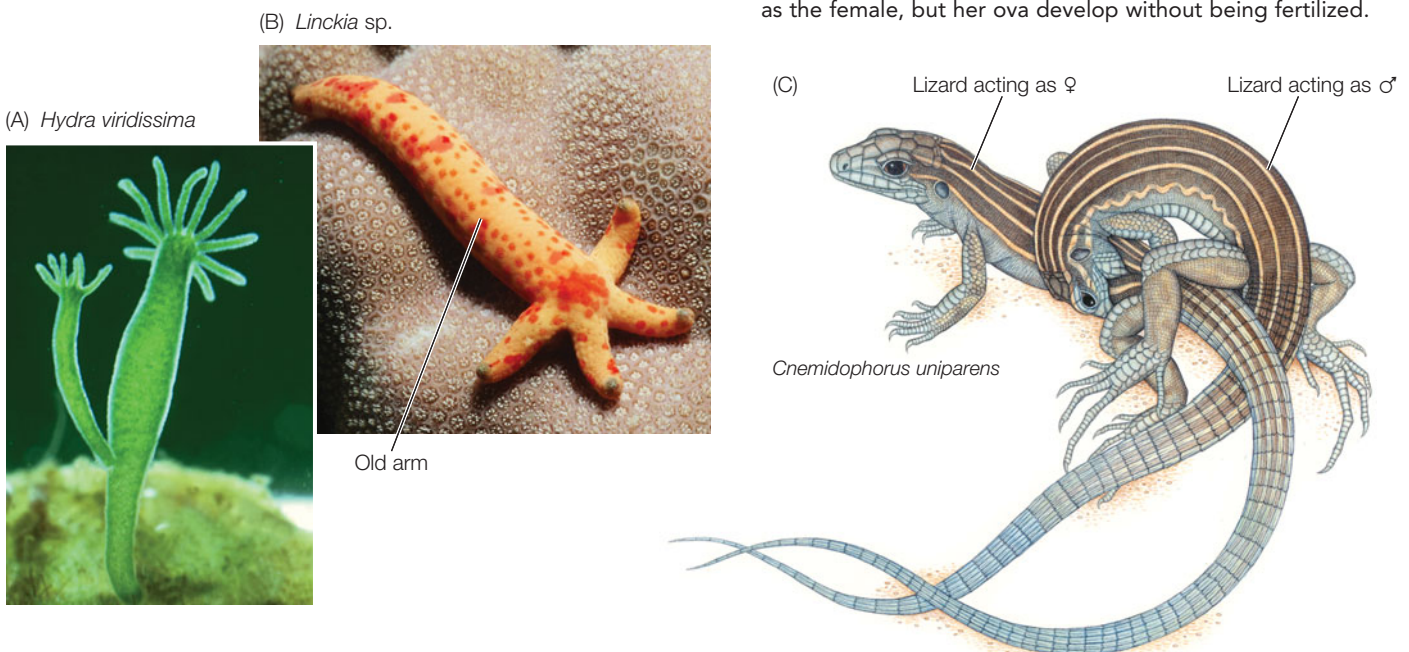

Parthenogenesis in some species requires sexual behavior even though no fertilization occurs. In a parthenogenetic species of whiptail lizard, stimulation from sexual activity triggers the release of eggs from the ovaries. This species has no males, but some of the females act as males in mating behavior, though they do not produce or transfer sperm (FIGURE 32.1C). Whether a specific female acts as a female or male depends on cyclical hormonal states. When her estrogen levels are high, she acts as a female. When her progesterone level peaks, she acts as a male.

In some species, parthenogenesis may also be part of the mechanism that determines sex. In honey bees (and in most ants and wasps), males develop from unfertilized eggs and are haploid, whereas females develop from fertilized eggs and are diploid.

Most animals reproduce sexually

Most animals reproduce by sexual reproduction—the joining of two haploid sex cells, called *gametes*, to form a diploid

FIGURE 32.1 Three Forms of Asexual Reproduction (A) Budding. A new individual forms as an outgrowth from an adult hydra. (B) Regeneration. A single severed arm and a piece of the central disc of a mature sea star can regenerate into an entire animal. (C) Parthenogenesis. Whiptail lizards are all females. Depending on their hormonal status, they act as males or females in reproductive behavior. That behavior stimulates ovulation in the lizard behaving as the female, but her ova develop without being fertilized.

offspring. Sexual reproduction in animals consists of three fundamental steps:

- **Gametogenesis:** production of haploid gametes via meiotic cell divisions
- **Spawning or mating:** behavior that brings gametes together
- **Fertilization:** fusion of gametes to form a diploid zygote

Sexual reproduction involves costs that asexual reproduction does not. Half of the individuals in a sexually reproducing population—the males—do not bear young even though they might help rear them. Potential mates have to find each other, and they must frequently engage in complex reproductive behaviors that have metabolic and opportunity costs and that expose them to predation. Nevertheless, sexual reproduction has one big advantage: the generation of genetic diversity. Two events in meiosis contribute to diversity: *crossing over* between homologous chromosomes and the *independent assortment* of chromosomes. The resulting genetic variation among the gametes of an individual parent and between any two parents produces an enormous potential for genetic variation in the offspring, an evolutionary advantage that can exceed the cost of sex.

Do You Understand Concept 32.1?

- What are the adaptive advantages and disadvantages of asexual reproduction?
- In spring, newly formed rosebuds sometimes become covered with aphids within days. All of these aphids are females and carry preformed female offspring within their bodies. In fall, however, the aphid population includes males, and the females produce eggs rather than live offspring. The eggs survive the winter and hatch into females the following spring. What forms of reproduction are the aphids using? Propose an evolutionary explanation for this strategy.

The next two concepts will examine the fundamental steps of sexual reproduction in more detail. How exactly are gametes produced, and how does fertilization occur?

concept 32.2 Gametogenesis Produces Haploid Gametes

Gametogenesis occurs in the gonads—the *testes* in males and *ovaries* in females. The tiny male gametes, the **sperm**, move by beating their flagella. The larger gametes of females, called *eggs* or **ova** (singular *ovum*), are nonmotile.

Gametes are produced from **germ cells**, which have their origin in the earliest cell divisions of the embryo and remain distinct from all other (*somatic*) cells of the body. The embryonic germ cells move into the gonads, where they proliferate by mitosis, producing diploid **spermatogonia** (singular *spermatogonium*) in males and **oogonia** (singular *oogonium*) in females. The diploid spermatogonia and oogonia then multiply

by mitosis, producing **primary spermatocytes** and **primary oocytes** that enter meiosis (see Figure 7.11) and produce the haploid gametes (sperm and ova). The production of sperm is called **spermatogenesis**, and the production of ova is called **oogenesis**.

Spermatogenesis produces four sperm from one parent cell

As illustrated in **FIGURE 32.2A**, a primary spermatocyte undergoes the first meiotic division to form two secondary spermatocytes. The second meiotic division produces four haploid **spermatids** (two from each secondary spermatocyte) which bear little resemblance to mature sperm. Through further differentiation, each spermatid becomes compact, streamlined, and grows a flagellum to become a motile sperm. We will look at the production of human sperm in detail in Concept 32.4.

Oogenesis produces one large ovum from one parent cell

Primary oocytes immediately enter prophase of the first meiotic division. In many species, including humans, the oocyte then undergoes developmental arrest and may remain in this stage for days, months, or years (**FIGURE 32.2B**). In the human female, this period of arrest may be at least 10 years (i.e., until puberty), and some primary oocytes may remain in prophase I for up to 50 years (i.e., until menopause). In contrast, spermatogenesis continues, uninterrupted, to completion once the primary spermatocyte has differentiated.

Near the end of the oocyte's prolonged prophase I, it grows larger and acquires all the nutrients, raw materials, and RNA that the ovum will need to survive its first few cell divisions after fertilization. The ovum must contain sufficient nutrients to maintain the embryo until it is either nourished by the maternal circulatory system or can feed on its own.

When a primary oocyte resumes meiosis, its nucleus completes the first meiotic division near the surface of the cell. The daughter cells of this division receive grossly unequal shares of cytoplasm. This asymmetry represents another major difference from spermatogenesis, in which cytoplasm is apportioned equally. The daughter cell that receives almost all the cytoplasm becomes the **secondary oocyte**, and the one that receives almost none forms the **first polar body**.

A second period of arrested development occurs after formation of the secondary oocyte. The egg may be expelled from the ovary in this condition. In many species, including humans, the second meiotic division is not completed until the egg is fertilized by a sperm.

The second meiotic division of the secondary oocyte is again characterized by an asymmetrical division of the cytoplasm. One daughter cell is a large **ootid**, which immediately differentiates to become a mature ovum. The other daughter cell forms the **second polar body**. Polar bodies degenerate, so the end result of oogenesis is only one mature ovum from each primary oocyte that enters meiosis. However, that ovum is a large, well-provisioned cell.

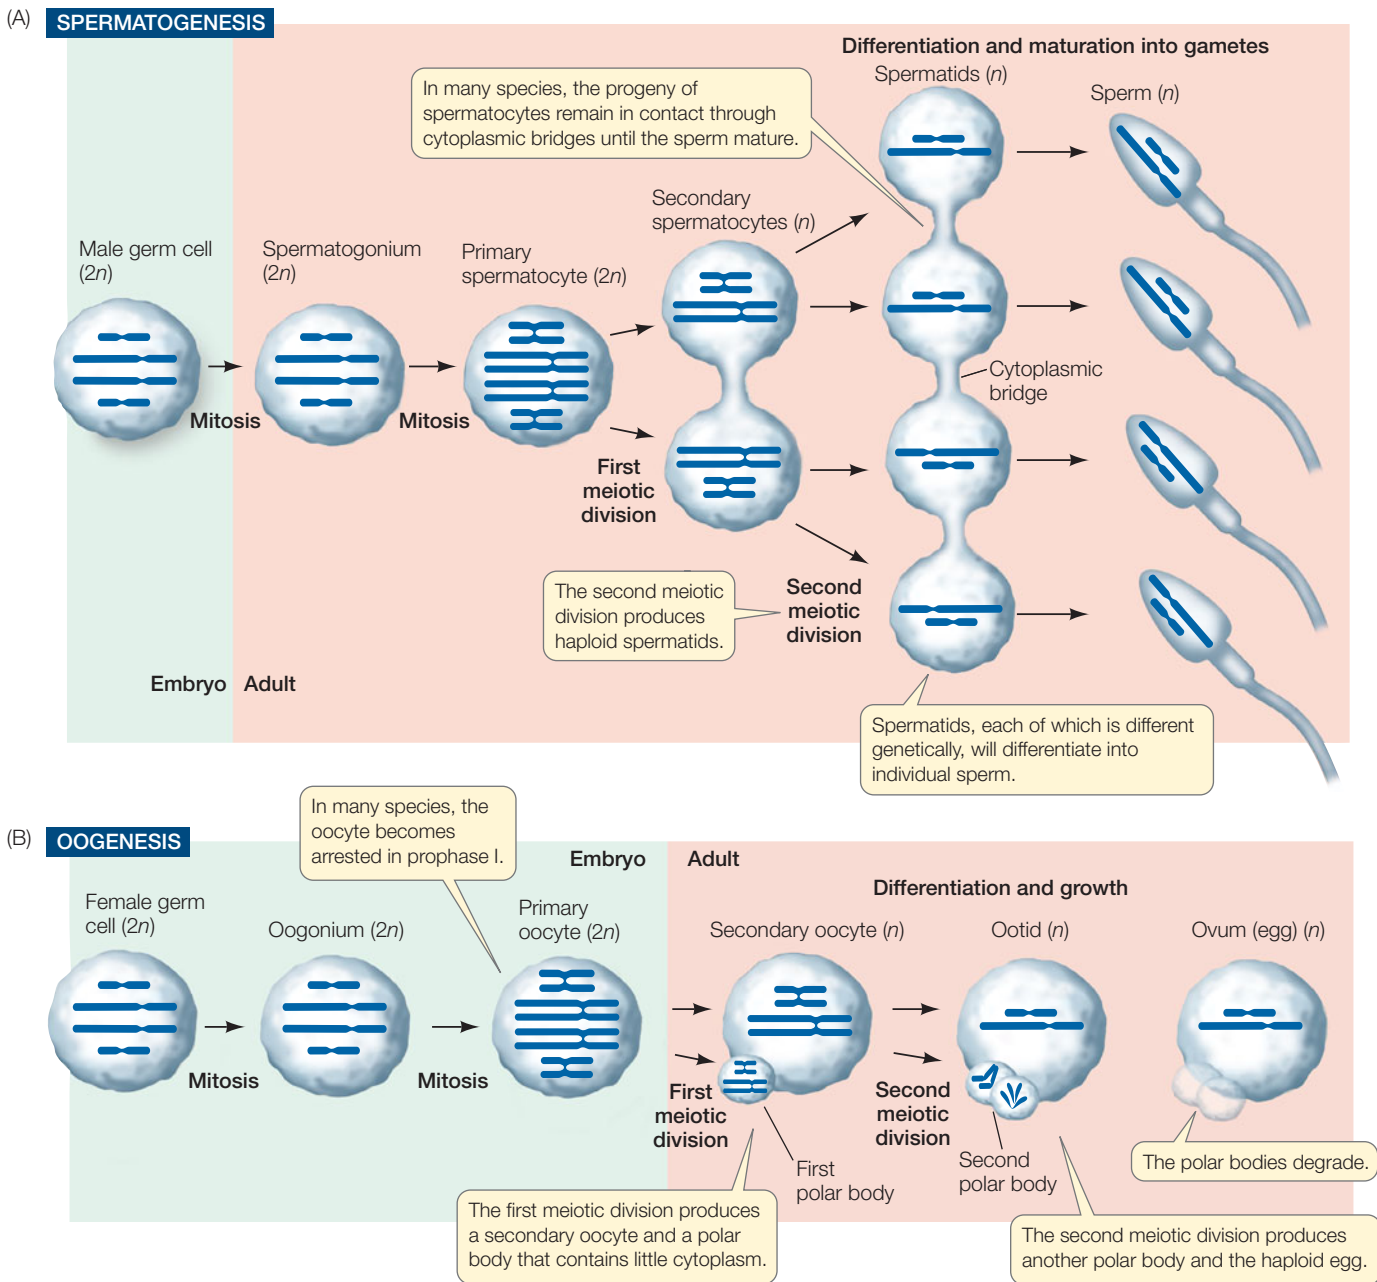

FIGURE 32.2 Gametogenesis Male and female germ cells proliferate by mitosis to produce diploid spermatogonia and oogonia, which mature into primary spermatocytes and oocytes before entering meiosis. (A) Spermatogonia continue to divide by mitosis in adult males, producing a steady supply of primary spermatocytes. The primary spermatocytes divide meiotically to produce haploid spermatids, which differentiate into sperm. (B) In many species, primary oocytes remain arrested in prophase I of meiosis for a long period. Each primary oocyte produces one haploid ovum.

Very few primary oocytes complete all the meiotic stages shown in Figure 32.2B, and as a result, females produce far fewer gametes than do males. For example, a newborn girl has about a million primary oocytes in each ovary. By the time she reaches puberty, she has about 200,000; the rest have degenerated. The average woman goes through about 450 menstrual

cycles during her fertile years, releasing one ovum each cycle. Around the age of 50, a woman reaches **menopause**—the end of fertility—at which time she may have few, if any, oocytes left. Thus a woman produces a total of only a few hundred ova in a lifetime, far below a man's production of over 100 million sperm per *day*.

Hermaphrodites can produce both sperm and ova

In most species, gametes are produced by individuals that are either male or female. In **hermaphroditic** species, however, a single individual may produce both sperm and ova; such species are found among both invertebrates and vertebrates. A mature earthworm, for example, produces both sperm and ova simultaneously. When two earthworms mate, they exchange

sperm, and as a result, the ova of each are fertilized by another, genetically different individual.

Some hermaphroditic species produce ova and sperm sequentially rather than simultaneously; they can switch from one sex to the other under certain circumstances. An example is the anemone fish. All anemone fish are born male, but the dominant fish in a group becomes a functional female. If that female is removed, the next dominant male changes sex to become the functional female producing ova.

Do You Understand Concept 32.2?

- List the stages of spermatogenesis and indicate which are haploid.
- Explain why gametogenesis must include meiotic cell divisions.
- What are the major differences between male and female gametes, and how do these differences arise in the processes of gametogenesis?

Once the male and female gametes are mature, they are capable of joining together and producing a new diploid individual. Bringing gametes together so they can fuse—fertilization—is crucial to life’s continuation, and across the animal kingdom, surprisingly similar mechanisms have evolved to ensure that sperm meet and fuse with eggs of the same species.

concept 32.3 Fertilization Is the Union of Sperm and Ovum

Fertilization is the fusion of the haploid sperm and the haploid ovum. The product of gamete fusion is a single diploid cell, the *zygote*, which will develop into an embryo (see Chapter 33). Fertilization does more than simply restore the full genetic complement of the animal, however. It involves a complex series of events:

- The sperm and ova recognize and bind to each other by means of species-specific molecules.
- The sperm is *activated*, enabling it to gain access to the plasma membrane of a single ovum.
- The plasma membrane of the ovum fuses with the plasma membrane of a single sperm; the ovum then blocks entry of any additional sperm.
- The ovum is metabolically activated and stimulated to start development.
- The ovum and sperm nuclei fuse to create the diploid nucleus of the zygote.

Before the events of fertilization can begin, however, the male and female gametes must meet.

Fertilization may be external or internal

Many aquatic animals bring their gametes together simply by releasing large numbers of gametes into the water. This prelude to *external fertilization*, called **spawning**, requires the production of prodigious numbers of gametes. A female oyster, for example, releases millions of ova when she spawns, and the number of sperm produced by a male oyster is astronomical.

Terrestrial animals, however, cannot simply release their gametes into the environment. Sperm can move only through liquid, and delicate gametes released into the air would dry out and die. *Internal fertilization* takes place in the moist environment of the female’s reproductive tract. Internal fertilization occurs in some aquatic animals and is ubiquitous in terrestrial animals.

Species that practice internal fertilization have anatomical structures called **accessory sex organs** to enable sperm transfer. Familiar examples are the penis and vagina of mammals. Species with internal fertilization also have an astonishing diversity of mating behaviors to ensure successful **copulation**: the physical joining of the male and female accessory sex organs.

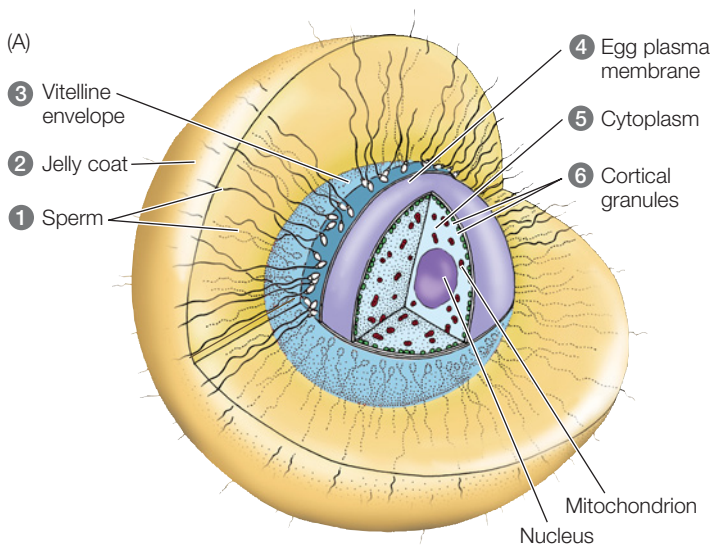

Whether fertilization is internal or external, once the sperm and ova do come into contact, the steps by which they fuse are fairly similar in most species.

Recognition molecules enable sperm to penetrate protective layers around the ovum

Species-specific recognition molecules of sperm and ova ensure that the activities of sperm are directed toward ova and not other cells, and they prevent ova from being fertilized by sperm from the wrong species. Recognition mechanisms are particularly important in aquatic species that practice external fertilization since the sperm and ova of different species may mix in the aquatic environment. The sea urchin is the best-studied example of such an organism.

SEA URCHINS Sea urchin ova release species-specific chemical attractants that increase the motility of conspecific (same-species) sperm and cause them to swim toward the ova. When a sperm reaches an ovum, it must get through two protective layers—a **jelly coat** and a proteinaceous **vitelline envelope**—before it comes into contact with the ovum’s plasma membrane (**FIGURE 32.3A**). The success of a sperm’s assault on the ovum’s protective layers depends on the **acrosome**, a structure at the tip of the sperm head that contains enzymes and other proteins enclosed by a membrane. When the sperm makes contact with the protective layers surrounding the egg, substances in those layers trigger an *acrosomal reaction* in the sperm that begins with the breakdown of the plasma membrane covering the sperm head (**FIGURE 32.3B**). The acrosomal enzymes are then released and digest a hole through the jelly coat.

A structure called the *acrosomal process*, produced by polymerization of the protein actin, then extends out of the head of the sperm. The sea urchin acrosomal process is coated with species-specific recognition molecules known as *bindins*. Bindins recognize and bind to receptors on the vitelline envelope and on the egg membrane. This final recognition process brings about

the slow block to polyspermy and egg activation. Plasma membranes of sperm and ovum fuse, forming a *fertilization cone* that engulfs the sperm head and brings it into the egg cytoplasm.

MAMMALS In animals in which fertilization is internal (i.e., occurs within the female's body), mating behaviors can guarantee species specificity, but ova-sperm recognition mechanisms still exist. The mammalian ovum is protected by a thick gelatinous layer called the **cumulus** surrounding a glycoprotein envelope called the **zona pellucida** (plural *zonae pellucidae*), or simply the *zona* (FIGURE 32.4). When sperm make contact with the zona, species-specific glycoproteins bind to recognition molecules on the sperm. This binding triggers the acrosomal reaction, releasing acrosomal enzymes that digest a path through the zona. When the sperm head reaches the ovum plasma membrane, other proteins facilitate the fusion.

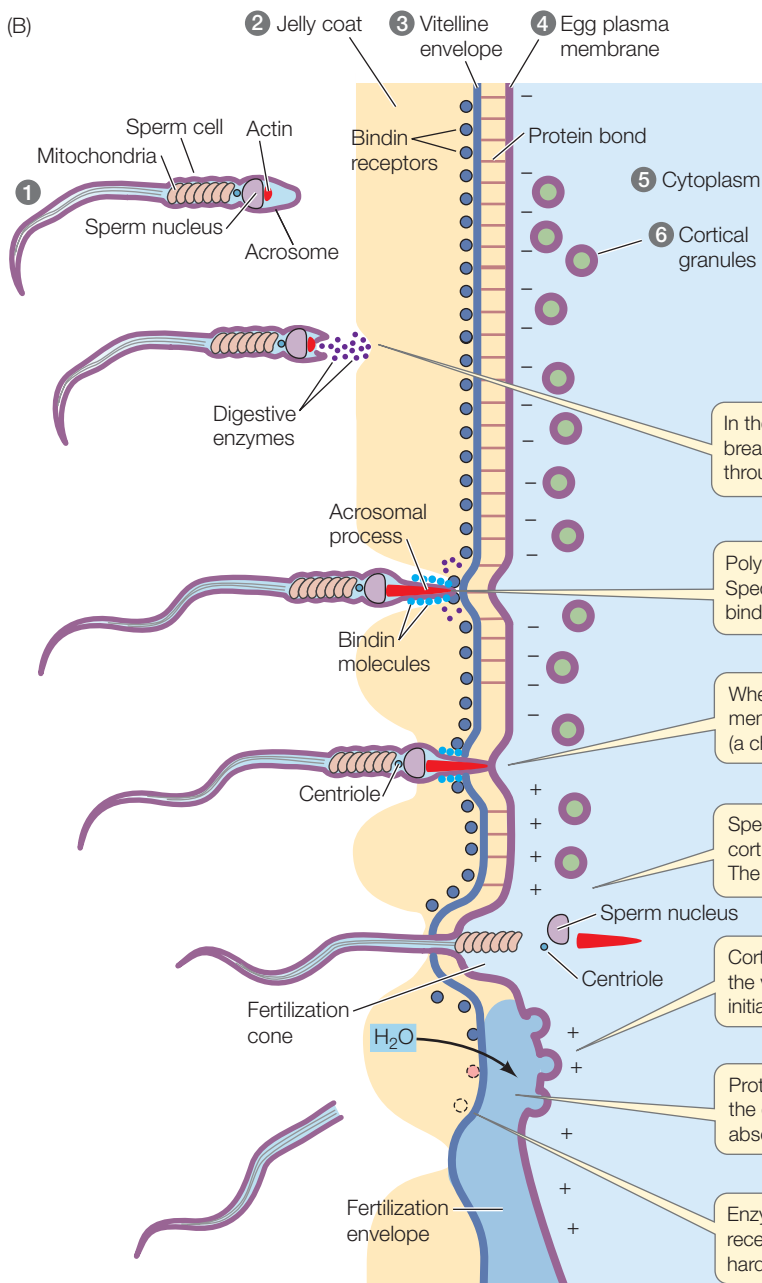

FIGURE 32.3 Fertilization of Sea Urchin Egg (A) A sea urchin egg is protected by a jelly layer and a proteinaceous vitelline envelope. A sperm must penetrate both layers to reach the egg plasma membrane. Circled numbers match structures with the events shown in panel B. (B) The acrosomal reaction allows a sea urchin sperm to pass through an egg's protective layers.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 32.1**
Fertilization in a Sea Urchin Egg

In the **acrosomal reaction**, the acrosomal membrane breaks down, releasing enzymes that digest a path through the egg's protective jelly coat.

Polymerization of actin creates the *acrosomal process*. Species-specific binding molecules on the acrosomal process bind to corresponding receptor molecules on the vitelline envelope.

When the acrosomal process contacts the egg plasma membrane, it triggers the **fast block to polyspermy** (a change in electric charge on the membrane).

Sperm entry into the egg stimulates Ca^{2+} release, causing cortical granules to fuse with the plasma membrane. The sperm nucleus and centriole enter the egg cytoplasm.

Cortical granule enzymes dissolve the bonds between the vitelline envelope and the plasma membrane, initiating the **slow block to polyspermy**.

Proteins released by the cortical granules absorb H_2O and swell.

Enzymes remove sperm-binding receptors. The vitelline envelope hardens, forming a fertilization envelope.

FIGURE 32.4 Barriers to Mammalian Sperm This human ovum, like other mammalian ova, is surrounded by a cumulus and a zona pellucida. A single sperm must penetrate both layers to fertilize the ovum.

The importance of these species-specific recognition mechanisms was revealed in experiments in which human ova were stripped of their zonae pellucidae and exposed to hamster sperm. Fertilization took place, resulting in a hamster–human hybrid zygote. The zygote did not survive its first cell division, but hybrid fertilization would never have occurred had the zona pellucida been intact.

Only one sperm can fertilize an ovum

The entry of a sperm into the ovum initiates a programmed sequence of events, the first of which are **blocks to polyspermy**—

that is, mechanisms that prevent additional sperm from entering the ovum.

SEA URCHINS Blocks to polyspermy have been studied extensively in sea urchin ova. Within seconds after the sperm and ovum plasma membranes make contact, an influx of sodium ions (Na^+) changes the electric charge difference across the ovum’s plasma membrane. This *fast block to polyspermy* prevents the fusion of any other sperm with the ovum’s plasma membrane. The change in membrane charge lasts only about a minute, but that is enough time to allow an additional block to sperm entry to develop.

The *slow block to polyspermy* converts the vitelline envelope into a physical barrier that sperm cannot penetrate. Just under the ovum’s plasma membrane are vesicles called *cortical granules* (see Figure 32.3) that contain enzymes and other proteins. Sperm entry stimulates the release of calcium ions (Ca^{2+}) from the ovum’s endoplasmic reticulum; this wave of Ca^{2+} causes the cortical granules to fuse with the plasma membrane and release their contents. Cortical granule enzymes break the bonds between the vitelline envelope and plasma membrane, and cortical granule proteins attract water into the space between the two layers. As a result, the vitelline envelope swells and rises from the surface of the ovum to form a *fertilization envelope*. Cortical granule enzymes also degrade the sperm-binding molecules on the surface of the fertilization envelope and cause it to harden. All of these mechanisms prevent additional sperm from reaching the surface of the ovum.

MAMMALS The fast block to polyspermy does not occur in mammals, but something similar to the slow block does. As in sea urchins, a release of Ca^{2+} results in the fusion of cortical granules with the ovum plasma membrane. Although no fertilization envelope forms, the cortical granule enzymes destroy the sperm-binding glycoproteins in the zona pellucida. The rise in Ca^{2+} in its cytosol also signals the ovum to complete meiosis. The stage is thus set for the fusion of the gametic nuclei of the sperm and ovum, followed by the first cell division.

APPLY THE CONCEPT

Fertilization is the union of sperm and ovum

The zona pellucida of mammalian ova is a glycoprotein matrix secreted by the developing oocyte. Several glycoproteins have been isolated from mouse zonae pellucidae and named ZP1, ZP2, and ZP3. To identify which, if any, of these glycoproteins bind to and activate sperm, investigators collected

	INCUBATION CONDITION (GLYCOPROTEIN AND RELATIVE CONCENTRATION)									
	CONTROL (NO GLYCOPROTEIN)	ZP1			ZP2			ZP3		
			1	3	5	1	3	5	1	3
Sperm binding (%)	100	95	98	92	88	94	93	54	42	30

mouse sperm and incubated them in media with different glycoprotein concentrations (here listed as 1, 3, and 5, in terms of their relative glycoprotein levels). Sperm were then exposed to mouse zonae to assess their binding capacity.

1. Plot these data using percentage of sperm binding as your y axis and glycoprotein concentration as your x axis.
2. Which glycoprotein stimulates the acrosomal reaction?
3. Design an additional experiment to test your conclusion.

Fertilized ova may be released into the environment or retained in the mother's body

The development of the embryo beyond the zygote stage is the subject of Chapter 33. However, we note here that among the animals, two patterns of care and nurture of the embryo have evolved: oviparity (egg laying) and viviparity (live bearing).

Oviparous animals deposit their fertilized ova in the environment, and their embryos develop outside the mother's body. Oviparous terrestrial animals such as insects, reptiles, and birds protect their ova with membranes or shells that deter some potential predators and decrease water loss.

Viviparous animals retain the embryo within the mother's body during its early developmental stages. Examples of viviparity exist in all vertebrate groups except the crocodiles, turtles, and birds. Viviparity is especially well developed in mammals. Almost all mammals have a specialized portion of the female reproductive tract, the **uterus** or *womb*, that holds the embryo and interacts with it to produce a **placenta**. The placenta enables the exchange of nutrients and wastes between the blood of the mother and that of the embryo.

Do You Understand Concept 32.3?

- What two layers surround a mammalian ovum? Where in these layers, and how, is the acrosomal reaction initiated?
- Describe the slow and fast blocks to polyspermy in sea urchin ova and explain how they prevent polyspermy.
- Suppose an ovum has a metabolic defect such that it contains very few calcium ions. How might this affect that ovum's capability to undergo fertilization?

Having covered the general aspects of animal gametogenesis and fertilization, we will next consider the male and female reproductive systems in mammals, using our own species as the primary example.

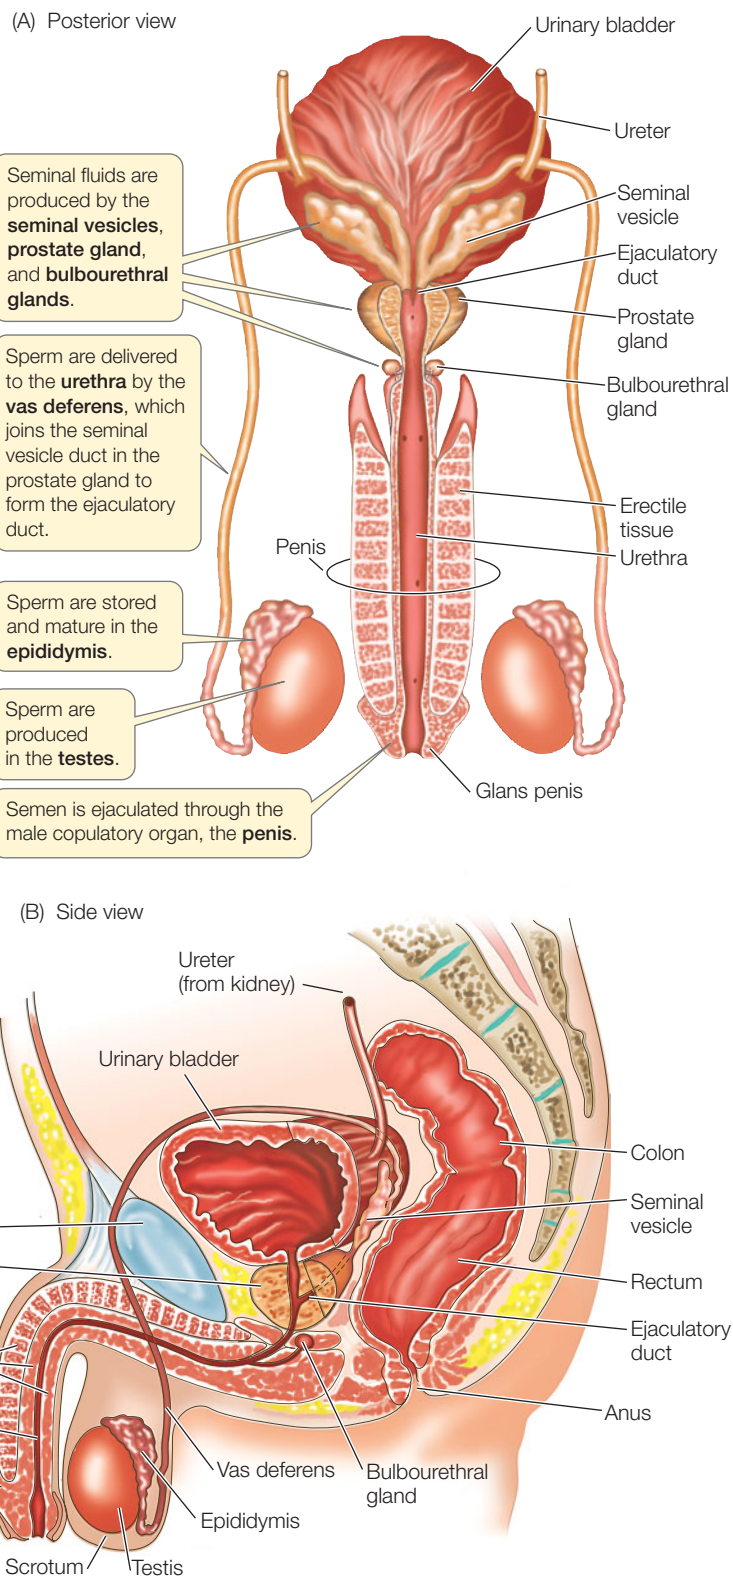

concept 32.4 Human Reproduction Is Hormonally Controlled

We learned in Chapter 30 that the gonads produce sex steroids as well as gametes, and we saw that these hormones play key roles in the development of the reproductive system. We will now see how these hormones regulate every aspect of mammalian sexual reproduction.

Male sex organs produce and deliver semen

The male reproductive organs are diagrammed in **FIGURE 32.5**. Sperm are produced in the testes (the paired male gonads). The testes of most

FIGURE 32.5 Reproductive Organs of the Human Male The organs of the male reproductive tract are shown (A) from the rear and (B) from the side.

yourBioPortal.com

Go to **WEB ACTIVITY 32.1**
The Human Male Reproductive Tract

mammals are located outside the body cavity in a pouch of skin called the **scrotum**. Why should the testes be located outside the body cavity? In most mammals, the optimal temperature for the health of the testes and for spermatogenesis is slightly lower than the normal body temperature. The scrotum keeps the testes at this optimum by expanding or contracting, thus placing the testes closer to or farther from the heat of the body.

Sperm are the product of the male reproductive system. In addition to sperm, **semen** contains a complex mixture of substances that support the sperm and facilitate fertilization. Sperm make up less than 5 percent of the volume of semen.

SPERMATOGENESIS Spermatogenesis begins at puberty and continues throughout a man's life. It takes place within the **seminiferous tubules**, great lengths of which are tightly coiled in each testis (FIGURE 32.6A). Between the seminiferous tubules are clusters of **Leydig cells**, which produce testosterone (FIGURE 32.6B). Spermatogonia reside in the outermost regions of the tubules (FIGURE 32.6C) and are intimately associated with **Sertoli cells**, which provide nutrients for the developing sperm.

Each primary spermatocyte gives rise to four spermatids (see Figure 32.2A) that develop into sperm as they migrate toward the lumen of the seminiferous tubule. The nucleus

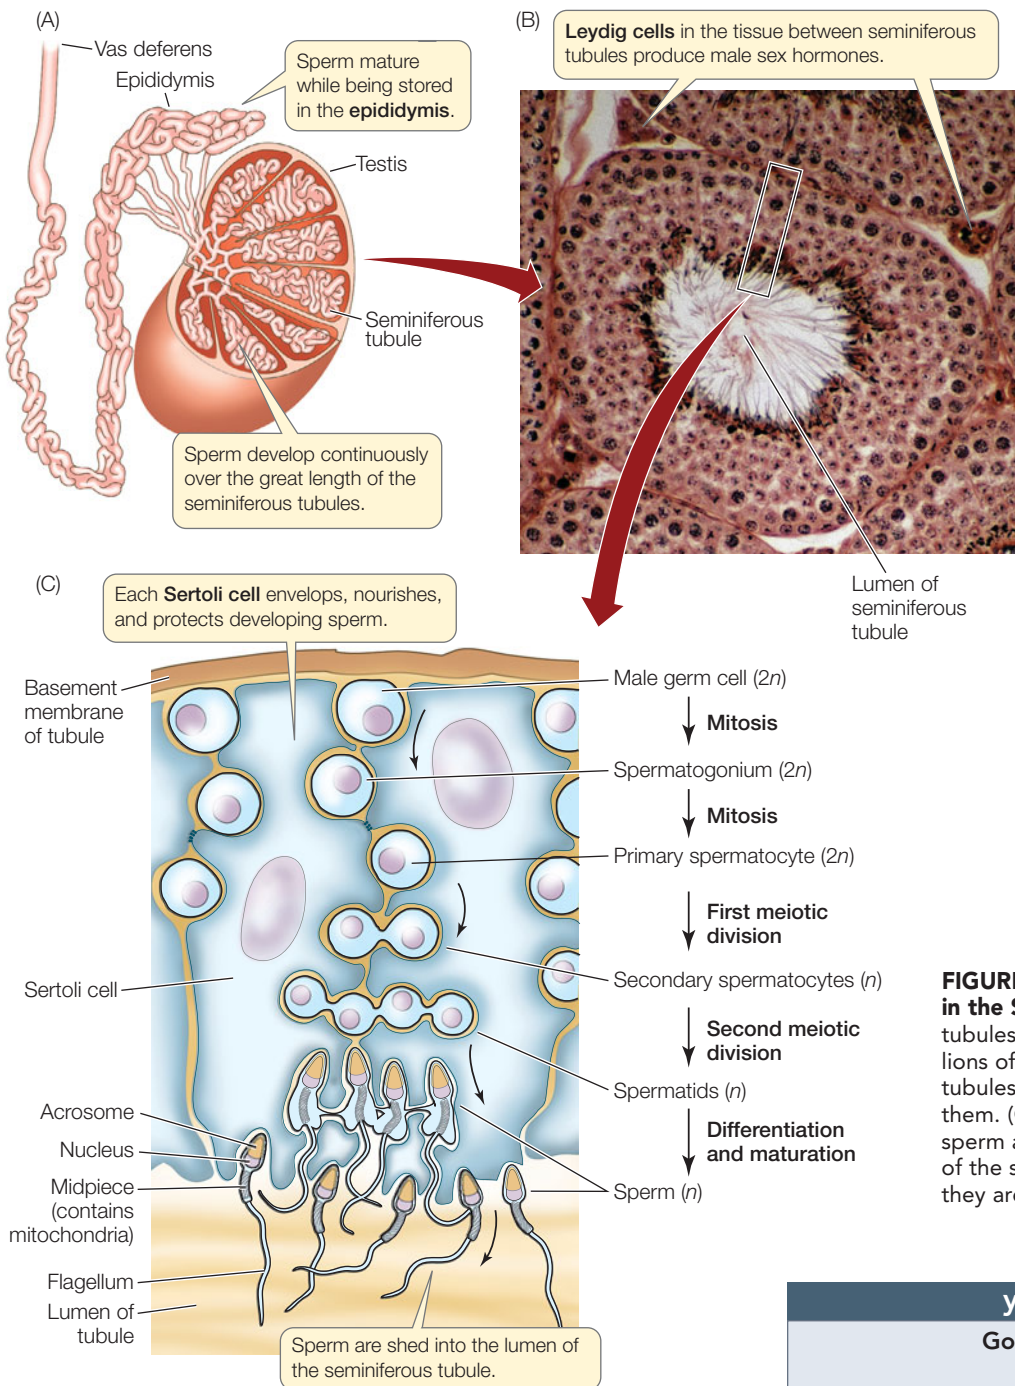

FIGURE 32.6 Spermatogenesis Takes Place in the Seminiferous Tubules (A) Seminiferous tubules fill the testes, continuously producing millions of sperm. (B) Cross section of seminiferous tubules and the Leydig cells in the spaces between them. (C) This enlarged cross section shows how, as sperm are formed, they move from the outer region of the seminiferous tubule toward its center, where they are shed into the lumen of the tubule.

yourBioPortal.com

Go to WEB ACTIVITY 32.2
Spermatogenesis

becomes compact, and the surrounding cytoplasm is lost. A flagellum develops, and mitochondria that will provide energy for its motility are packed into a midpiece between the head and the flagellum. An acrosome forms over the nucleus in the head of the sperm.

Immature sperm are shed into the lumen of the seminiferous tubules. From there, they move into the *epididymis*, where they mature and become motile. From the epididymis, the sperm travel in the *vas deferens* (plural *vasa deferentia*) to a point where the vas deferens joins the duct from the seminal vesicles and becomes the semen-carrying *ejaculatory duct*, which joins the *urethra* at the base of the penis. The urethra—the common final duct for both the urinary and reproductive systems—originates in the bladder, runs through the penis, and opens to the outside of the body at the tip of the penis (see Figure 32.5).

SEMINAL FLUID The components of the semen other than sperm are referred to as *seminal fluid* and are the products of several accessory glands: the paired *seminal vesicles*, the *prostate gland*, and the *bulbourethral glands* (see Figure 32.5). Seminal fluid is thick because it contains mucus and fibrinogen. It also contains fructose, an energy source for the sperm.

The *prostate gland* produces an alkaline fluid that neutralizes the acidity in the male and female reproductive tracts and makes those environments more hospitable to sperm. Prostate fluid also contains a clotting enzyme that causes fibrinogen to convert the semen into a gelatinous mass, facilitating its ejaculation into and retention in the upper regions of the female reproductive tract. Another enzyme in the prostate fluid, fibrinolysin, is activated shortly after it enters the female reproductive tract, where it dissolves clotted semen and liberates the sperm.

The *bulbourethral glands* produce a small volume of an alkaline secretion that helps neutralize acidity in the urethra and lubricates it to facilitate ejaculation. Secretions of the bulbourethral glands precede ejaculation and can carry with them residual sperm from prior sexual activity. Thus it is possible for pregnancy to occur even if the penis is withdrawn from the female just before ejaculation (a rather ineffective birth control practice known as *coitus interruptus*).

MALE SEXUAL FUNCTION The **penis** is the male copulatory organ. The shaft of the penis is covered with normal skin, but the highly sensitive tip, the *glans penis*, is covered with thinner, more sensitive skin. A fold of skin called the *foreskin* (or prepuce) covers the glans penis. The procedure known as *circumcision* removes a portion of the foreskin.

Sexual stimulation triggers responses in the nervous system that result in penile **erection**. Nerve endings release a gaseous neurotransmitter, nitric oxide (NO), onto blood vessels leading into the penis. NO stimulates production of the second messenger cGMP, which causes the vessels to dilate, filling shafts of spongy *erectile tissue* along the length of the penis with blood and compressing the vessels that normally carry blood out of the penis. As a result, the penis becomes stiff and engorged with blood.

At the climax of copulation, 2 to 6 milliliters of semen are *ejaculated*—propelled via smooth muscle contractions through the *vasa deferentia* and the urethra. The muscle contractions are

accompanied by feelings of intense pleasure known as *orgasm*. After ejaculation, NO decreases and enzymes break down cGMP, causing the blood vessels flowing into the penis to constrict. The blood pressure in the erectile tissue decreases, relieving the compression of the blood vessels leaving the penis, and the erection declines. Following an ejaculation, there is a *refractory period*, during which sexual stimulation cannot generate an erection.

Erectile dysfunction (ED), or *impotence*, is the inability to achieve or sustain an erection. Drugs used to treat ED act by inhibiting the breakdown of cGMP, thus enhancing the effect of NO.

Male sexual function is controlled by hormones

Like the maintenance of the male secondary sexual characteristics described in Chapter 30 (body form, facial hair, and a deep voice), spermatogenesis depends on the hormone testosterone, which is produced by the Leydig cells of the testes. Regular pulses of gonadotropin-releasing hormone (GnRH) secreted by the hypothalamus stimulate anterior pituitary cells to increase their secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (FIGURE 32.7). LH then stimulates the Leydig cells to secrete testosterone. FSH and testosterone together stimulate the Sertoli cells to support spermatogenesis. The Sertoli cells also produce a hormone called *inhibin*, which exerts negative feedback on the anterior pituitary cells that produce and secrete FSH.

LINK For more information on the gonadal hormones, or sex steroids, see Concept 30.4

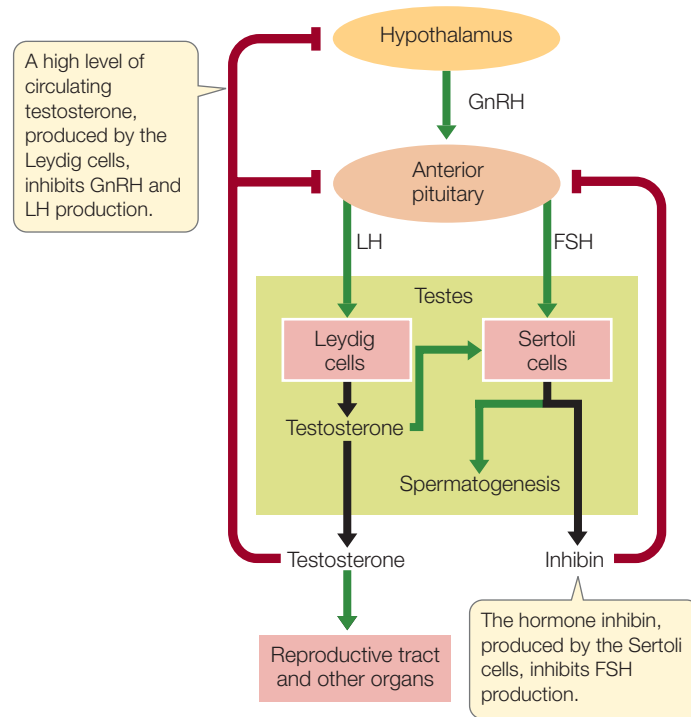

FIGURE 32.7 Male Reproductive Hormones The male reproductive system is under hormonal control by the hypothalamus and the anterior pituitary.

APPLY THE CONCEPT

Human reproduction is hormonally controlled

In human males the testes develop in the abdomen over the course of gestation and normally descend into the scrotum shortly before birth. If they do not descend—a condition known as cryptorchidism—the functional cells of the testes undergo changes that can result in reduced fertility. In most cases, the testes descend on their own during an infant's first year, but if they do not, surgical intervention is common. A medical question is whether it is advantageous for the surgery to take place at a very early age.

The data in the table represent measures of testicular function (sperm count and blood levels of four reproductive hormones) for 85 young adult men who underwent surgery at different ages.

1. Explain why we can claim significant correlations with inhibin and testosterone levels, but only a trend for FSH levels.
2. Referring to Figure 32.7, explain the possible relationship between the inhibin and FSH results.

ADULT FUNCTIONAL MEASURE ^a	AGE AT SURGERY				P-VALUE ^b
	0–2 YRS	2–5 YRS	5–8 YRS	8–11 YRS	
Sperm count ($\times 10^6/\text{mL}$)	60 \pm 42	48 \pm 47	46 \pm 34	53 \pm 52	<0.85
Testosterone (ng/dL)	653 \pm 118	656 \pm 171	570 \pm 143	557 \pm 193	<0.03
Inhibin (pg/mL)	159 \pm 60	106 \pm 54	121 \pm 59	103 \pm 36	<0.03
FSH (units/L)	4.4 \pm 3.2	6.1 \pm 3.3	6.5 \pm 6.4	7.4 \pm 4.3	<0.09
LH (units/L)	4.8 \pm 3.0	4.0 \pm 1.4	4.9 \pm 5.5	4.2 \pm 1.8	<0.81

^a Measures are given as the mean value \pm 1 standard deviation (see Appendix B).
^b P-values indicate the level of significance of the correlation between age at surgery and the adult testicular function measured.

3. Given the observed differences in inhibin, testosterone, and FSH, suggest why there is no significant difference in sperm counts.
4. Based on the results shown here, would you advise the parents of an infant with cryptorchidism to have the procedure done as soon as possible or to postpone surgery until middle childhood?

Female sex organs produce ova, receive sperm, and nurture the embryo

The female reproductive organs are diagrammed in **FIGURE 32.8**. When an ovum matures, it is released from the ovary and moves into one of the **oviducts** (also known as the *Fallopian tubes*). Fertilization, if it occurs, takes place in the upper region of the oviduct. Whether or not the ovum is fertilized, cilia lining the oviduct propel it slowly toward the uterus. The uterus is a muscular, thick-walled organ within which the embryo develops. At the bottom, the uterus narrows into a region called the **cervix** (Latin, “neck”), which leads into the **vagina** that opens to the outside of the body. Sperm deposited in the vagina during copulation move up through the cervix and uterus into the oviducts.

In humans, two sets of skin folds surround the opening of the vagina and the opening of the urethra. The inner, more delicate folds are the *labia minora*; the outer, thicker folds are the *labia majora*. At the anterior tip of the labia minora is the *clitoris*, a small bulb of erectile tissue that has the same developmental origins as the penis (see Figure 30.13). The clitoris is highly sensitive and plays an important role in sexual response. The labia minora and the clitoris become engorged with blood in response to sexual stimulation. Unlike men, women do not have a well-defined refractory period, and some women can experience several orgasms in rapid succession.

The female reproductive cycle is controlled by hormones

Women undergo a regularly repeating reproductive cycle that is about 28 days long. In the first half of the cycle, an ovum matures and is released from the ovary. In the second half of the cycle, the ovary ceases growth and maturation of ova, and the uterus prepares for the possible arrival of an embryo. If no embryo appears, the uterus sheds its lining, and the cycle begins again. Thus the female reproductive cycle consists of two simultaneous cycles: an *ovarian cycle* that produces mature ova and hormones; and a *uterine, or menstrual, cycle* that prepares the uterus for the arrival of an embryo.

In the ovary, each primary oocyte is surrounded by a layer of ovarian cells. An oocyte and its surrounding cells constitute a **follicle** (**FIGURE 32.9**). At the beginning of a cycle, the anterior pituitary increases its secretion of FSH and LH. In response, some 6 to 12 follicles begin to grow in the ovary. Thus the first 2 weeks of the ovarian cycle are called the *follicular phase*.

As the follicles grow, they synthesize and secrete increasing amounts of estrogen. After about a week, one follicle is larger than the rest; it continues to grow while the others cease to develop and die (they undergo *atresia*). At first, estrogen exerts negative feedback control on gonadotropin release by the anterior pituitary. Then, on about day 12, estrogen exerts positive feedback control on the pituitary, resulting in a surge

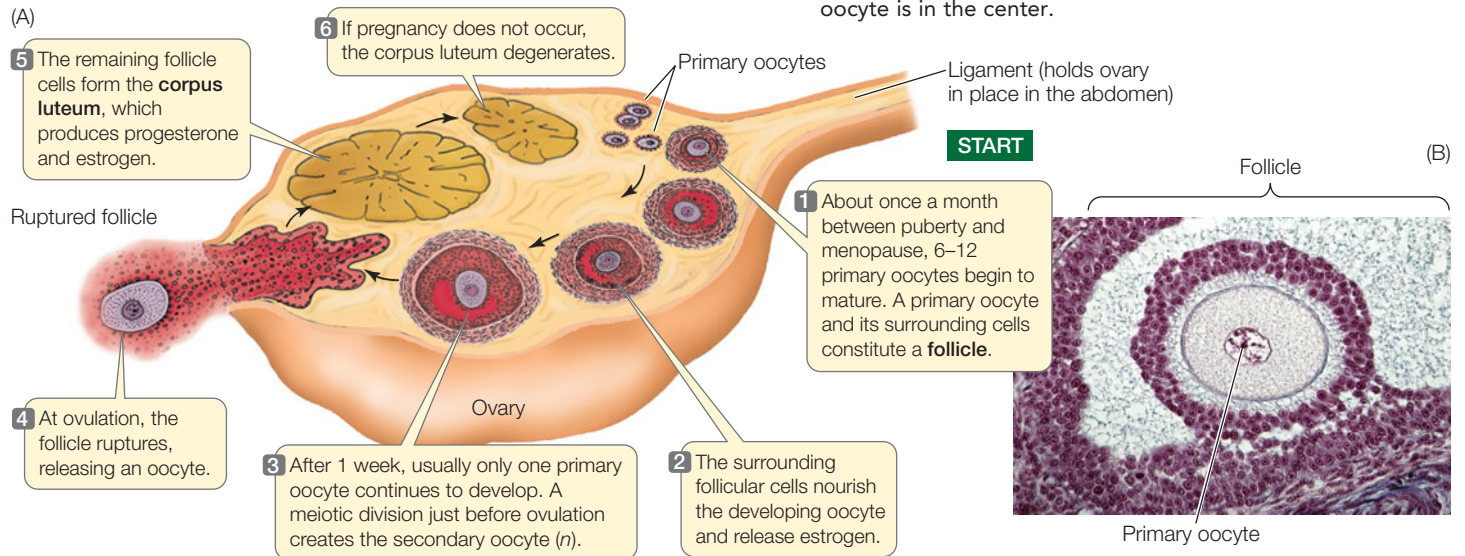

FIGURE 32.9 The Ovarian Cycle The ovarian cycle progresses from the development of a follicle to ovulation and finally to growth and degeneration of the corpus luteum. The micrograph at right shows a mature mammalian follicle; the oocyte is in the center.

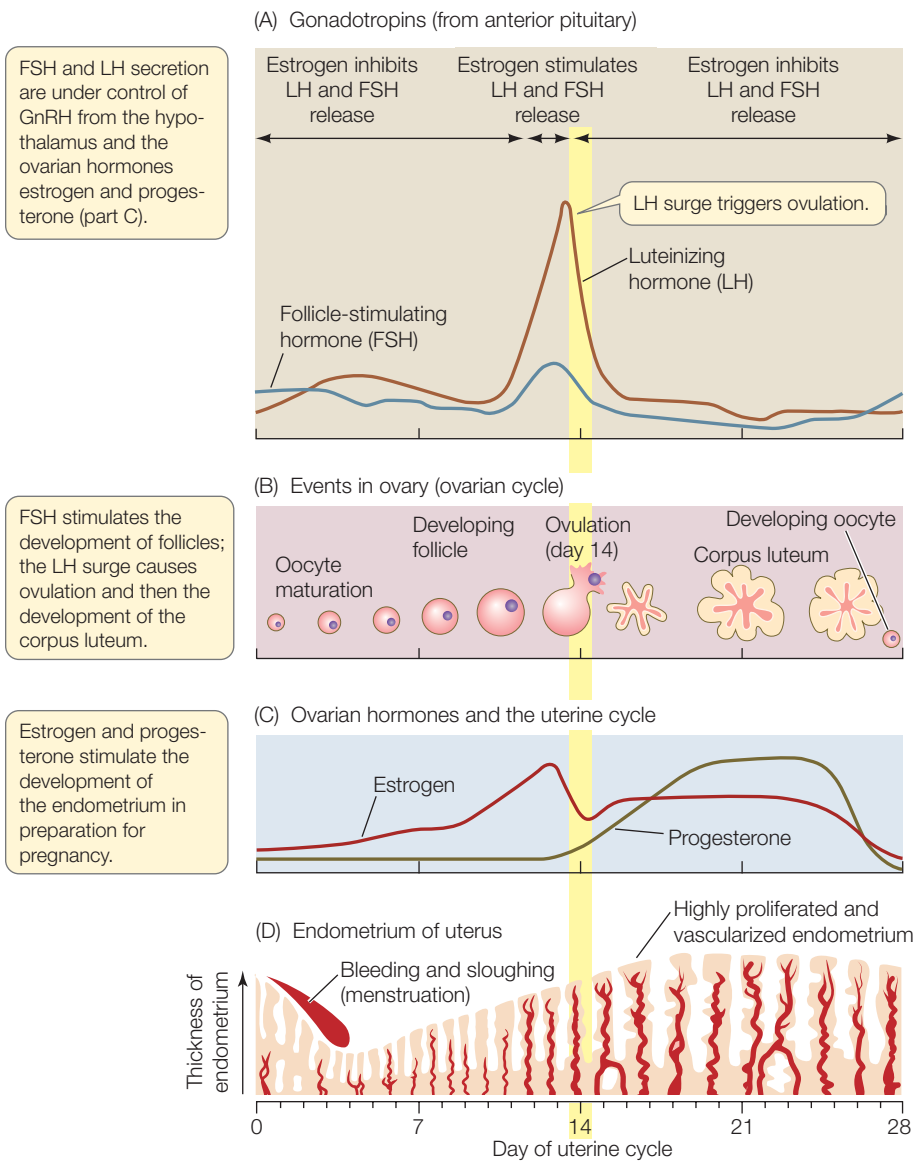

FIGURE 32.10 The Ovarian and Uterine Cycles During a woman’s ovarian and uterine cycles, coordinated changes occur in (A) gonadotropin release by the anterior pituitary, (B) the ovary, (C) the release of female sex steroids, and (D) the uterus. The cycles begin with the onset of menstruation; ovulation is at midcycle (yellow bar).

yourBioPortal.com

Go to ANIMATED TUTORIAL 32.2
The Ovarian and Uterine Cycles

the granulosa cells to produce more FSH receptors (positive feedback). The increasing levels of estrogen in the circulation have a negative feedback effect on the hypothalamus and the anterior pituitary (FIGURE 32.11). As a result, FSH and LH levels fall. Negative feedback on FSH production also derives from *inhibin* released from granulosa cells (similar to the release of inhibin by Sertoli cells in the testes). As a result of these sources of negative feedback, gonadotropin levels decline, so the follicle that has the most FSH receptors is the one that survives.

At the time of ovulation, most follicle cells remain behind in the ovary, where they proliferate to form a mass of yellow tissue called the *corpus luteum* (Latin, “yellow body”). The corpus luteum secretes high levels of progesterone, along with some estrogen, for about 2 weeks (the *luteal phase* of the ovarian cycle). Progesterone causes the epithelial lining of the uterus, called the **endometrium**, to thicken in preparation for a possible pregnancy. Progesterone and estrogen, along with inhibin, exert negative feedback control on the pituitary, inhibiting gonadotropin release and thus preventing new follicles from beginning to mature.

of LH and a lesser surge of FSH. The LH surge triggers *ovulation*—rupture of the follicle and release of the oocyte from the ovary (FIGURE 32.10).

Why is it that usually only one follicle reaches the stage of ovulation? The follicle consists of two types of cells. Those immediately surrounding the oocyte are *granulosa cells*, and those enclosing the whole follicle are *thecal cells*. Thecal cells (like Leydig cells in the testes) produce androgens when stimulated by LH. Granulosa cells (like Sertoli cells in the testes) support the developing oocyte and are stimulated by FSH. Androgens diffuse from the thecal cells to the granulosa cells, which produce the enzyme *aromatase* that converts androgens to estrogen. Estrogen released from the granulosa cells also stimulates

FIGURE 32.11 Hormones Control the Female Reproductive Cycles The ovarian and uterine cycles are under a complex series of positive and negative feedback controls involving several hormones, as described in the text. Estrogen has a positive feedback effect on the granulosa cells by stimulating the expression of FSH receptors. The follicle with the most FSH receptors survives declining FSH production and goes on to mature and release its ovum.

If an embryo does not arrive in the uterus within 2 weeks after ovulation, the corpus luteum degenerates and stops secreting estrogen, progesterone, and inhibin. The falling progesterone causes the endometrium to break down, and the sloughed-off tissue, including blood, flows from the body through the vagina—the process of **menstruation** (Latin *menses*, “month”).

The decrease in estrogen, progesterone, and inhibin also releases the hypothalamus and pituitary from negative feedback control, so GnRH, FSH, and LH all begin to increase. The increase in these hormones induces the next round of follicle development, and the ovarian cycle begins again.

The uterine cycles of most mammals other than humans do not include menstruation; instead, the uterine lining typically is reabsorbed. In these species, the most obvious correlate of the ovarian cycle is a state of sexual receptivity called *estrus* at about the time of ovulation. When the female mammal comes into estrus, or “heat,” she actively solicits male attention and may be aggressive to other females. Humans are unusual among mammals in that females are potentially sexually receptive throughout their ovarian cycles and at all seasons of the year.

In pregnancy, tissues derived from the embryo produce hormones

If fertilization occurs, the zygote undergoes its first few cell divisions as it moves down the oviduct to the uterus, where it attaches itself to the endometrium as a blastocyst. It then burrows into the endometrium—a process called *implantation*—and interacts with it to form the placenta (see Figure 33.4). Once implantation has occurred, a layer of cells covering the embryo begins to secrete a new hormone, **human chorionic gonadotropin (hCG)**. This hormone stimulates the corpus luteum to continue to produce progesterone, along with some estrogen, to support the endometrium and thereby prevent menstruation. Pregnancy tests use an antibody to detect hCG in urine.

The placenta forms from a combination of embryonic and maternal tissues (see Figure 33.16). The placenta produces estrogen and progesterone, eventually replacing the corpus luteum as the most important source of these hormones. Continued high levels of progesterone maintain the endometrial lining, and both hormones prevent the pituitary from secreting gonadotropins; thus the ovarian cycle ceases for the duration of pregnancy.

Hormonal and mechanical stimuli trigger childbirth

A normal human pregnancy lasts about 38 weeks. Both hormonal and mechanical stimuli contribute to the onset of labor (the uterine muscle contractions that push the child through the birth canal). Progesterone inhibits and estrogen stimulates contractions of uterine muscle. Toward the last month of pregnancy, the estrogen–progesterone ratio shifts in favor of estrogen. The onset of labor is marked by increased secretion of the hormone oxytocin—a powerful stimulant of uterine muscle contraction—by the posterior pituitaries of both mother and fetus.

Mechanical stimuli, from the stretching of the uterus and pressure on the cervix by the growing fetus, increase the release of oxytocin by the mother’s posterior pituitary, which in

turn increases the activity of uterine muscle, which causes even more pressure on the cervix. This positive feedback loop results in stronger contractions. The hormonal changes and the pressure created by the contractions cause the cervix to dilate (expand) until it is large enough to allow the baby to pass through. When the cervix is fully dilated (to a diameter of about 10 centimeters), the baby’s head can move into the vagina; its passage through the vagina is assisted by the mother’s bearing down (“pushing”) with her abdominal and other muscles. Once the baby’s head and shoulders clear the cervix, the rest of its body eases out rapidly.

If the baby suckles at the breast immediately following birth, its suckling stimulates additional secretion of oxytocin, which augments uterine contractions that reduce the size of the uterus and help stop bleeding. Oxytocin also promotes bonding between the mother and infant.

Do You Understand Concept 32.4?

- Diagram the hormonal controls of male and female reproduction. What roles do the same hormones play in each sex? Given that the female system cycles and the male system does not, what phase of the female cycle is most similar to the state of the male system?
- Suppose a mutation prevented the production of normal hCG. What problems would this create for a pregnancy?
- Describe two examples of positive feedback control in the human reproductive system.

Our growing understanding of the physiology of human reproduction has led to numerous methods and technologies for controlling it, either to prevent unwanted pregnancies or to overcome infertility.

concept 32.5 Humans Use a Variety of Methods to Control Fertility

According to a recent study, almost half of the more than 6 million pregnancies that occur in the United States each year are unintended. For women of college age, a single act of unprotected sexual intercourse in the two days prior to ovulation carries a chance of conception as high as 50 percent.

Many contraceptive methods are available

The only failure-proof methods of preventing pregnancy are complete abstinence from sexual activity or the surgical removal of the gonads. There are, however, other, less drastic methods, many of which prevent fertilization or implantation (*conception*) and are therefore referred to as **contraception**. **TABLE 32.1** lists the most commonly used contraceptive methods and their relative failure rates; note that the different methods vary enormously in their effectiveness.

TABLE 32.1 Methods of Contraception

METHOD	MODE OF ACTION	FAILURE RATE ^a	COMMENTS
Unprotected	No form of birth control	85	High risk of pregnancy, especially for women 15–30.
Nontechnological methods			
Rhythm method	The couple abstains from intercourse between days 10 and 20 of the ovarian cycle (peak fertility).	15–35	High failure rate due to miscalculation and/or variation of individual cycles.
Coitus interruptus	The man withdraws his penis prior to ejaculation with the intention of not depositing sperm into the vagina.	20–40	Requires self-control, especially by the man. Very high failure rate.
Barrier methods^b			
Condom	A sheath of impermeable material (often latex) is fitted over the erect penis. Semen is trapped in the condom, so no sperm are deposited in the vagina.	15	If fitted correctly, an intact condom can prevent pregnancy and provide protection against sexually transmitted diseases (STDs), including HIV (AIDS).
Spermicidal jellies	Applied inside the vagina, these chemical compounds kill or immobilize sperm.	25	Used alone, spermicidal compounds have a fairly high failure rate.
Diaphragms, cervical caps	Inserted by the woman prior to intercourse, these devices work by blocking the cervix so that sperm cannot pass into the uterus.	10–15	Approximately the same failure rate as condom use by men, but do not protect against STDs. Can be used in conjunction with spermicidal jelly for extra protection.
Hormone-based contraceptives			
Oral hormones (“the pill”)	A daily pill for women containing a combination of synthetic estrogens and progesterone (progestin). These hormones mimic pregnancy to the extent that the ovarian cycle and ovulation are suspended. The uterine cycle is allowed to continue by including a week of non-hormone administration every 21–28 days.	0–3	Requires medical consultation and prescription. Taken correctly, oral contraceptives are extremely effective. In the U.S., more than 12 million women use them each year; they are sometimes prescribed to treat menstrual disorders.
Non-orally administered hormones	Making use of same hormonal actions as the pill, these methods include long-acting injections, patches that release hormones transdermally (through the skin), and a hormone-containing vaginal ring.	<1	Same as oral hormones. A slightly lower failure rate because the woman does not have to remember to take a daily pill.
Progestin-only pill	An oral contraceptive meant to be taken within 72 hours after unprotected sex. A high dose of progestin in two pills prevents ovulation in the same manner birth control pills do.	5–40 ^c	Not an “abortion pill,” this drug will not terminate an existing pregnancy. Currently available to women over 17 without a prescription.
Implantation blockers			
Intrauterine device (IUD)	A medical professional inserts a small plastic or metal device into the uterus. The resulting inflammation reaction (see Chapter 31) releases prostaglandins, which prevent implantation of the fertilized egg.	0.5–5	A highly effective contraceptive, it is the most widely used birth control device in China (and hence the world). With medical monitoring, can remain in place for several years.
Mifepristone (RU-486)	This drug blocks progesterone receptors necessary to maintain the endometrium during implantation and pregnancy.	0.5–6	Prevents implantation when taken up to several days after unprotected intercourse. Can terminate a pregnancy up to the time of the first missed menstrual period. In the U.S., available from specialized providers.
Sterilization			
Vasectomy	The vasa deferentia (see Figure 32.5A) are cut and tied off so that sperm can no longer pass into the urethra. Sperm continue to be produced but are reabsorbed by the man’s body. Male hormone levels and sexual responses are not affected.	0–0.15	A simple surgical procedure performed under local anesthetic in a doctor’s office. Although it can theoretically be reversed, vasectomy should be considered permanent.
Tubal ligation	The oviducts (see Figure 32.8A) are tied off so that eggs cannot reach the uterus and sperm cannot reach the egg. As with vasectomy, hormone levels and sexual responses are not affected.	0–0.05	This surgical procedure is somewhat more complex than vasectomy. It is often performed in conjunction with childbirth when a woman has decided that her family is complete.

^a “Failure rate” refers to the number of pregnancies per 100 women per year.

^b All of these barrier methods are routinely available without medical prescription.

^c Failure rate varies widely depending on when taken.

Once a fertilized egg is successfully implanted in the uterus, any termination of the pregnancy is called an **abortion**. A *spontaneous abortion* is the medical term for what is commonly called a miscarriage. Spontaneous abortions are quite frequent early in pregnancy and are usually the result of either a chromosomal abnormality in the embryo or a breakdown in the process of implantation. Many spontaneous abortions occur before a woman even realizes she is pregnant.

Abortions that result from medical intervention may be performed either for therapeutic purposes or for fertility control. A therapeutic abortion may be necessary to protect the health of the mother, or it may be performed because prenatal testing reveals that the fetus has a severe defect. In a medical abortion, the cervix is dilated and some of the endometrium, along with the implanted embryo, is removed from the uterus. When performed in the first trimester (the first 12 weeks) of a pregnancy, a medical abortion carries less risk of death to the mother than a full-term pregnancy. The risk rises after the first trimester but still remains less than that of a full-term pregnancy through the second trimester.

Reproductive technologies help solve problems of infertility

There are many reasons for infertility—usually defined as the persistent inability of a couple to conceive a child—and they are equally distributed between men and women. A number of technologies have been developed to overcome barriers to both conceiving and bearing a child.

The simplest treatment available is **artificial insemination**, in which the physician positions sperm within the woman's reproductive tract. This technique is useful if the male partner's sperm count is low or his sperm lack motility, or if certain conditions in the woman's reproductive tract prevent the normal progress of sperm to the ovum. It is also useful if a woman does not have a male partner.

FRONTIERS Most domestic cattle are produced through artificial insemination. Dairy farming is far more efficient and profitable when cows produce female rather than male offspring, and dairy farmers preferentially produce female offspring based on the DNA content of the sperm they use to inseminate their cows. Sperm sorting uses an instrument called a flow cytometer to separate sperm based on the density of a fluorescent dye marker. X-bearing (female-producing) sperm have more DNA than Y-bearing sperm and thus can be distinguished by the greater amount of dye they absorb. Human sperm can be sorted in a similar way, raising controversy over the desirability of allowing parents to choose the sex of their offspring.

For situations in which artificial insemination does not work, there are more complex procedures called **assisted reproductive technologies**, or **ARTs**. These procedures involve removing unfertilized eggs from the ovary, combining them with sperm outside the body, and then placing fertilized eggs or egg-sperm mixtures in the appropriate location in the woman's reproductive tract for implantation. The first successful

ART was *in vitro fertilization* (IVF). In IVF, the woman is treated with hormones that stimulate many follicles in her ovaries to mature. Eggs are collected from these follicles and combined with sperm collected from the man. The resulting embryos can be injected into the mother's uterus or kept frozen for implantation later. The first "test-tube baby" resulting from IVF was Louise Brown, born in England in 1978. Since then, more than 3 million babies have been produced using this ART. For creating this technology, Robert Edwards received the 2010 Nobel Prize in Physiology and Medicine.

Do You Understand Concept 32.5?

- According to the data in Table 32.1, what are the two least effective methods of contraception? Which is the only method that protects against sexually transmitted diseases?
- What are some possible reasons that a sperm might be unable to fertilize an ovum?
- Explain how reproductive technologies such as artificial insemination and IVF make it possible for parents to choose the sex of their offspring. What are some of the arguments in favor of and against doing so?

The fertilized ovum, or zygote, of a sexually reproducing organism is a single cell containing all the genetic information needed to create a new organism. The emergence of the new adult organism from a zygote is the process of *development*, the subject of Chapter 33.

How does "the pill" prevent conception?

ANSWER The basic mechanism of the birth control pill is to create in the female a hormonal condition similar to that of pregnancy. Most birth control pills are the so-called combined pill that contains synthetic hormones resembling both estrogen and progesterone. Some pills, sometimes called "minipills," contain only synthetic progesterone. Daily doses of either pill type mimic the secretion of the hormones of pregnancy by the corpus luteum and the placenta, as described in Concept 32.4. Heightened levels of these hormones in the circulation exert negative feedback on the hypothalamus and the anterior pituitary so that release of GnRH by the hypothalamus and of FSH and LH by the anterior pituitary remains low. As a result, follicles do not mature and ovulation does not occur (review Figures 32.9 and 32.10).

Minipills are taken every day. Combined pills are taken once a day for 21 days, followed by 7 days with either no pills or dummy pills. The drop in hormone levels during that 7 days allows menstruation to occur.

32

SUMMARY

concept 32.1 Reproduction Can Be Sexual or Asexual

- Asexual reproduction produces offspring that are genetically identical to their parent and to one another; it produces no genetic diversity.
- Modes of asexual reproduction include **budding**, **regeneration**, and **parthenogenesis**. **Review Figure 32.1**
- Sexual reproduction consists of three basic steps: **gametogenesis**, spawning or mating, and **fertilization**.

concept 32.2 Gametogenesis Produces Haploid Gametes

- Gametogenesis occurs in **testes** and **ovaries**. In **spermatogenesis** (the production of **sperm**) and **oogenesis** (the production of **ova**), the **germ cells** proliferate mitotically, undergo meiosis, and mature into gametes. **Review Figure 32.2**
- Each **primary spermatocyte** produces four haploid sperm through the two cell divisions of meiosis.
- **Primary oocytes** immediately enter prophase of the first meiotic division, and in many species, including humans, their development is arrested at this point. Each primary oocyte produces only one ovum.
- In **hermaphroditic** species, the same individual can produce both sperm and ova, either simultaneously or sequentially.

concept 32.3 Fertilization Is the Union of Sperm and Ovum

- External fertilization is common in aquatic species. **Spawning** is the release of large numbers of gametes into the water.
- Internal fertilization is necessary in terrestrial species. It usually requires **copulation**, the physical joining of the male and female **accessory sex organs**.
- Fertilization involves species-specific binding of sperm to ovum, the acrosomal reaction, the sperm's passage through the protective layers covering the ovum, and fusion of sperm and ovum plasma membranes. **Review Figure 32.3 and ANIMATED TUTORIAL 32.1**

- The entry of the sperm into the ovum triggers **blocks to polyspermy**, which prevent additional sperm from entering the ovum, and in mammals, signal the ovum to complete meiosis.

concept 32.4 Human Reproduction Is Hormonally Controlled

- The male sex organs produce and deliver **semen**. Semen consists of sperm suspended in seminal fluid, which nourishes the sperm and facilitates fertilization. **Review Figure 32.5 and WEB ACTIVITY 32.1**
- Sperm are produced in the **seminiferous tubules** of the testes, mature in the epididymis, and are delivered to the urethra through the vasa deferentia. **Review Figure 32.6 and WEB ACTIVITY 32.2**
- Spermatogenesis depends on testosterone secreted by the Leydig cells of the testes, which are under the control of hormones produced in the anterior pituitary and hypothalamus. **Review Figure 32.7**
- Ova mature in the female's ovaries and are released into the **oviducts**. Sperm deposited in the **vagina** during copulation move up through the **cervix** and **uterus** into the oviducts, where fertilization occurs. **Review Figure 32.8 and WEB ACTIVITY 32.3**
- The maturation and release of ova constitute an ovarian cycle. This cycle takes about 28 days. The uterine cycle prepares the **endometrium** of the uterus for receipt of an embryo. If no embryo arrives, the endometrium sloughs off in the process of **menstruation**. **Review Figures 32.9 and 32.10 and ANIMATED TUTORIAL 32.2**
- Both the ovarian and the uterine cycles are under the control of hypothalamic and pituitary hormones, which in turn are under the feedback control of estrogen and other hormones. **Review Figure 32.11**

concept 32.5 Humans Use a Variety of Methods to Control Fertility

- Methods of **contraception** include abstinence from intercourse and the use of technologies that decrease the probability of fertilization and implantation. **Review Table 32.1**
- A number of **assisted reproductive technologies (ARTs)** have been developed to treat infertility.

Animal Development

33

In Homer's *Odyssey*, the mythic hero Odysseus visits the island of the Cyclopes, a race of one-eyed giants. He and his men come across an enormous cave inhabited by one of these beings. After feasting on the cyclops's stored food, they hide as the monster returns: "The cyclops ... blotted out the light in the doorway. He was as tall and rugged as an alp. One huge eye glared out of the center of his forehead."

The one-eyed monster of Greek mythology has a basis in reality. A common birth defect in humans is a condition known as holoprosencephaly (Greek, "one forebrain"). In its extreme form, as the name implies, the forebrain does not develop as two hemispheres but as one, and the face can develop with a single, centrally located eye. These extreme cases of holoprosencephaly invariably lead to death of the fetus and a miscarriage. Less extreme cases, however, result in infants born with cleft lips and cleft palates.

A number of factors have been implicated in holoprosencephaly, most of them genetic. Mutations in several genes that are part of the hedgehog signaling factor family can cause this condition. The first *hedgehog* gene was discovered in fruit flies, where it plays a role in determining the differences in the body segments of the fly. The name arises from the fact that flies with a defect in this gene are hunched up and have a continuous covering of tiny projections, so they resemble a hedgehog. The homologous vertebrate gene, *Sonic hedgehog* (named for the video game character), is critical in central nervous system development.

Environmental factors can induce holoprosencephaly. A particularly powerful mutagen is a molecule found in the corn lily, *Veratrum californicum*. Cows and ewes grazing in fields where this plant grows have high incidences of stillbirths with extreme forms of holoprosencephaly; in fact, when the molecule was extracted and purified from corn lily, it was named cyclopamine. In humans, the ingestion early in pregnancy of a class of drugs called statins has been associated with these birth defects. Learning how these environmental factors cause holoprosencephalic development helps explain why *Sonic hedgehog* is critical in limb and nervous system development.

In mammals, normal *Sonic hedgehog* gene expression over the course of development leads to the formation of two separate eye fields.

How does the *Sonic hedgehog* pathway control development of the vertebrate brain and eyes?

KEY CONCEPTS

- 33.1 Fertilization Activates Development
- 33.2 Cleavage Repackages the Cytoplasm of the Zygote
- 33.3 Gastrulation Creates Three Tissue Layers
- 33.4 Neurulation Creates the Nervous System

concept 33.1 Fertilization Activates Development

In sexually reproducing animals, fertilization is the joining of sperm and egg to form a diploid zygote, as described in Concept 32.3. You might think of fertilization as the event that begins development. However, it is preceded by critical events in the maturing egg that influence subsequent development. Here we take a closer look at the cellular and molecular interactions of sperm and egg that activate the continuing processes of development.

The sperm and ovum make different contributions to the zygote

In most species, eggs are much larger than sperm. The sperm contains almost no cytoplasm and is little more than a DNA delivery vehicle. In addition to providing its haploid nucleus, however, the sperm makes an additional, and vital, contribution to the zygote in most species: a *centriole*. The centrosome of the egg degrades during oogenesis, so the sperm centriole becomes the centrosome of the zygote and plays essential roles in microtubule organization and formation of the primary cilium (see Concept 7.2).

In contrast to sperm, the egg has copious cytoplasm stocked with organelles, nutrients, and a variety of molecules, including transcription factors and mRNAs. Nearly everything the embryo needs during its first stages of development comes from the mother. Cytoplasmic factors in the egg play important roles in setting up the signaling cascades that orchestrate the major processes of development described in Chapter 14: *determination, differentiation, morphogenesis, and growth* (see p. 264). Throughout this chapter, we will see how these processes underlie the development of a multicellular individual from a single cell.

LINK Concepts 14.1 through 14.3 explain how differential gene expression acts during early development

Rearrangements of egg cytoplasm set the stage for determination

Certain molecules in the egg's cytoplasm are not homogeneously distributed even before fertilization, and the entry of the sperm into the egg stimulates further rearrangements. These rearrangements establish the *polarity* of the zygote, and when cell divisions begin, the informational molecules that will guide development are not divided equally among daughter cells.

Cytoplasmic rearrangement following fertilization is easily observed in some frog species because their eggs have pigments in the cytoplasm. The nutrients in an unfertilized frog egg are dense yolk granules that are concentrated by gravity in the lower half of the egg, or **vegetal hemisphere**. The haploid nucleus of the egg is located at the opposite end, in the **animal hemisphere**. The outermost (*cortical*) cytoplasm of the animal hemisphere is heavily pigmented, and the underlying

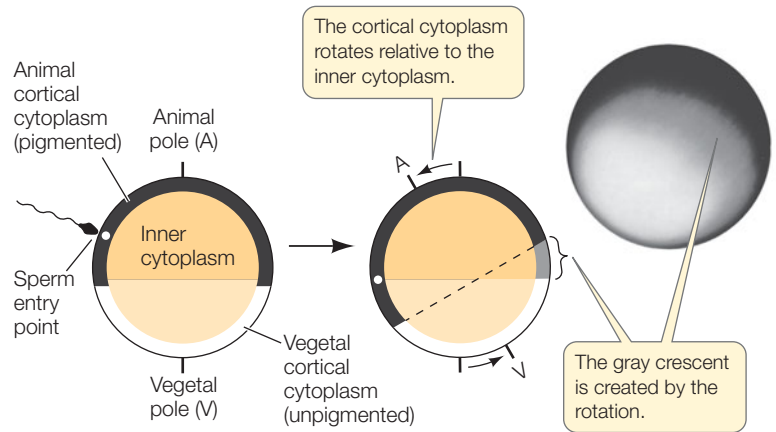

FIGURE 33.1 The Gray Crescent Rearrangement of the cytoplasm of frog eggs after fertilization creates the gray crescent and imposes an anterior–posterior axis on the egg.

cytoplasm has more diffuse pigmentation. The vegetal hemisphere is not pigmented.

Sperm-binding sites are localized on the surface of the animal hemisphere, so that is where the sperm enters the egg. When a sperm enters the egg, cortical cytoplasm rotates toward the site of sperm entry. This rotation brings different regions of cytoplasm into contact with each other on opposite sides of the egg, producing a band of diffusely pigmented cytoplasm on the side opposite the site of sperm entry. This band, called the **gray crescent**, marks the location of important developmental events in some amphibians (**FIGURE 33.1**). These rearrangements also impose an anterior–posterior axis on the egg, so that the zygote now has bilateral symmetry as well as a prospective head and tail.

Cytoplasmic reorganization is initiated by the one non-nuclear organelle that the sperm contributes to the egg: the centriole. The centriole organizes the microtubules in a parallel array extending through the vegetal hemisphere cytoplasm. This array guides the movement of the cortical cytoplasm. These microtubules also appear to be directly responsible for movement of specific organelles and proteins that travel from the vegetal hemisphere to the gray crescent region faster than the cortical cytoplasm rotates.

The movement of cytoplasm, proteins, and organelles changes the distribution of critical developmental signals. For example, the transcription factor β -catenin, necessary for specifying and positioning the cells of the three embryonic *germ layers* (see Concept 33.3), is produced from maternal mRNA (i.e., mRNA produced and stored in the egg while it was maturing in the ovary). Both β -catenin mRNA and a protein kinase called glycogen synthase kinase-3 (GSK-3) are found throughout the cytoplasm; GSK-3 targets β -catenin for degradation. However, an *inhibitor* of GSK-3 is segregated in the egg's vegetal cortex. After sperm entry, this inhibitor migrates along microtubules to the gray crescent, where it prevents the degradation of β -catenin. As a result, the concentration of β -catenin is higher on the dorsal than on the ventral side of the developing embryo (**FIGURE 33.2**).

FIGURE 33.2 Cytoplasmic Factors Set Up Signaling Cascades Cytoplasmic movement changes the distributions of critical developmental signals. In the frog zygote, the interaction of the protein kinase GSK-3, its inhibitor, and the protein β-catenin are crucial in specifying the dorsal–ventral axis of the embryo.

Do You Understand Concept 33.1?

- What organelles does the sperm contribute to the zygote?
- Describe how cytoplasmic rearrangements in the frog egg set up the anterior–posterior and dorsal–ventral body axes.
- In most species, no genes are transcribed immediately following fertilization and during the early cell divisions. What sources of information determine the spatial organization of an early-stage embryo?

β-Catenin plays a major role in the signaling cascade that begins the process of cell specification and determination. But before cell–cell signaling can occur, there must be multiple cells. We turn next to the early series of cell divisions that produces a multicellular embryo.

concept 33.2 Cleavage Repackages the Cytoplasm of the Zygote

The diploid zygote becomes a mass of cells through a rapid series of cell divisions called **cleavage**. Because the cytoplasm of the zygote is not homogeneous (see Concept 33.1), these first cell divisions result in the differential distribution of nutrients and cytoplasmic determinants (mRNA and proteins).

Cleavage increases cell number without cell growth

In most animals, cleavage proceeds with rapid DNA replication and mitosis but with no cell growth and little gene expression. The embryo becomes a ball of ever-smaller cells. Eventually, this ball forms a central fluid-filled cavity called a **blastocoel**, at which point the embryo is called a **blastula**. Its individual cells are called **blastomeres**. The pattern of cleavage in different species influences the form of their blastulas.

- **Complete cleavage** occurs in most eggs that have little *yolk* (stored nutrients). In this pattern, early cleavage furrows divide the egg completely and all the blastomeres are of similar size. The frog egg undergoes complete cleavage, but because its vegetal pole contains more yolk, the division of the cytoplasm is unequal and the blastomeres in the animal hemisphere are smaller than those in the vegetal hemisphere (**FIGURE 33.3A**).
- **Incomplete cleavage** occurs in many species in which the egg contains a lot of yolk and the cleavage furrows do not penetrate it all. **Discoidal cleavage** is a type of incomplete cleavage that is common in fishes, reptiles, and birds, the eggs of which contain a dense yolk mass. The embryo forms as a disc of cells, called a **blastodisc**, that sits on top of the yolk mass (**FIGURE 33.3B**).
- Cleavage in mammals combines characteristics of both of the above types. Mammalian eggs contain little yolk and

(A) Complete cleavage (frog)

The planes of the second cleavage are displaced only slightly by yolk in the cytoplasm.

Vegetal cells have incorporated yolk and are thus larger than the animal cells in the 16-cell embryo.

The embryo forms as a blastodisc that sits on top of the yolk mass.

(B) Incomplete cleavage (zebrafish)

In birds and fishes, cleavage furrows do not penetrate the large yolk mass.

(C) Superficial cleavage (*Drosophila*)

1 Mitosis (nuclear division) occurs without cell division.

3 The nuclei migrate to the inner edge of the plasma membrane.

2 A syncytium—a single cell with many nuclei—is produced.

4 Cellularization occurs, creating a blastoderm.

FIGURE 33.3 Some Patterns of Cleavage Differences in patterns of early embryonic development reflect differences in the way the egg cytoplasm is organized. (A) The frog is a model organism representing complete cleavage. (B) Zebrafish embryos illustrate incomplete cleavage, in which the large yolk mass limits the planes of cleavage. (C) Nuclear staining reveals the syncytial nuclei characteristic of the early embryo of a fruit fly. These nuclei migrate to the periphery. Cleavage furrows then move inward to separate the nuclei into individual cells, forming the blastoderm.

undergo complete cleavage, yet the blastula develops as a blastodisc—most likely a carryover from shared ancestry with reptiles and birds.

- **Superficial cleavage** is a variation of incomplete cleavage that occurs in insects such as the fruit fly (*Drosophila*). Early in development, cycles of mitosis occur without cell division, producing a *syncytium*—a single cell with many nuclei (FIGURE 33.3C). The nuclei eventually migrate to the periphery of the egg, after which the plasma membrane of the egg grows inward, partitioning the nuclei into individual cells surrounding a core of yolk.

Cleavage in mammals is unique

Several features of early cell divisions in placental mammals are different from those seen in other animals. Early cell divisions in mammals are very slow—some 12 to 24 hours apart, compared with tens of minutes to a few hours in non-mammalian species. In mammals, genes are transcribed earlier in cleavage than in most other species.

Another unique feature of mammalian cleavage occurs during the fourth division, when the cells separate into two groups. The **inner cell mass** will become the embryo, while the

surrounding outer cells become an encompassing sac called the **trophoblast**. The cells of the inner cell mass are not yet determined but are *pluripotent* (“capable of much”). When grown in culture these cells are the *embryonic stem cells* (ESCs) that are the subject of intense research on their therapeutic potential (see Concept 14.1). The trophoblast cells secrete fluid, creating a blastocoel with the inner cell mass at one end (FIGURE 33.4A). At this stage, the mammalian embryo is called a **blastocyst**, distinguishing it from the *blastulas* of other animal groups.

Why is mammalian cleavage so distinctive? A key factor is that mammalian eggs contain almost no yolk; the embryo develops within the mother’s uterus and derives its nutrients from the mother’s bloodstream. Thus, the mammalian blastocyst produces both an embryo (from the inner cell mass) and the support structures necessary to attach the embryo to the mother’s uterine wall (from the trophoblast).

Fertilization in mammals occurs in the upper reaches of the mother’s oviduct, and cleavage occurs as the zygote travels down the oviduct to the uterus. When the blastocyst arrives in the uterus, the zygote hatches out of the zona pellucida (see Concept 32.3). The trophoblast then adheres to the lining of the uterus (the *endometrium*), beginning the process

FIGURE 33.4 A Human Blastocyst at Implantation

(A) Seen in cross section under a light microscope, the mammalian blastocyst consists of an inner cell mass adjacent to a fluid-filled blastocoel and surrounded by trophoblast cells. (B) Molecules and enzymes secreted by trophoblast cells allow the blastocyst to burrow into the endometrium. Once the blastocyst is implanted in the uterine wall, the trophoblast cells send out *chorionic villi*—projections that increase the embryo's area of contact with the maternal bloodstream.

of **implantation**—burrowing into the uterine wall. In humans, implantation begins about 6 days after fertilization (**FIGURE 33.4B**).

Specific blastomeres generate specific tissues and organs

During the next stage of development, the cells of the blastula will move around and come into new associations with one another, communicate instructions to one another, and begin to differentiate. In many animals, these blastomere movements are so regular and well orchestrated that it is possible to label a specific blastomere (e.g., with a dye) and identify the tissues and organs that form from its progeny. Such labeling experiments produce **fate maps** of the blastula (**FIGURE 33.5**).

Blastomeres become **determined**—irreversibly committed to specific fates—at different times in different species. In some species, such as roundworms, blastomere fates are restricted as early as the two-cell stage. If one of these blastomeres is experimentally removed, a particular portion of the embryo will not form. This type of development has been called **mosaic development** because each blastomere appears to contribute a specific set of “tiles” to the final “mosaic” that is the adult animal.

In contrast to mosaic development, the loss of some cells during cleavage in **regulative development** does not affect the

developing embryo, because the remaining cells compensate for the loss. Regulative development is typical of many vertebrate species, including humans.

If some blastomeres can change their fate to compensate for the loss of other cells during cleavage and blastula formation, can those cells form an entire embryo? To a certain extent, yes. During cleavage or early blastocyst formation in mammals, for example, if the blastomeres are physically separated into two groups, both groups can produce complete embryos. Since the two embryos come from the same zygote, they will be genetically identical—*monozygotic twins*. If the inner cell mass splits only partially, the result may be *conjoined twins*—monozygotic twins who are physically attached and usually share some organs and/or limbs. *Dizygotic twins* occur when two separate eggs are fertilized by two separate sperm. Sometimes referred

FIGURE 33.5 Fate Map of a Frog Blastula Colors indicate the portions of the blastula that will form the three germ layers and subsequently the frog's tissues and organs.

to as “fraternal twins,” dizygotic twins are genetically nonidentical full siblings.

Do You Understand Concept 33.2?

- How does early cell division differ in a mammal and a frog?
- Characterize complete, incomplete, and discoidal cleavage and explain where mammals fit into this scheme.
- An important function of early cell divisions is to differentially distribute cytoplasmic determinants that will initiate the processes of differentiation of cell types and localize them to the correct region of the body. In superficial cleavage, such early partitioning of cytoplasmic determinants does not occur. How do you think positional information is organized in early insect development? (Consider the fact that the anterior–posterior and dorsal–ventral axes reflect the position that the egg had in the ovary.)

Of the next stage of development—gastrulation—the developmental biologist Louis Wolpert once said, “It is not birth, marriage, or death, but gastrulation which is the most important time in your life.” During gastrulation, cell movements create the three-layered body plan and set the stage for development of the first organs.

concept 33.3 Gastrulation Creates Three Tissue Layers

Gastrulation is the process whereby the blastula is transformed by massive movements of cells into an embryo with multiple tissue layers and distinct body axes. The resulting spatial relationships between tissues make possible the interactions between cells that trigger differentiation and organ formation.

During gastrulation, three **germ layers** (also called *cell layers* or *tissue layers*) form (see Figure 33.5):

- The innermost germ layer, the **endoderm**, forms from blastomeres that migrate to the inside of the embryo. The endoderm produces the linings of internal spaces such as those of the digestive and respiratory tracts and the urinary bladder. It also contributes to the structure of some internal organs, including the endocrine glands, pancreas, and liver.
- The **ectoderm** is the outer germ layer, formed from those cells remaining on the outside of the embryo. The ectoderm gives rise to the nervous system, including the eyes and ears, and produces the epidermal layer of the skin (and structures derived from skin, such as hair, feathers, and teeth).
- The middle layer, the **mesoderm**, is made up of cells that migrate between the endoderm and the ectoderm. The mesoderm gives rise to the heart, blood vessels, muscles, bones, and several other organs.

What directs the cell movements of gastrulation, and what is responsible for the resulting patterns of cell differentiation and organ formation? We will begin with sea urchin gastrulation because it is the simplest to conceptualize in spatial terms. We will then describe the more complex pattern of gastrulation in frogs, which in turn will help elucidate the still more complex patterns in reptiles, birds, and mammals.

LINK Early development and the germ layers reflect phylogenetic relationships among the animals; see Concept 23.1

Invagination of the vegetal pole characterizes gastrulation in the sea urchin

The sea urchin blastula is a hollow ball of cells only one cell thick. The beginning of gastrulation is marked by a flattening of the vegetal hemisphere as the individual blastomeres change shape (FIGURE 33.6). These cells, which are originally rather cuboidal, become wedge-shaped, with smaller outer edges and larger inner edges. As a result, the vegetal pole bulges inward, or

FIGURE 33.6 Gastrulation in Sea Urchins During gastrulation, cells move to new positions and form the three germ layers from which differentiated tissues develop.

invaginates, as if someone were poking a finger into a hollow ball (see Figure 33.6). The invaginating cells become endoderm and form a primitive gut called the **archenteron**. Meanwhile, some cells of the vegetal pole break away from neighboring cells and migrate into the central cavity. These cells become **mesenchyme**—cells of the middle germ layer. Mesenchymal cells act as independent units, migrating into and among the other tissue layers.

Changes in cell shapes cause the initial invagination of the archenteron, but eventually it is pulled by additional mesenchyme cells that form at the tip of the archenteron and send out extensions called *filopodia* that adhere to the overlying ectoderm. When the filopodia contract, they pull the archenteron toward the ectoderm at the opposite end of the embryo from where the invagination began. The mouth of the animal forms where the archenteron makes contact with this overlying ectoderm. The opening created by the invagination of the vegetal pole is called the **blastopore**; it will become the anus of this deuterostome animal (see p. 459).

Only cells from the vegetal pole are capable of bulging inward to initiate gastrulation, probably because of uneven distribution of regulatory proteins in the egg cytoplasm. As cleavage progresses, the regulatory proteins are localized in different groups of cells. Thereafter, specific sets of genes are activated in different cells, determining their different developmental capacities.

We turn now to gastrulation in the frog, in which several key signaling molecules have been identified.

Gastrulation in the frog begins at the gray crescent

Amphibian blastulas have considerable yolk and, unlike sea urchin blastulas, are more than one cell thick. Although the

Gastrulation

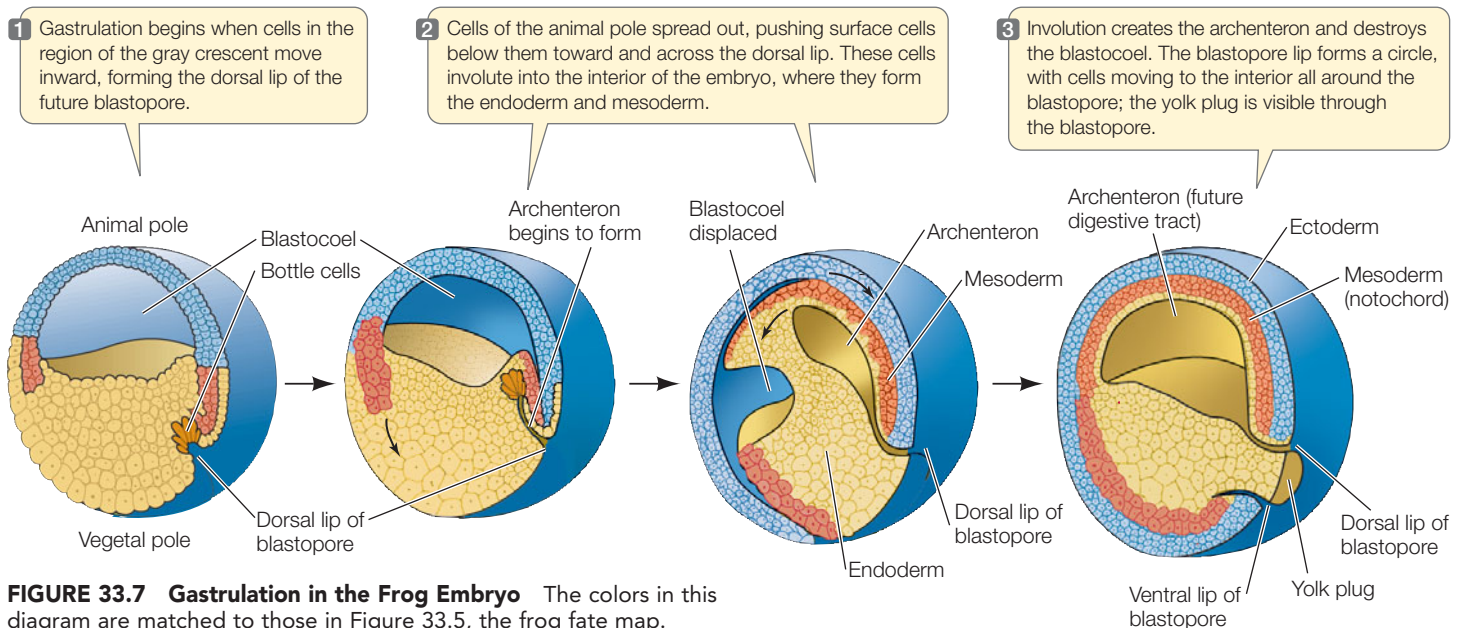

FIGURE 33.7 Gastrulation in the Frog Embryo The colors in this diagram are matched to those in Figure 33.5, the frog fate map.

details vary among species, in general amphibian gastrulation begins when certain cells in the gray crescent region change their shapes and cell adhesion properties. These cells bulge inward toward the blastocoel while remaining attached to the outer surface of the blastula by slender necks. Because of their shape, these are called *bottle cells*.

Bottle cells mark the spot where the **dorsal lip** of the blastopore will form (**FIGURE 33.7**). As the bottle cells move inward, the dorsal lip is created, and a sheet of cells moves over it into the blastocoel. This process is called **involution**. One group of involuting cells is the prospective endoderm; these cells form the primitive gut, or archenteron. Another group will move between the endoderm and the outermost cells to form the mesoderm.

As gastrulation proceeds, cells from the animal hemisphere flatten and move toward the site of involution, a process known as **epiboly**. The blastopore lip widens and eventually forms a complete circle surrounding a “plug” of yolk-rich cells. As cells continue to move inward through the blastopore, the archenteron grows, gradually displacing the blastocoel.

As gastrulation comes to an end, the amphibian embryo consists of three germ layers: ectoderm on the outside, endoderm on the inside, and mesoderm in between. The embryo also has a dorsal–ventral and anterior–posterior organization. Most importantly, the fates of specific regions of the endoderm, mesoderm, and ectoderm have been determined. The experiments that revealed how determination takes place in the amphibian embryo are an old but exciting story.

The dorsal lip of the blastopore organizes amphibian embryo formation

In the early 1900s, the German biologist Hans Spemann was studying the development of salamander eggs. With great patience and dexterity, he formed loops from single hairs taken

FIGURE 33.8 Gastrulation and the Gray Crescent Spemann's research revealed that gastrulation and subsequent normal development in salamanders depend on cytoplasmic determinants localized in the gray crescent.

(FIGURE 33.8). Spemann hypothesized that cytoplasmic factors unequally distributed in the fertilized egg were necessary for gastrulation and the development of a normal salamander.

To test the hypothesis that cells receiving different complements of cytoplasmic factors had different developmental fates, Spemann transplanted pieces of gastrulas to various locations on other gastrulas. When he performed these experiments in early gastrulas, the transplanted pieces always developed into tissues that were appropriate for their new locations. In late gastrulas, however, the transplanted cells became tissues appropriate to their original location. For example, if late-gastrula cells were transplanted from a region that would become skin to a region that would become nervous system, the transplanted cells produced patches of skin cells within the nervous system. At some point during gastrulation, the fates of the embryonic cells had become determined.

Spemann's next experiment, done with his student Hilde Mangold, was to transplant the dorsal blastopore lip. The results were momentous. When this small piece of tissue was transplanted into the presumptive belly area of another gastrula, it stimulated a second site of gastrulation, and a second complete embryo formed belly-to-belly with the original embryo (FIGURE 33.9). Because the dorsal blastopore lip of amphibians was apparently capable of inducing host tissue to form an entire embryo, Spemann and Mangold dubbed this tissue the *primary embryonic organizer* or, simply, the **organizer**.

from his baby daughter and tied them around fertilized eggs, effectively dividing the eggs in half. When his loops bisected the gray crescent, both halves of the zygote developed into a complete embryo. When he tied the loops so the gray crescent was on only one side of the constriction, the half lacking gray crescent material underwent cell division but became a clump of undifferentiated cells that Spemann called a "belly piece"

APPLY THE CONCEPT

Gastrulation creates three tissue layers

What about the amphibian dorsal blastopore lip makes it so crucial to "organizing" the three germ layers? The distribution of β -catenin in the late blastula corresponds to the location of this organizer in the early gastrula. A series of experiments endeavored to ascertain whether β -catenin is indeed "necessary and sufficient" for subsequent functions of the organizer. Review the results of these experiments in the table at right, and answer the questions that follow.

1. Which experiment shows that β -catenin is *necessary* for induction of the organizer? Explain.
2. Which experiment shows that β -catenin is *sufficient* for induction of the organizer? Explain.
3. What was the purpose of experiment B? Of experiment D?
4. The series of experiments above demonstrates what is sometimes called the "find it, lose it, move it" approach to understanding a gene's function. Explain why this catchy phrase is appropriate.

EXPERIMENT	RESULT
A. "Knock out" β -catenin by injecting β -catenin antisense mRNA into frog egg (see Figure 13.9).	Dorsal lip of blastopore does not form.
B. Repeat experiment A, but follow injection of antisense mRNA with an injection of exogenous (i.e., from an external source) β -catenin protein into the egg.	Gastrulation is normal.
C. Inject exogenous β -catenin into ventral region of an early gastrula (where β -catenin does not normally occur).	A second site of gastrulation is stimulated, producing results similar to those of Spemann and Mangold (see Figure 33.9).
D. Repeat experiment C, but follow exogenous β -catenin with β -catenin antisense mRNA.	Gastrulation is normal.

Go to ANIMATED TUTORIAL 33.2
Tissue Transplants Reveal the Process of Determination

For more than 80 years, the organizer has been an active area of research. Molecular biologists are making great strides at elucidating the molecular mechanisms of the organizer, and

the transcription factor β -catenin (see Concept 33.1) has been suspected of being a key inductive signal.

The distribution of β -catenin in the late blastula (see Figure 33.2) corresponds to the location of the organizer in the early gastrula, but this observation is only a correlation. To prove that a protein is an inductive signal, it has to be shown that its presence is both *necessary* and *sufficient* for the proposed inductive effect. In other words, the induction should not occur if the

candidate protein is not present (necessity), and the candidate protein should be capable of inducing the induction where it would otherwise not occur (sufficiency). Thanks to a series of experiments in the 1980s and 1990s (see Apply the Concept, previous page), we now know that β -catenin triggers a complex series of interactions between various transcription factors and growth factors that control gene expression and determine which cells become the primary organizer. Several of these transcription factors have been identified.

Transcription factors underlie the organizer's actions

The first organizer cells to enter the embryo migrate anteriorly and *induce* formation of the structures of the head—that is, they cause neighboring cells to form head structures. Organizer cells that migrate into the embryo later will induce structures of the trunk, and the last of the organizer cells to migrate inward will induce structures of the tail. How do these organizer cells induce these different structures?

As organizer cells move forward in the blastocoel, they come into contact with new populations of cells that produce a number of different growth factors. For head structures to form, certain of these growth factors have to be suppressed. The anteriormost organizer cells release *antagonists* to those growth factors, suppressing them and allowing head structures to form (FIGURE 33.10).

The induction of trunk structures requires suppression of a different set of growth factors. In organizer cells that involute later than the head organizers, different growth factor antagonists are expressed. The induction of tail structures requires still different activities of the organizer cells that involute last. Thus, the organizer cells express appropriate sets of growth factor antagonists at the right times to achieve different patterns of differentiation on the anterior–posterior axis.

Reptilian and avian gastrulation is an adaptation to yolk eggs

The eggs of reptiles and birds contain a mass of yolk, and the blastulas of these groups develop as a disc of cells on top of the yolk (see Figure 33.3B).

INVESTIGATION

FIGURE 33.9 The Dorsal Lip Induces Embryonic Organization In a classic experiment, Hans Spemann and Hilde Mangold transplanted the dorsal blastopore lip mesoderm of an early gastrula stage salamander embryo. The results showed that the cells of this embryonic region, which they dubbed “the organizer,” could direct the formation of an entire embryo.

HYPOTHESIS

Cytoplasmic factors in the early dorsal blastopore lip organize cell differentiation in amphibian embryos.

METHOD

1. Excise a patch of mesoderm tissue from above the dorsal blastopore lip of an early gastrula stage salamander embryo (the donor).
2. Transplant the donor tissue onto a recipient embryo at the same stage. The donor tissue is transplanted onto a region of ectoderm that should become epidermis (skin).

RESULTS

1 The donor tissue induces a secondary involution...

3 Eventually a complete secondary embryo forms, attached to the original embryo at the belly.

CONCLUSION

The cells of the dorsal blastopore lip can induce other cells to change their developmental fates.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

INVESTIGATION

FIGURE 33.10 Differentiation Can Be Due to Inhibition of Transcription Factors When organizer cells involute to underlie dorsal ectoderm along the embryo midline, that overlying ectoderm becomes neural tissue rather than skin (epidermis). But do the organizer cells cause dorsal ectoderm to become neural tissue, or do they *prevent* this ectoderm from becoming skin?

HYPOTHESIS

The default state of amphibian dorsal ectoderm is neural; it is induced by underlying mesoderm to become epidermis.

METHOD

- Excise animal caps (presumptive ectoderm) from amphibian blastulas. Culture presumptive mesodermal cells from early gastrulas and extract BMP4. BMP4 is a growth factor released from the notochord that induces overlying ectoderm to become skin.

- Prepare four separate cultures of embryonic ectodermal cells. Incubate with no additions (control); with BMP4 from step 1; with a BMP4 inhibitor; and with both molecules.

- After incubation, extract mRNAs from the cultured ectodermal cells and run on gels to reveal expression of NCAM (a neural tissue marker) and keratin (an epidermal tissue marker).

RESULTS

Gels reveal that different treatments with BMP4 and its inhibitor alter patterns of gene expression in cultured ectodermal cells.

CONCLUSION

The organizer cells secrete an inhibitor of BMP4.

ANALYZE THE DATA

Use the gel results shown above to answer the questions.

- Does BMP4 induce expression of neural specific or epidermal specific genes?
- Does BMP4 block any gene expression in the ectodermal cells?
- What is the evidence that BMP4 has an inductive and/or an inhibitory effect on gene expression in ectodermal cells?
- Do these results support the hypothesis?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

We will use the chicken egg to show how gastrulation proceeds in such eggs.

Cleavage in the chick results in a flat, circular layer of cells called a blastodisc (**FIGURE 33.11**). Between the blastodisc and the yolk mass there is a fluid-filled space. Some cells from the blastodisc break free and move into this space. These cells come together to form a continuous layer called the **hypoblast**, which will later contribute to *extraembryonic membranes* that will support and nourish the developing embryo. The overlying cells make up the **epiblast**, from which the embryo proper will form. Thus, the avian blastula is a flattened structure consisting of an upper epiblast and a lower hypoblast that are joined at the margins of the blastodisc.

Gastrulation begins with a thickening in the posterior region of the epiblast, caused by the movement of cells toward the midline and then forward along the midline (see Figure 33.11). The result is a midline ridge called the *primitive streak*. A depression called the *primitive groove* forms along the length of the primitive streak. The primitive groove functions as the blastopore, and cells migrate through it into the blastocoel to become endoderm and mesoderm.

In the chick embryo, no archenteron forms, but the endoderm and mesoderm migrate forward to form the gut and other structures. At the anterior end of the primitive groove is a thickening called **Hensen's node**, which in birds, reptiles, and mammals is the equivalent of the dorsal lip of the amphibian blastopore. Many signaling molecules that have been identified in the frog organizer are also expressed in Hensen's node.

FRONTIERS Early development explains why we are bilaterally symmetrical—two ears, arms, lungs, and so on. Despite this symmetry, the human heart and stomach are usually positioned toward the left side of the body, the liver and appendix to the right. Where does left–right positional information come from? At the anterior end of the primitive groove, cells with motile cilia move extracellular fluid through the groove. Other cells have nonmotile stereocilia. Movement of fluid exposes the nonmotile stereocilia to signaling molecules and bending forces that induce signaling cascades that affect organ development. Because the flow of extracellular fluid has a left–right directionality, the cascade introduces a left–right pattern into the process of organogenesis. There are individuals whose organ symmetry is reversed, and they may be unaware of it unless the reversal is revealed by imaging or surgery.

Placental mammals retain the avian/reptilian gastrulation pattern but lack yolk

Mammals, reptiles, and birds are amniotes—they produce eggs that develop extraembryonic membranes—so it is not surprising that they share certain patterns

FIGURE 33.11 Gastrulation in Birds Because their eggs contain a large yolk mass, bird and reptile embryos have a flattened blastodisc and display a pattern of gastrulation very different from that of amphibians.

of early development. In Concept 33.2 we described the development of the mammalian inner cell mass and the outer trophoblast. As in avian development, the inner cell mass of placental mammals splits into an upper layer called the epiblast and a lower layer called the hypoblast. The embryo forms from the epiblast, while the hypoblast contributes to the extraembryonic membranes that will encase the developing embryo and help form the *placenta* (see Figure 33.4). Gastrulation occurs in the mammalian epiblast just as it does in the avian epiblast. A primitive groove forms, and epiblast cells migrate through the groove to become layers of endoderm and mesoderm.

Do You Understand Concept 33.3?

- What are the major similarities and differences between sea urchin gastrulation and frog gastrulation?
- Explain how Spemann's tissue transplant experiments on gastrulas disproved his initial hypothesis and generated a new hypothesis.
- Explain why Hensen's node in the chick is the equivalent of the dorsal lip of the amphibian blastopore.

Gastrulation produces an embryo with three germ layers that are positioned to influence one another through inductive tissue interactions. During the next phase of development, called **organogenesis**, the major organs and organ systems develop.

concept 33.4 Neurulation Creates the Nervous System

The first major event of vertebrate organogenesis, and the only one we will describe in detail here, is **neurulation**—the formation of the nervous system. We will detail neurulation in the amphibian embryo, but it occurs in a similar fashion in reptiles, birds, and mammals.

The notochord induces formation of the neural tube

As we learned in Concept 33.3, one group of cells that passes over the dorsal lip of the blastopore moves anteriorly and becomes the endodermal lining of the digestive tract. The other group of cells that involutes over the dorsal lip becomes *chordamesoderm*, so named because it forms a rod of mesoderm—the **notochord**—that extends down the center of the embryo. The notochord gives structural support to the developing embryo and also plays a critical role in inducing neurulation.

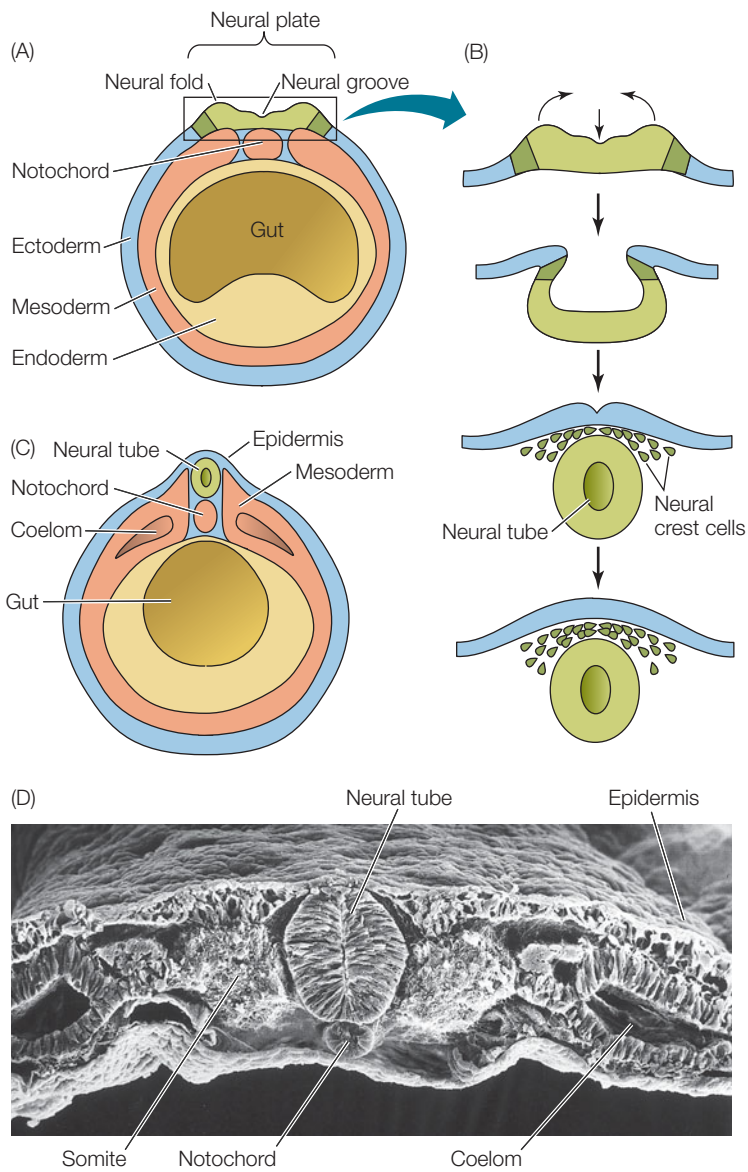

FIGURE 33.12 Neurulation in a Vertebrate (A) At the start of neurulation, the ectoderm of the neural plate (green) is flat. (B) The neural plate invaginates and folds, forming a tube. (C,D) The completely formed neural tube seen in (C) diagrammatic form and (D) in a scanning electron micrograph of a chick embryo.

Neurulation involves the formation of an internal neural tube from an external sheet of cells. The first signs of neurulation are flattening and thickening of the ectoderm overlying the notochord; this thickened area forms the *neural plate* (FIGURE 33.12A). The edges of the neural plate continue to thicken to form folds. Between these neural folds, a groove forms and deepens. The folds move toward each other to fuse in the midline, forming a hollow cylinder, the **neural tube**, and a continuous overlying layer of epidermal ectoderm (FIGURE 33.12B–D). Signaling molecules from the notochord are involved in the differentiation of the neural tube into the various structures of the nervous system. Two of these signaling molecules are appropriately named *Noggin* and *Chordin*. Another important

factor controlling differentiation of the neural tube is *Sonic hedgehog* (*Shh*), the transcription factor mentioned at the start of this chapter. *Shh* is released by the notochord and diffuses into the ventral region of the neural tube, where it directs the development of this region into the ventral structures and circuits of the spinal cord. These spinal cord circuits will carry the major output from the motor pathways of the nervous system.

Cells from the most lateral portions of the neural plate do not become part of the neural tube, but disassociate from it and come to lie between the neural tube and the overlying epidermis. These **neural crest cells** migrate outward to lead the development of the connections between the central nervous system (brain and spinal cord) and the rest of the body.

The central nervous system develops from the embryonic neural tube

At its anterior end, the vertebrate neural tube forms three swellings that become the major divisions of the adult brain: the **hindbrain**, **midbrain**, and **forebrain**. The rest of the neural tube becomes the spinal cord. This general pattern holds for all vertebrates, although the complexity of certain structures, notably the cerebral hemispheres, is greatest among the mammals. Here we detail the development of the human brain.

Although the developing brain folds and becomes an astonishingly complex structure, information flow in the mature nervous system (which will be the subject of Chapters 34 and 35) follows paths that can be traced back to the simple, linear neural tube of the early embryo (FIGURE 33.13A,B). The hindbrain and midbrain give rise to structures that collectively are called the **brain stem** and that govern critical physiological functions such as heartbeat and breathing; the hindbrain also produces the **cerebellum**, a structure that governs motor control and some cognitive functions. The forebrain develops into the **cerebral hemispheres**—the major information-processing areas of the brain—plus the underlying *thalamus*, *hypothalamus*, and *pituitary* (FIGURE 33.13C). The thalamus is the major relay station for sensory information coming into the cerebral hemispheres, and the hypothalamus receives information relevant to the regulation of the internal environment such as temperature and hormone levels, as described in Chapters 29 and 30.

Information traveling between the forebrain and other regions of the body passes through the brain stem. Structures in the brain stem make use of this information to regulate many basic functions such as breathing, circulation, and motor coordination. We will discuss the organization of the nervous system in more detail in Chapter 34, and the functions of specific regions in controlling body functions in the chapters devoted to those physiological systems.

Body segmentation develops during neurulation

The vertebrate body plan, like that of arthropods, consists of repeating segments that are modified during development. These segments are most evident as the repeating patterns of vertebrae, ribs, nerves, and muscles along the anterior–posterior axis.

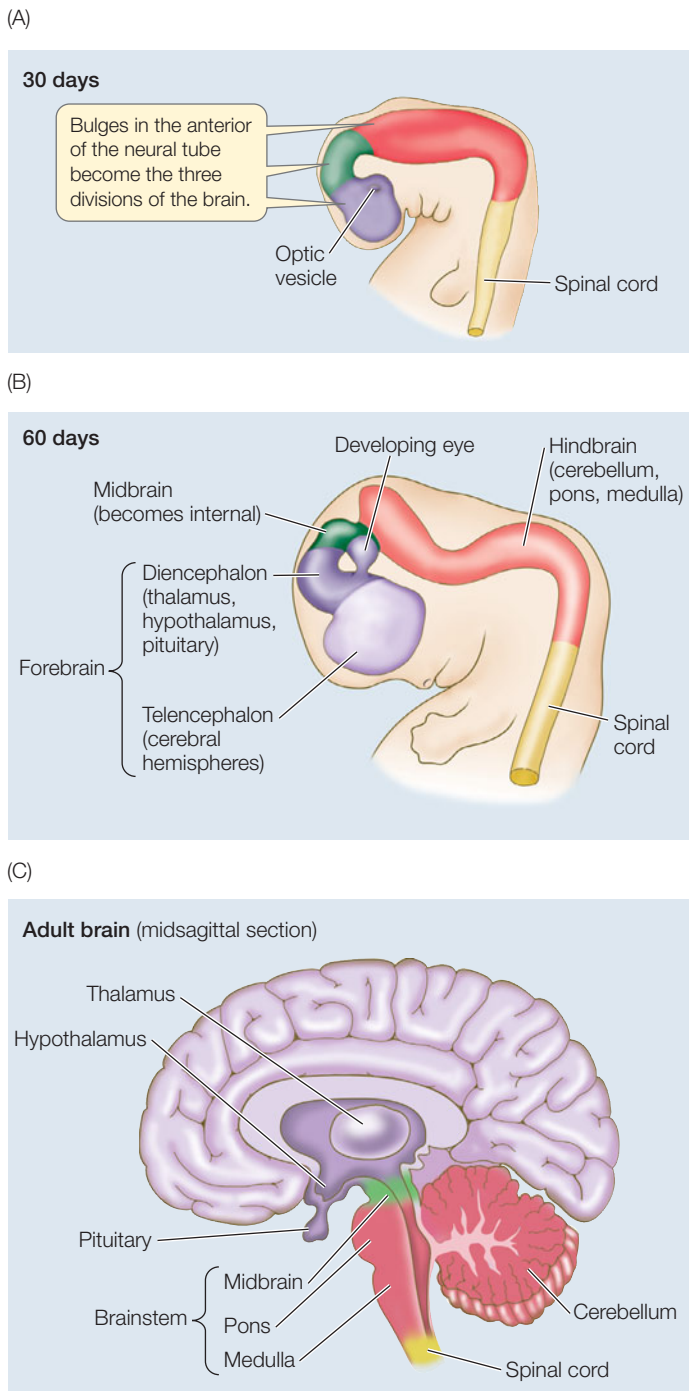

FIGURE 33.13 Development of the Central Nervous System In vertebrate embryos, the anterior end of the hollow neural tube differentiates into forebrain, midbrain, and hindbrain. Each of these regions develops into several structures in the adult brain. The remainder of the neural tube becomes the spinal cord.

As the neural tube forms, mesodermal tissues gather along the sides of the notochord to form separate, segmented blocks of cells called **somites** (FIGURE 33.14). The somites produce cells that will become the vertebrae, ribs, muscles of the trunk and limbs, and lower layer of the skin. Again, tissue interactions and signaling molecules direct these various processes

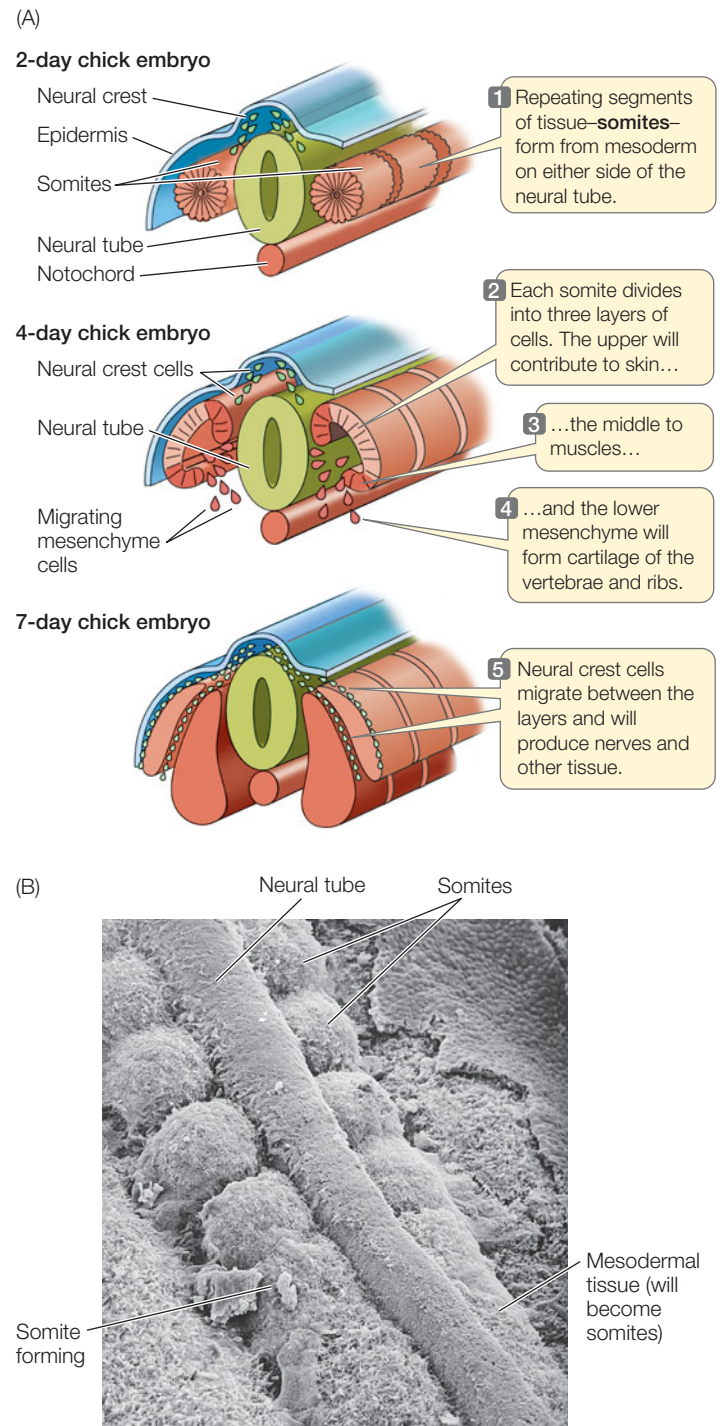

FIGURE 33.14 Body Segmentation (A) Repeating blocks of tissue called somites form on either side of the neural tube. Muscle, cartilage, bone, and the lower layer of the skin form from the somites. (B) In this scanning electron micrograph of somite formation in a chick embryo, the overlying ectoderm has been removed and the neural tube and somites are seen from above.

of differentiation. For example, the transcription factor Sonic hedgehog, mentioned above as being released from the notochord and diffusing to the neural tube, also diffuses laterally to reach the ventral region of the somites. Shh directs cells in

that region into the developmental pathways that form skeletal structures.

As development progresses, the different segments of the body change. Regions of the vertebral column differ in that some vertebrae grow ribs of various sizes and others do not, forelegs arise in the anterior part of the embryo, and hind legs arise in the posterior region. Gene expression patterns (including those of *Hox genes*) give cells information about their position on the anterior–posterior body axis, causing appropriate structures to develop.

LINK Gene expression patterns and morphogenic gradients that lead to segmentation during development are described in Concept 14.3

After the body segments have been specified, the formation of other organs and organ systems progresses rapidly, directed by further inductive tissue interactions involving a host of transcription factors and other molecules.

Do You Understand Concept 33.4?

- What is the role of the notochord in neurulation?
- How does the process of neurulation explain why the spinal cord has a central cavity, or lumen?
- The epidermis of the skin forms from ectoderm. Under the epidermis are muscle tissues derived from mesoderm. Within and under the muscle tissues are nerves derived from ectoderm. Explain how ectodermally derived tissues come to lie under mesodermally derived tissues.

In mammals, the circulatory systems of the fetus and mother are separate, yet the fetus derives nutrition and metabolic support from the maternal circulation. The next concept examines the placenta—the structure that makes these exchanges between the maternal and fetal blood possible.

concept 33.5 Extraembryonic Membranes Nourish the Growing Embryo

Reptiles, birds, and mammals are all *amniotes*, meaning they produce amniote eggs—or in the case of placental mammals, structures that are homologous with those found in the amniote egg. We saw in Concept 23.6 the evolutionary significance

FIGURE 33.15 The Extraembryonic Membranes of Amniotes In birds, reptiles, and mammals, the embryo constructs four extraembryonic membranes. The yolk sac encloses the yolk, and the amnion and chorion enclose the embryo. Fluids secreted by the amnion fill the amniotic cavity, providing an aqueous environment for the embryo. The chorion, along with the allantoic membrane, mediates gas exchange between the embryo and its environment. The allantois stores the embryo's waste products.

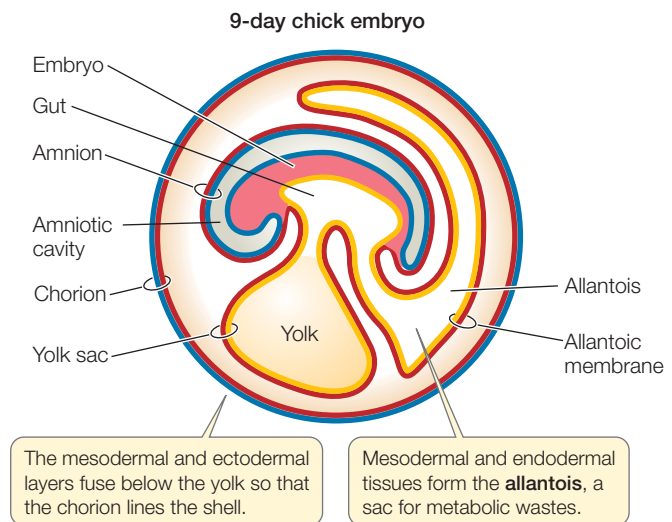

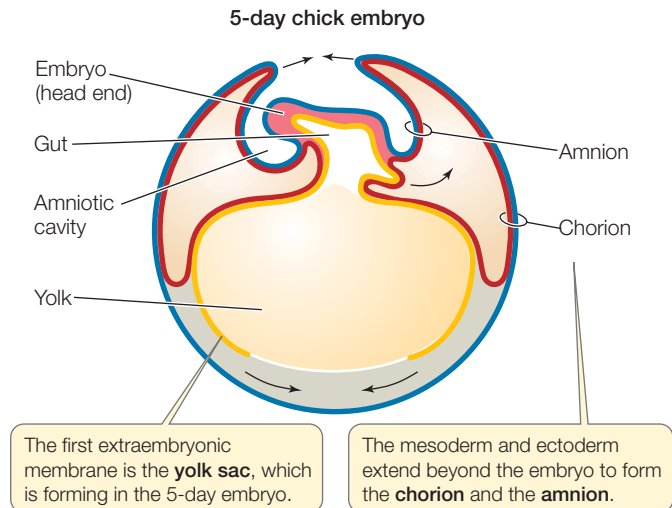

of the amniote egg: the contained aqueous environment it provides for the embryo, freeing the processes of reproduction and development from dependence on an external water supply.

Embryos in amniote eggs are surrounded by four **extraembryonic membranes** that function in nutrition, gas exchange, and waste removal. The chicken embryo provides a good example of how these membranes form.

Extraembryonic membranes form with contributions from all germ layers

In the chick, four membranes form—the *yolk sac*, the *allantoic membrane*, the *amnion*, and the *chorion* (FIGURE 33.15). The **yolk sac** is the first to form, by extension of the hypoblast layer along with some adjacent mesoderm. The yolk sac grows to enclose the yolk in the egg and provides nutrients to the embryo. It constricts at the top to create a tube that is continuous with the gut of the embryo. The **allantoic membrane** is also an outgrowth

yourBioPortal.com Go to WEB ACTIVITY 33.1 Extraembryonic Membranes

FIGURE 33.16 The Mammalian Placenta

In humans and most other mammals, nutrients and wastes are exchanged between maternal and fetal blood in the placenta, which forms from the chorion and tissues of the uterine wall. The embryo is attached to the placenta by the umbilical cord. Embryonic blood vessels invade the placental tissue to form fingerlike *chorionic villi*. Maternal blood flows into the spaces surrounding the villi, and placental blood flows through the villi so nutrients and respiratory gases can be exchanged between the maternal and fetal blood.

of the extraembryonic endoderm plus adjacent mesoderm. It forms the allantois, a sac for storage of metabolic wastes.

The other two membranes are formed by ectoderm and mesoderm that extend all along the inside of the eggshell, both over the embryo and below the yolk sac. Where they meet, they fuse, forming two membranes, the inner amnion and the outer chorion. The **amnion** surrounds the embryo, forming the amniotic cavity. The amnion secretes fluid into the cavity, providing a protective environment for the embryo. The **chorion**, located just beneath the egg's shell, forms a continuous membrane that limits water loss from the egg and works with the allantoic membrane to exchange respiratory gases between the embryo and the outside world.

Extraembryonic membranes in mammals form the placenta

In placental mammals, the trophoblast adheres to the uterine wall, secretes proteolytic enzymes, and burrows into the endometrium, beginning the process of implantation (see Figure 33.4). Eventually, the entire trophoblast (and the enclosed embryo) is embedded within the wall of the uterus. Meanwhile, the hypoblast cells proliferate to form what in the bird would be the yolk sac. But there is no yolk in eggs of placental mammals, so the yolk sac contributes mesodermal tissues that interact with trophoblast tissues to form the chorion. The chorion, along with maternal tissues of the uterine wall, produces the placenta (**FIGURE 33.16**). Meanwhile, the epiblast produces the amnion, which grows to enclose the entire embryo in a fluid-filled amniotic cavity. (A pregnant woman's "water breaks" when the amnion bursts at the onset of or during labor and releases the amniotic fluid.)

An allantois also develops in mammals, but its importance depends on how well nitrogenous wastes can be transferred

across the placenta. In humans the allantois is minor; in pigs it is important. In humans and other placental mammals, allantoic tissues contribute to the formation of the umbilical cord, by which the embryo is attached to the placenta.

FRONTIERS Oxygen and nutrients are not the only things a fetus obtains from its mother. As we will see in Chapter 39, the human gut is richly populated with bacteria that are necessary for normal digestion. Where do these bacteria come from? A recent study shows that the gut flora of children resemble the species assemblage found in their mothers. In adults, the bacterial assemblages in siblings are more similar to each other than to that of their marriage partner. Thus, early transmission of bacteria from mother to infant is indicated. Further studies show that children who were vaginally delivered have gut bacteria more similar to their mothers' than do children born by Caesarean section, so it appears that one route of transmission is via the vaginal canal during birth.

Human gestation is traditionally divided into three periods of roughly 12 weeks each, called *trimesters*. In the first trimester, gastrulation occurs, tissues differentiate, and the placenta forms. This is a time of rapid cell division and tissue differentiation, and the embryo is very sensitive to damage from radiation, drugs, chemicals, and pathogens that can cause birth defects. By the end of the first trimester, most organs have started to form, and the embryo is about 8 centimeters long. At about this time, the human embryo is medically and legally referred to as a **fetus**. During the second and third trimesters, the fetus grows rapidly. Toward the end of the third trimester the internal organs mature. A human infant is born as soon as the last of its critical organs matures—the lungs.

Do You Understand Concept 33.5?

- Name the four extraembryonic membranes of a chick embryo and describe their functions.
- Would you expect a frog embryo to have the same extraembryonic membranes as a lizard? Why or why not?
- Compare the mammalian placenta with a chicken egg. What are the similarities? What do you think is the evolutionary reason for the similarities?

Development does not end with birth. Growth continues until adult size is reached, and even when growth stops, organs of the body continue to repair and renew themselves. In humans, the brain in particular continues to develop and mature long after birth. The mechanisms of the vertebrate (and particularly the human) nervous system, the end results of which are remarkable levels of sensation and perception as well as extensive motor control, will be detailed in the next three chapters.

How does the Sonic hedgehog pathway control development of the vertebrate brain and eyes?

ANSWER As we learned in Concept 33.4, Sonic hedgehog (Shh) is a transcription factor secreted by the notochord that diffuses to the overlying neural tube, where it induces differentiation of the ventral neural tube into motor neurons and other features of the ventral regions of the spinal cord. Shh also plays different inductive roles at other locations. At the anterior end of the neural tube where the forebrain will develop, the closed neural tube undergoes reciprocal inductive tissue interactions with the overlying ectoderm. Signaling molecules from the neural tissue induce the ectoderm to form the lens of the eye, and the developing lens produces signaling molecules that induce the underlying neural tissue to form an optic cup that will differentiate into the retina. But why do these events happen bilaterally?

Mesoderm that is anterior to the notochord produces and releases Shh, as does the notochord. Shh induces the ventral

FIGURE 33.17 Environmentally Induced Holoprosencephaly

A stillborn lamb born of a ewe that grazed on corn lily leaves. Alkaloids in the plant interfered with the Sonic hedgehog signaling pathway in the embryo, resulting in fusion of the cerebral hemispheres and the formation of a single eye.

region of the anterior neural tube to differentiate into the structures of the forebrain. One of the actions of Shh is to inhibit a transcription factor called Pax6 that is expressed by the neural tissue. Pax6 is essential for determination of the eye field (i.e., tissues that are competent to undergo the inductive interactions with the neural tissue to form eyes). The midline expression of Shh splits the eye field into two and also enables the forebrain to develop into left and right hemispheres.

When environmental factors affect the action of Shh, holoprosencephaly can result. When pregnant cows or ewes graze on *Veratrum californicum* at certain critical points in gestation, the embryo is exposed to cyclopamine and the Shh signaling pathway is blocked. Depending on when the exposure occurs, bilateral development of the forebrain may not take place, resulting in holoprosencephaly and cyclopia (**FIGURE 33.17**). Another environmental factor of great interest for humans is the fact that Shh requires cholesterol to be an effective signal, and abnormally low levels of cholesterol during pregnancy (such as might occur with the use of certain statin drugs) could cause some of the aspects of holoprosencephaly.

33

SUMMARY

concept 33.1 Fertilization Activates Development

- The sperm and egg make different contributions to the zygote. The egg contributes a haploid nucleus, nutrients, ribosomes, mitochondria, mRNAs, and proteins. The sperm contributes a haploid nucleus and, in most species, a centriole.
- In amphibians, the cytoplasmic contents of the egg are not distributed homogeneously, and they are rearranged after fertilization to set up the major axes of the future embryo. The nutrient molecules are generally found in the **vegetal hemisphere**, whereas the nucleus is found in the **animal hemisphere**. **Review Figures 33.1 and 33.2**

concept 33.2 Cleavage Repackages the Cytoplasm of the Zygote

- **Cleavage** is a period of rapid cell division without cell growth. Except in mammals, little if any gene expression occurs during cleavage. Cleavage can be complete or incomplete. The result of cleavage is a ball or mass of cells called a **blastula**. **Review Figure 33.3**
- Early cell divisions in mammals are unique in being slow and allowing for gene expression. These cell divisions produce a **blastocyst** composed of an **inner cell mass** that becomes the embryo and an outer layer of cells that becomes the **trophoblast**. The trophoblast helps the blastocyst implant in the uterine wall. **Review Figures 33.4 and 33.5**
- Some species undergo **mosaic development**, in which the fate of each cell is determined during early divisions. Other species, including vertebrates, undergo **regulative development**, in which remaining cells can compensate for cells lost in early cleavages.

concept 33.3 Gastrulation Creates Three Tissue Layers

- **Gastrulation** involves massive cell movements that produce three **germ layers** and place cells from various regions of the blastula into new associations with one another. **Review Figure 33.6**
- The initial step of sea urchin and amphibian gastrulation is inward movement of certain blastomeres. The site of inward movement becomes the **blastopore**. Cells that move into the blastula become the **endoderm** and **mesoderm**; cells remaining on the outside become the **ectoderm**. **Review Figures 33.6 and 33.7 and ANIMATED TUTORIAL 33.1**
- The **dorsal lip** of the amphibian blastopore is a critical site for cell determination. It has been called the **organizer** because it induces determination in cells that pass over it during gastrulation. **Review Figures 33.7, 33.8, 33.9 and ANIMATED TUTORIAL 33.2**

- The protein β -catenin activates a signaling cascade that induces the primary embryonic organizer and sets up the anterior–posterior body axis.
- Gastrulation in reptiles and birds differs from that in sea urchins and frogs because the large amount of yolk in reptile and bird eggs causes the blastula to form a flattened disc of cells. **Review Figure 33.11**
- Although their eggs have no yolk, placental mammals have a pattern of gastrulation similar to that of reptiles and birds.
- Gastrulation is followed by **organogenesis**, the process whereby tissues interact to form organs and organ systems.

concept 33.4 Neurulation Creates the Nervous System

- In the formation of the vertebrate nervous system, one group of cells that migrates over the blastopore lip becomes the **notochord**. The notochord organizes the overlying ectoderm to form a **neural tube**. **Review Figure 33.12**
- The anterior region of the neural tube becomes the brain. Different regions differentiate into the **forebrain**, **midbrain**, and **hindbrain**. The posterior region of the neural tube becomes the spinal cord. **Review Figure 33.13**
- The notochord and **neural crest cells** participate in the segmental organization of mesoderm into structures called **somites** along the body axis. Rudimentary organs and organ systems form during these stages. **Review Figure 33.14**

concept 33.5 Extraembryonic Membranes Nourish the Growing Embryo

- Amniote eggs contain four **extraembryonic membranes**. In a bird or reptile, the **yolk sac** surrounds the yolk and provides nutrients to the embryo, the **chorion** lines the eggshell and participates in gas exchange, the **amnion** surrounds the embryo and encloses it in an aqueous environment, and the **allantoic membrane** forms the allantois, a storage sac for metabolic wastes. **Review Figure 33.15 and WEB ACTIVITY 33.1**
- In placental mammals, the chorion interacts with maternal uterine tissues to form a placenta, which provides the embryo with nutrients and gas exchange. The amnion encloses the embryo in an aqueous environment. **Review Figure 33.16**
- Development continues throughout life.

Neurons and Nervous Systems

34

Fear is a strong emotion that you probably would not immediately think of as pleasant. Yet many of us seek opportunities to experience fear. Riding roller coasters, sky diving, driving fast, surfing, skiing, even watching horror movies—all of these activities can produce a thrill of fear that many people find enjoyable.

Physiologically, fear is a protective emotion that comes in two forms, reactive and proactive. A sudden and unexpected threat generates reactive fear that is associated with the fight-or-flight response—its function is to get you out of danger quickly. Proactive fear gets you ready for an anticipated threat by sharpening your senses, putting you on alert, and preparing you to take action. In short, fear stimulates the nervous system, and that can be an experience that is sought after, as well as being something that can save your life.

Fear can also be pathological. Extreme, irrational fears are described as *phobias*; claustrophobia (fear of enclosed spaces), agoraphobia (fear of public or unfamiliar places), and xenophobia (fear of strangers) are a few common examples. Such extreme fears can be incapacitating and can drive people to irrational behaviors.

Both adaptive fear and pathological fear are functions of the nervous system. How can we understand the neural basis for this emotional reaction and develop effective therapies when it is abnormal, such as in posttraumatic stress disorder? Sometimes case histories are instructive.

Charles Whitman was a normal and responsible child. He became one of the youngest Eagle Scouts in the country. He was a fine son and husband and received commendations as a U.S. Marine. While in the service, however, he began having unexplained fits of anger and other personality disorders. He was discharged from

the Marines and entered the University of Texas. Several times he visited campus doctors and complained about having violent and irrational thoughts. Then, in the early morning hours of August 1, 1966, he killed his mother and his wife, leaving notes of love and regret. He then packed weapons and supplies and went to the campus where he barricaded himself inside the top floor of the clock tower. Using high-powered rifles, he killed 14 people and wounded 38 others before being shot and killed by Austin police.

Charles Whitman left a suicide note requesting that proceeds from his insurance be donated to a mental health foundation. He also requested an autopsy, and that autopsy revealed a small brain tumor.

How can a small brain tumor so dramatically affect personality and behavior?

Some humans enjoy stimulating their fear response through risk-taking behavior.

KEY CONCEPTS

- 34.1** Nervous Systems Consist of Neurons and Glia
- 34.2** Neurons Generate and Transmit Electrical Signals
- 34.3** Neurons Communicate with Other Cells at Synapses
- 34.4** The Vertebrate Nervous System Has Many Interacting Components
- 34.5** Specific Brain Areas Underlie the Complex Abilities of Humans

concept 34.1 Nervous Systems Consist of Neurons and Glia

Nervous systems are composed of two types of cells: *nerve cells*, or **neurons**, and *glial cells*, or **glia**. We will describe each of these cell types separately before considering how they are linked together to form nervous systems.

Neurons transmit electrical and chemical signals

Most neurons have four regions—a *cell body*, *dendrites*, one or more *axons*, and *axon terminals* (FIGURE 34.1). The *cell body* contains the nucleus and most of the cell's organelles. Extending from the cell body are many shrublike **dendrites** (from the Greek *dendron*, “tree”), which bring information from other neurons or sensory cells to the cell body. The degree of branching of the dendrites differs among different types of neurons. Neurons are *excitable*, meaning they generate and transmit electrical signals. These signals are called *nerve impulses*, or *action potentials*, and we will describe them in detail in Concept 34.2.

In most neurons, one projection—the **axon**—is much longer than the others, and may extend long distances such as from your spinal cord to your toes. Axons are the “telephone lines” of the nervous system. Acting on information received by dendrites, an axon generates action potentials that are conducted down the axon toward a target cell. A **nerve** (as distinct from a neuron) is a bundle of axons that come from many different neurons.

At the target cell, the axon divides into a spray of fine nerve endings, each with a swelling called an **axon terminal** that comes very close to the membrane of the target cell to form a **synapse**. A **synapse** is a tiny gap across which two neurons communicate, either with electrical signals or with chemical signaling molecules called *neurotransmitters*. The neuron sending the information is the **presynaptic neuron**, and the neuron receiving the information is the **postsynaptic neuron** (see Concept 34.3).

FRONTIERS Most neurons do not undergo mitosis and the cycle of cell death and replacement typical of other cells. Until recently, it was believed that an animal is born with all the neurons it will ever have, and that neurons that die are not replaced. That was until scientists discovered that songbirds produce a complement of new neurons each year when the birds come into reproductive condition and begin to sing. Subsequent research on mammals has shown that, in at least two regions of the brain, new neurons are produced regularly. This generation of neurons is believed to be stimulated by new experiences and by exercise. The study of mammalian neurogenesis is an exciting and expanding area of research.

Glia support, nourish, and insulate neurons

There are many more glia than neurons in the human brain. Glia do not generate or conduct action potentials, but they can release neurotransmitter molecules. During embryonic development, some glia physically support developing neurons and orient

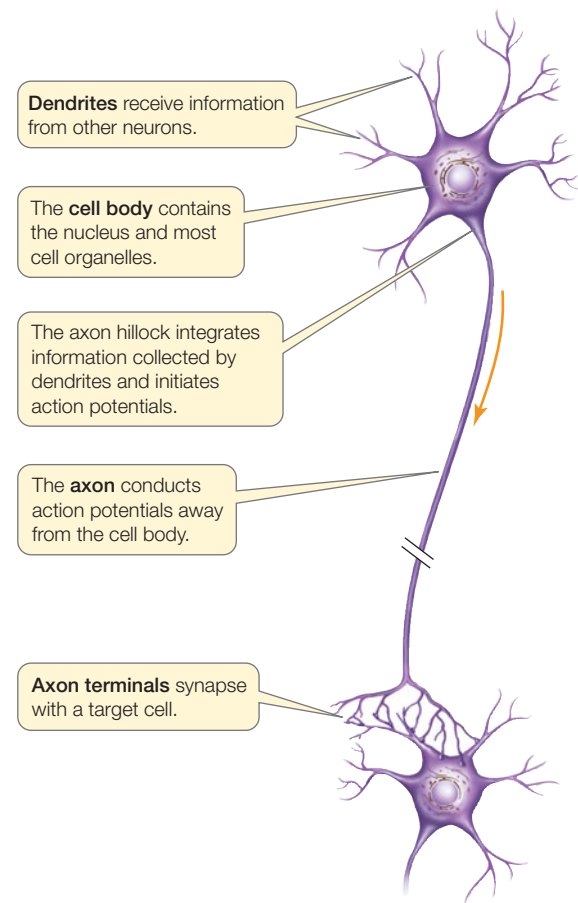

FIGURE 34.1 A Generalized Neuron The diagram shows the features typical of most neurons. The form of these features, including axon length and the density and branching patterns of dendrites, can vary greatly among the many different types of neurons.

them toward their targets. In the postembryonic brain, glia provide homeostatic support for neurons by maintaining the local extracellular environment and provide energy substrates when needed. They help clear the synapse of neurotransmitters and modulate neurotransmission by releasing their own chemicals. Glia play important roles in synapse modification, a phenomenon known as *neuroplasticity*. They also assist in neuronal repair and remove debris such as dead neurons.

Glia called **astrocytes** surround the smallest, most permeable blood vessels in the brain, contributing to a **blood–brain barrier** that prevents toxic chemicals (and most water-soluble or large molecules) from reaching the brain. The barrier is not perfect, however. The blood–brain barrier consists of plasma membranes and is permeable to fat-soluble substances such as anesthetics and alcohol; thus, these substances have rapid and marked effects on the nervous system. The blood–brain barrier usually prevents antibodies from entering the brain. To provide the brain with immune defenses, glia called **microglia** act as macrophages and mediators of inflammatory responses.

One crucial function of glia is to electrically insulate axons by wrapping around them, covering them with concentric layers of insulating plasma membrane. In the brain and spinal cord, the membranes of glia called **oligodendrocytes** wrap around axons; in nerves outside the brain and spinal cord, a

FIGURE 34.2 Wrapping Up an Axon (A) Schwann cells produce layers of myelin, a type of plasma membrane that provides electrical insulation to the axon. At the intervals between Schwann cells—the nodes of Ranvier—the axon is exposed. Action potentials travel along the axon by “jumping” from node to node. (B) A myelinated axon, seen in cross section through an electron microscope.

different type of glia called **Schwann cells** perform this function (**FIGURE 34.2**). This multilayered wrap of glial membranes on axons forms a lipid-rich, nonconductive sheath called **myelin**. Parts of the nervous system consisting mostly of myelinated axons have a glistening white appearance, giving rise to the term *white matter*. Areas of the nervous system that are rich in cell bodies do not appear white and are called *gray matter*. Not all axons are myelinated, but those that are can conduct action potentials more rapidly than unmyelinated axons.

Diseases that affect myelin impair conduction of action potentials. The most common demyelinating disease is *multiple sclerosis*, an autoimmune disease in which antibodies attack proteins in the myelin. Symptoms can vary dramatically, depending on which part of the nervous system is affected. Unfortunately, there are no known cures for demyelinating diseases.

Neurons are linked into information-processing networks

Neurons are organized into information-processing **neural networks**. These networks include three functional categories of neurons, which can be thought of as being involved with input, output, and integration, respectively:

- **Afferent neurons** carry sensory information into the nervous system. That information comes from specialized **sensory cells** that transduce (convert) sensory stimuli (e.g., light, pressure) into action potentials.
- **Efferent neurons** carry commands to physiological and behavioral *effectors* such as muscles and glands. **Motor neurons** are a type of effector neuron that carry commands to muscle cells.
- **Interneurons** integrate and store information and communicate between afferent and efferent neurons. Most neurons in the human brain are interneurons.

Neural networks can be simple, like the reflex that causes your leg to kick when a physician taps your knee (see **Figure 34.14**); or exceedingly complex, like the network that enables you to read, comprehend, and remember the words and ideas in this chapter. Stationary, simple animals such as cnidarians (e.g., sea anemones) generally process information with *nerve nets*—neural networks that do little more than provide direct lines of communication from sensory cells to effectors (**FIGURE 34.3A**). There is little or no integration or processing of signals.

Animals that actively move about need to process and integrate larger amounts of information. The neurons of earthworms, for example, are organized into clusters called **ganglia** (singular *ganglion*; **FIGURE 34.3B**). In bilaterally symmetrical animals, ganglia frequently come in pairs, with one on each side of the body. In animals with complex behavior, some ganglia

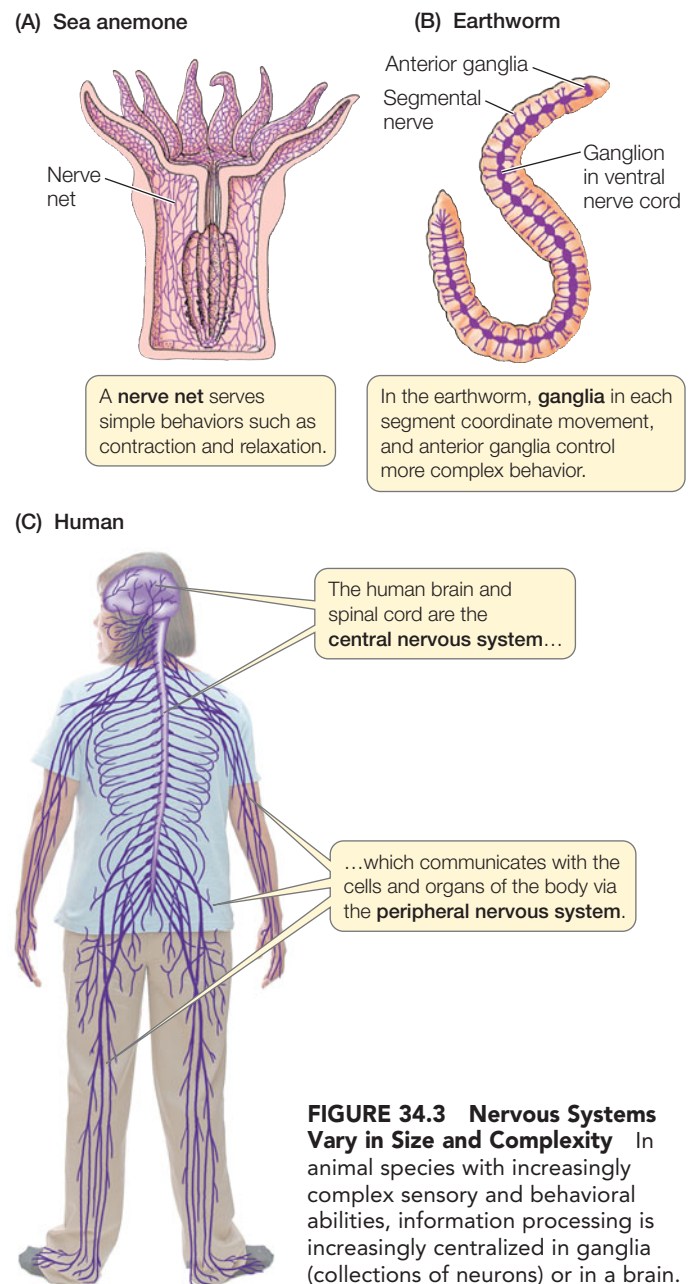

FIGURE 34.3 Nervous Systems Vary in Size and Complexity In animal species with increasingly complex sensory and behavioral abilities, information processing is increasingly centralized in ganglia (collections of neurons) or in a brain.

are enlarged or fused together at the anterior end, forming a larger, centralized integrative center—in other words, a **brain** (FIGURE 34.3C).

Do You Understand Concept 34.1?

- Describe how the different parts of a neuron function in the flow of information through the neuron.
- What are the roles of the different types of glia?
- Propose, in terms of simple neural networks, how input coming from different sources can be integrated to produce a single output in an efferent neuron.

The one feature common to all nervous systems is that they encode and transmit information in the form of action potentials. In the next concept we will focus on how action potentials are generated and transmitted by neurons.

concept 34.2 Neurons Generate and Transmit Electrical Signals

Neurons generate changes in *membrane potential*—the difference in electrical charge across their plasma membranes. These electrical changes generate the nerve impulses, or *action potentials*, that carry information along neurons. **Action potentials** are sudden, large, transient changes in membrane potential

that travel along axons and cause the release of chemical signals at the axon terminals. Here we will cover the generation of action potentials in detail, starting with a review of some basic electrical principles.

Simple electrical concepts underlie neural function

Voltage is a measure of the *difference in electrical charge between two points*. Voltage represents potential energy (see Concept 2.5) because opposite charges will move together if given a chance. For example, when the negative and positive poles of a battery are connected by a wire, an electric current flows through the wire because there is a voltage difference between the two poles. This flow of electric current can be used to do work, just as the force of a water current can be used to do work.

In wires, electric current is carried by electrons; in solutions and across cell membranes, electric current is carried by ions. The major ions that carry electric charges across the membranes of neurons are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-). In cells, these ions are kept at different concentrations inside and outside the cell. The result of these differing concentrations is a voltage across the cell membrane, known as a **membrane potential**.

Membrane potentials exist and can be measured in all cells (FIGURE 34.4). In an inactive neuron, this membrane potential is referred to as the **resting potential**, which is typically between -60 and -70 millivolts (mV). The minus sign indicates that the inside of the cell is electrically *negative* compared with the outside. Action potentials are generated when the membrane

RESEARCH TOOLS

FIGURE 34.4 Measuring the Membrane Potential

one electrode is placed inside the plasma membrane of an axon and another is placed just outside the axon, the difference in voltage can be measured.

potential changes suddenly to become more *positive* inside than outside. How do the movements of ions establish the resting potential and generate action potentials?

The Resting Membrane Potential

The sodium–potassium pump sets up concentration gradients of Na⁺ and K⁺

The plasma membranes of neurons, like those of all other cells, are lipid bilayers that are impermeable to ions but contain ion transporters and channels. A major ion transporter in the plasma membranes of neurons (and all other cells) is the **sodium–potassium pump** (also known as *sodium–potassium ATPase*), which uses the energy of ATP to actively expel Na⁺ ions from inside the cell, exchanging them for K⁺ ions from the outside (FIGURE 34.5A).

LINK The energetics of the sodium–potassium pump are described in Concept 5.3

Because Na⁺ and Cl[−] are the predominant ions in the extracellular fluid, and the sodium–potassium pump is constantly pumping Na⁺ out and K⁺ in, the concentration of Na⁺ is higher outside the cell than inside, and the K⁺ concentration is higher

(A) Na⁺–K⁺ pump (ATPase)

(B) Na⁺–K⁺ channels

inside than outside. In other words, the pump creates *concentration gradients* for both ions. If the ions could suddenly move freely down their concentration gradients, K⁺ would diffuse out of the cell and Na⁺ would diffuse in. As we will see, these concentration gradients can be used to generate the resting potential. Importantly, they can also generate *changes* in the resting potential.

The resting potential is mainly caused by K⁺ leak channels

If you placed two electrodes at different locations in a resting neuron, you would not record a voltage difference between the electrodes. Similarly, if you placed two electrodes outside a resting neuron, you would not record a voltage difference between them. However, if you placed *one electrode outside and one inside the cell*, you would note a voltage difference, with the inside being negative to the outside (see Figure 34.4). Why is this so?

The voltage difference is the result of *leak currents*. Leak currents occur because there are open channels that allow only certain ions to “leak” passively across the cell membrane (FIGURE 34.5B). Potassium channels are the most common open, or *leak*, channels in the membranes of resting neurons. Because there are more potassium ions inside than outside, K⁺ diffuses out of the cell through the open channels, down its concentration gradient. But this leakage of K⁺ leaves behind an unbalanced negative charge that tends to pull K⁺ back into the cell. These two motive forces—concentration gradient and overall electrical gradient—constitute an ion’s **electrochemical gradient**.

Potassium ions diffuse through K⁺ channels until the concentration gradient pushing K⁺ out exactly equals the electrical charge pulling K⁺ back in. At this equilibrium point the electrochemical gradient is zero, and there is no net movement of K⁺. The membrane potential at this point is the **equilibrium potential** of K⁺. Simply put, if potassium is the only ion that is free to move, it will drive the cell’s membrane potential toward the potassium equilibrium potential; thus K⁺ leak channels are largely responsible for the membrane’s resting potential.

The Nernst equation can predict a neuron’s membrane potential

The equilibrium potential for potassium, E_K , can be calculated from the concentrations of K⁺ on the two sides of the membrane using the **Nernst equation**:

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

FIGURE 34.5 Ion Transporters and Channels (A) The sodium–potassium pump actively moves K⁺ to the inside of a neuron and Na⁺ to the outside. (B) Ion channels allow specific ions to diffuse down their concentration gradients; K⁺ tends to leave neurons when potassium channels are open, and Na⁺ tends to enter neurons when sodium channels are open. Leak channels like the K⁺ channel shown are always open and create the resting membrane potential. Gated channels like the Na⁺ channels shown are opened by chemical or electrical stimulation.

In this equation, R is the universal gas constant, T is the absolute temperature, F is the Faraday constant, and z is the charge of the ion. Plugging in the constant values, and assuming that reactions proceed at “room temperature” (20°C), $2.3 RT/F = 58$. Thus the equation simplifies as follows:

$$E_{\text{ion}} = \frac{58 \text{ mV}}{z} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

The practical utility of the Nernst equation is that it can predict a neuron’s membrane potential if one ion is significantly freer to move than other ions. In resting neurons, K^+ is freer to move than other ions, so the actual resting potential is quite close to the potassium equilibrium potential predicted by the Nernst equation. That the resting potential is in fact slightly less negative than E_K is because resting neurons are slightly permeable to other ions besides K^+ (such as Na^+ and Cl^- ; see Apply the Concept below).

yourBioPortal.com

Go to WEB ACTIVITY 34.1
The Nernst Equation

Gated ion channels can alter membrane potential

Potassium leak channels are always open, but other ion channels behave as if they contain “gates”: they are open under some conditions and closed under other conditions. *Gating provides a means for neurons to change their membrane potentials in response to a stimulus.* **Voltage-gated channels** open or close in response to local changes in voltage across the membrane. **Chemically gated channels** open or close in response to binding a specific molecule. **Mechanically gated channels** open or close in response to mechanical force applied to the cell membrane.

Openings and closings of gated channels can alter the membrane potential. For example, imagine what happens if sodium channels in the plasma membrane open, given that Na^+ ions are more abundant outside the cell than inside, and that the

inside of the resting cell is negatively charged. If Na^+ channels open, some Na^+ ions enter and the inside of the cell becomes less negative. When the inside of a neuron becomes less negative (or, alternatively, more positive) in comparison to its resting condition, its plasma membrane is **depolarized** (FIGURE 34.6). An opposite change in polarity occurs if gated K^+ channels open. When K^+ leaving the neuron surpasses the normal leak current, the membrane potential becomes even more negative than its resting state, and the membrane is **hyperpolarized**.

The openings and closings of ion channels that result in changes in the voltage across the plasma membrane are the basic mechanisms by which neurons respond to stimuli, be they electrical, chemical, or mechanical.

Graded changes in membrane potential spread to nearby parts of the neuron

If a gated ion channel is stimulated by the appropriate stimulus, it can open or close to cause a local change in membrane potential. These small, local changes in membrane potential are called **graded membrane potentials**, so named because they can vary in magnitude. For example, if a single chemically gated Na^+ channel on a dendrite is stimulated by a neurotransmitter molecule and opens, a small amount of Na^+ will enter the cell, causing a local graded potential in that dendrite (in this case, depolarizing the cell slightly). If more neurotransmitter molecules open more gated Na^+ channels, more Na^+ enters and the graded potential becomes larger, depolarizing the cell even further. Graded potentials are a means of integrating inputs to a cell: the degree of membrane depolarization or hyperpolarization is determined by summing all of the inputs.

Graded potentials spread quickly to nearby areas of the neuron. However, this local flow of electric current decays as it spreads, like water flowing through a leaky hose. Graded potentials do not spread far, and they die out entirely before they get very far along the axon. To carry a signal to the end of an axon, the cell must generate an action potential.

APPLY THE CONCEPT

Neurons generate and transmit electrical signals

The data below were recorded from the large axon of a squid (see pp. 679–680). They show the concentrations of four ions both inside the axon’s cytoplasm and outside the cell, in a seawater bath.

ION	ION CONCENTRATION (mM)	
	IN SEAWATER	IN SQUID CYTOPLASM
K^+	400	20
Na^+	50	460
Ca^{2+}	0.5	10
Cl^-	50	560

1. Use the Nernst equation to predict the equilibrium potential for each of the four ions.
2. The measured resting potential of this axon is -66 mV. How can you explain that resting potential on the basis of the equilibrium potentials you calculated?
3. Another equation—the Goldman–Hodgkin–Katz equation—includes a relative permeability of the membrane for each ion. Why is this necessary for accurately predicting the membrane potential?

FIGURE 34.6 Membranes Can Be Depolarized or Hyperpolarized The resting potential is produced by leak K^+ channels. A shift from the resting potential to a less negative membrane potential, as occurs when Na^+ enters the cell through a gated sodium channel, is called depolarization. Hyperpolarization occurs when the membrane potential becomes more negative, as when additional K^+ leaves the cell through gated K^+ channels.

Sudden changes in Na^+ and K^+ channels generate action potentials

If we place a pair of electrodes on either side of the plasma membrane of a resting axon, the voltage reading might be about -60 mV. If these electrodes are in place when an action potential travels down the axon, they register a rapid depolarization of the membrane potential, from -60 mV to about $+50$ mV. The membrane potential returns to its resting level of -60 mV soon after the action potential passes (**FIGURE 34.7**). Unlike graded potentials, action potentials always produce the same amount of depolarization, and they can travel a long distance.

The action potential is generated by voltage-gated Na^+ and K^+ channels in the plasma membrane of the axon. At the resting potential, most of these channels are closed (step 1 in Figure 34.7). Local depolarization caused by gated channels in the dendrites produces a graded potential that spreads to the **axon hillock**, the region of the cell body at the base of the axon (see Figure 34.1). Voltage-gated Na^+ channels are concentrated in the axon hillock. If the plasma membrane in this area depolarizes to 5–15 mV above the resting potential, a **threshold** is reached at which many voltage-gated Na^+ channels open rapidly (step 3 in Figure 34.7). Enough Na^+ enters that the

membrane potential becomes positive. Within 1–2 milliseconds, the membrane potential once again becomes negative.

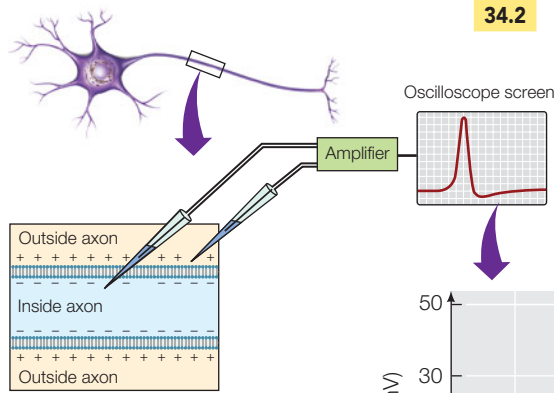

Why does the axon return to resting potential? There are two contributing factors: first, voltage-gated K^+ channels open, and then with a slight delay the inactivation gates of the Na^+ channels close (step 4 in Figure 34.7). The voltage-gated K^+ channels open more slowly than the Na^+ channels and stay open longer, allowing K^+ to carry excess positive charges out of the axon. As a result, the membrane potential returns to a negative value (and in fact usually becomes even more negative than the resting potential until the voltage-gated K^+ channels close; step 5 in Figure 34.7).

Another feature of the voltage-gated Na^+ channels is that once they have opened and closed, they have a *refractory period* during which they cannot open again. Thus once an action potential has occurred at a particular region of membrane, that region cannot generate another action potential for a few milliseconds.

Action potentials are conducted along axons without loss of signal

Action potentials can travel over long distances with no loss of signal strength. If we place pairs of electrodes at two different locations along an axon, we can record the action potential at those two locations as it travels along the axon. The magnitude of the action potential does not change between the two recording sites. This constancy is possible because an action potential is an all-or-nothing, self-regenerating event.

- An action potential is *all-or-nothing* because of the interaction between the voltage-gated Na^+ channels and the membrane

yourBioPortal.com
Go to ANIMATED TUTORIAL 34.2
The Action Potential

FIGURE 34.7 The Course of an Action Potential Action potentials result from rapid changes in voltage-gated Na^+ and K^+ channels.

potential. If the membrane is depolarized slightly, some voltage-gated Na^+ channels open. Some sodium ions cross the plasma membrane and depolarize it even more, opening more voltage-gated Na^+ channels, and so on, until the membrane reaches threshold and generates an action potential. This positive feedback mechanism ensures that action potentials always rise to their maximum value.

- An action potential is *self-regenerating* because it spreads by local current flow to adjacent regions of the plasma membrane. The resulting depolarization brings those neighboring areas of membrane to threshold. So when an action potential occurs at one location on an axon, it stimulates the adjacent region of axon to generate an action potential, and so on down the length of the axon.

Normally, an action potential is propagated in only one direction—away from the cell body. It cannot reverse itself because

the voltage-gated Na^+ channels in the region of the membrane it came from are in their refractory period.

Action potentials travel faster in large axons and in myelinated axons

Action potentials do not travel along all axons at the same speed. They travel faster in large-diameter than in small-diameter axons because the resistance to current flow decreases as an axon's diameter gets bigger. Many invertebrate animals rely on increased axon diameter to increase the speed of action potential conduction. In squid, neurons involved in escape responses have exceptionally large-diameter axons, allowing the mollusk to respond rapidly to threats. These squid axons are so large—up to 1 millimeter in diameter—that they are relatively easy to manipulate and study. Many of the basic principles

of neuronal and action potential function were discovered by studying these “giant axons.”

In vertebrate nervous systems, increasing the diameter of axons to increase the speed of action potentials is less common because of the huge number of axons involved. Vertebrates have evolved a different way of increasing conduction velocity of axons, and that adaptation is *myelination*. When glia wrap themselves around axons, covering them with concentric layers of myelin (see Figure 34.2), they leave **nodes of Ranvier**: regularly spaced gaps where the axon is not covered. Myelin reduces leakage of ions across the membrane, so electric current can spread farther along the inside of a myelinated axon than it can along a nonmyelinated axon. Additionally, voltage-gated ion channels are clustered at the nodes of Ranvier. Thus an axon can fire action potentials only at nodes. The positive charges that flow into the axon at the node move rapidly down the inside of the axon in the form of electric current. When the current reaches the next node, the plasma membrane at that node is depolarized to threshold and fires another action potential. Action potentials therefore appear to “jump” from node

to node (**FIGURE 34.8**). This form of rapid impulse propagation is called **saltatory conduction** (Latin *saltare*, “to jump”).

Saltatory conduction by myelinated axons is extremely fast because electric current flows much faster through the cytoplasm than membrane ion channels can open and close. In unmyelinated axons, action potentials can be conducted at speeds up to 2 meters per second, but in myelinated axons the conduction velocity can be 100 meters per second.

Do You Understand Concept 34.2?

- Give a specific example of each of the following types of ion transporters: a leak channel, an ion pump, a voltage-gated channel, and a chemically gated channel.
- Describe two different evolutionary adaptations to speed the conduction of action potentials.
- Why do neurons generate action potentials at all? That is, why don't they just use graded potentials to carry information to the end of the axon?
- Explain what is meant by the statement that an action potential is an all-or-nothing, self-regenerating event.

Now that we have described how action potentials are generated and transmitted along an axon, we will next address the question of what happens when the action potential arrives at the axon terminal. How is the information communicated to the next cell?

FIGURE 34.8
Saltatory Action Potentials Action potentials appear to jump from node to node in myelinated axons.

concept 34.3 Neurons Communicate with Other Cells at Synapses

Neurons communicate with each other and with other cells at synapses. The number of synapses can make a nervous system extraordinarily complex. A neuron in a brain may have 1,000 or more synapses. The human brain contains roughly 10^{14} synapses (10^{11} neurons, $\times 10^3$ synapses per neuron).

The most common type of synapse is the **chemical synapse**, in which neurotransmitters released from a *presynaptic cell* bind to receptors in the membrane of a *postsynaptic cell*, inducing changes in the postsynaptic cell. At chemical synapses, a space about 25 nanometers wide—called the **synaptic cleft**—separates the presynaptic and postsynaptic cells.

Electrical synapses physically join the cytoplasm of pre- and postsynaptic cells through *gap junctions*. As we saw in Figure 4.18, a gap junction is made up of proteins (*connexins*) that create channels between cells. Ions can flow through these channels, allowing the action potential to spread passively from the

presynaptic to the postsynaptic cell. The advantage of electrical synapses is that they enable fast transmission of information; their disadvantage is that they do not allow complex integration of inputs from multiple sources—which, as we will see, are important properties of chemical synapses. We will focus here on chemical synapses that are characteristic of most parts of the vertebrate nervous system.

The neuromuscular junction is a model chemical synapse

Neuromuscular junctions are synapses between motor neurons and skeletal muscle cells. They are excellent examples of how chemical synaptic transmission works (FIGURE 34.9). The axon of a motor neuron branches into numerous axon terminals that may synapse with many muscle cells. Each axon terminal ends in a buttonlike structure (*bouton*) containing vesicles filled with neurotransmitter molecules. The neurotransmitter used by all vertebrate neuromuscular synapses is *acetylcholine* (ACh).

ACh is released when an action potential arrives at the axon terminal. The action potential causes the opening of voltage-gated Ca^{2+} channels in the presynaptic membrane. Because Ca^{2+} concentration is greater outside the cell than inside, Ca^{2+} enters the axon terminal. Increased Ca^{2+} inside the axon terminal causes the ACh vesicles to fuse with the presynaptic membrane, releasing ACh via exocytosis into the synaptic cleft.

The postsynaptic membrane of the neuromuscular junction forms a depression called a **motor end plate**. The terminals of the motor neuron sit in this depression. When ACh is released at the synaptic cleft, some of it binds to ACh receptors on the motor end plate. These receptors allow both Na^+ and K^+ to flow through (FIGURE 34.10). Since the electrochemical gradients favor a greater influx of Na^+ , the response of the motor end plate to ACh is to depolarize. This causes a graded potential that spreads to nearby regions of the membrane, which contain voltage-gated Na^+ and K^+ channels.

If the axon terminal of a motor neuron releases sufficient ACh to adequately depolarize the motor end plate, voltage-gated Na^+ channels are activated, causing the muscle cell to fire its own action potential. This action potential is then conducted throughout the muscle cell's system of membranes, activating the contractile mechanism.

LINK The physical and molecular interactions of muscle contraction are described in Concept 36.1

The postsynaptic cell sums excitatory and inhibitory input

In vertebrates, the synapses between motor neurons and muscle cells are always **excitatory**; that is, motor end plates always respond to ACh with a depolarization (greater positive charge). However, synapses between neurons can also be **inhibitory**, causing hyperpolarization. For example, there are more chloride ions (Cl^-) outside cells than inside. If a neurotransmitter causes opening of a Cl^- channel, Cl^- ions enter the postsynaptic

FIGURE 34.10 Chemically Gated Channels The motor end plate contains acetylcholine (ACh) receptors, which are chemically gated ion channels. When one of these receptors binds ACh, its channel pore opens and Na^+ ions move into the postsynaptic cell, depolarizing its plasma membrane. The enzyme acetylcholinesterase breaks down ACh in the synapse, closing the channel; the breakdown products (acetate and choline) are then taken up by the presynaptic membrane and resynthesized into more ACh.

cell and hyperpolarize it (make it more negative). Hyperpolarization takes the postsynaptic cell farther from threshold, making it less likely that the cell will fire action potentials.

FRONTIERS Brain function depends on a balance between excitation and inhibition. Too much excitation can result in psychotic behavior and even seizures. Too much inhibition results in mental impairment and even coma. The major inhibitory neurotransmitter in the human brain is γ -aminobutyric acid (GABA), which controls Cl^- channels. Recent research has shown that low doses of drugs that block GABA activity can greatly reduce the learning disabilities associated with Down syndrome.

A single postsynaptic neuron may receive over 1,000 synapses from presynaptic neurons. The different presynaptic neurons release a variety of different neurotransmitters that may cause depolarization or hyperpolarization at a given synapse. At the axon hillock of the postsynaptic neuron, all of these depolarizations and hyperpolarizations are summed up in the form of a graded potential that brings the axon hillock either closer to or farther from threshold. In this way, a single neuron can integrate many different inputs, a process called *summation*. At any given time, the information from all of the inputs is translated into the rate at which that neuron generates action potentials.

Summation can occur over space and over time. **Spatial summation** adds up the simultaneous influences of synapses at different sites on the postsynaptic cell (FIGURE 34.11A). **Temporal summation** adds up postsynaptic potentials generated at the same site in a rapid sequence (FIGURE 34.11B).

To turn off responses, synapses must be cleared of neurotransmitter

Turning off neurotransmitter action is as important as turning it on. If released neurotransmitter molecules simply remained in the synaptic cleft, the postsynaptic membrane would become saturated with neurotransmitter, and receptors would be constantly activated. As a result, the postsynaptic cell would remain hyperpolarized or depolarized. Thus neurotransmitter must be cleared from the synaptic cleft shortly after it is released by the axon terminal.

Neurotransmitter action may be terminated in several ways. First, enzymes may destroy the neurotransmitter. ACh, for example, is rapidly destroyed in the synaptic cleft by the enzyme acetylcholinesterase (see Figure 34.10). Neurotransmitter also may simply diffuse away from the cleft, or be taken up via active transport by nearby cell membranes of neurons and glia.

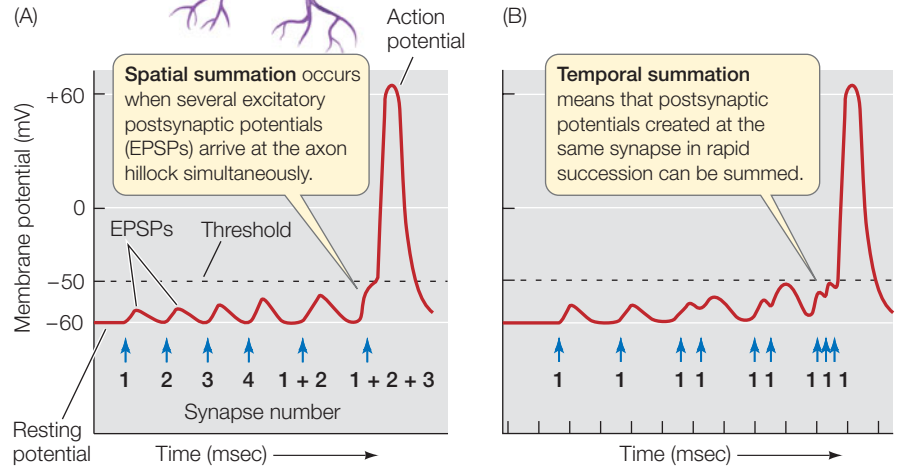

FIGURE 34.11 The Postsynaptic Neuron Sums Information
 Individual neurons sum excitatory and inhibitory postsynaptic potentials over (A) space and (B) time. When the sum of the potentials depolarizes the axon hillock to threshold, the neuron generates an action potential.

Some antidepressant drugs (e.g., Prozac) slow reuptake of the neurotransmitter serotonin, thus enhancing its activity at the synapse.

There are many types of neurotransmitters

More than 50 neurotransmitters are now recognized, and more will surely be discovered. In addition to being used by vertebrate motor neurons, acetylcholine is also used in the brain, but the brain also has many other neurotransmitters, including simple amino acids such as glutamate and γ -aminobutyric acid (GABA); modified amino acid derivatives such as

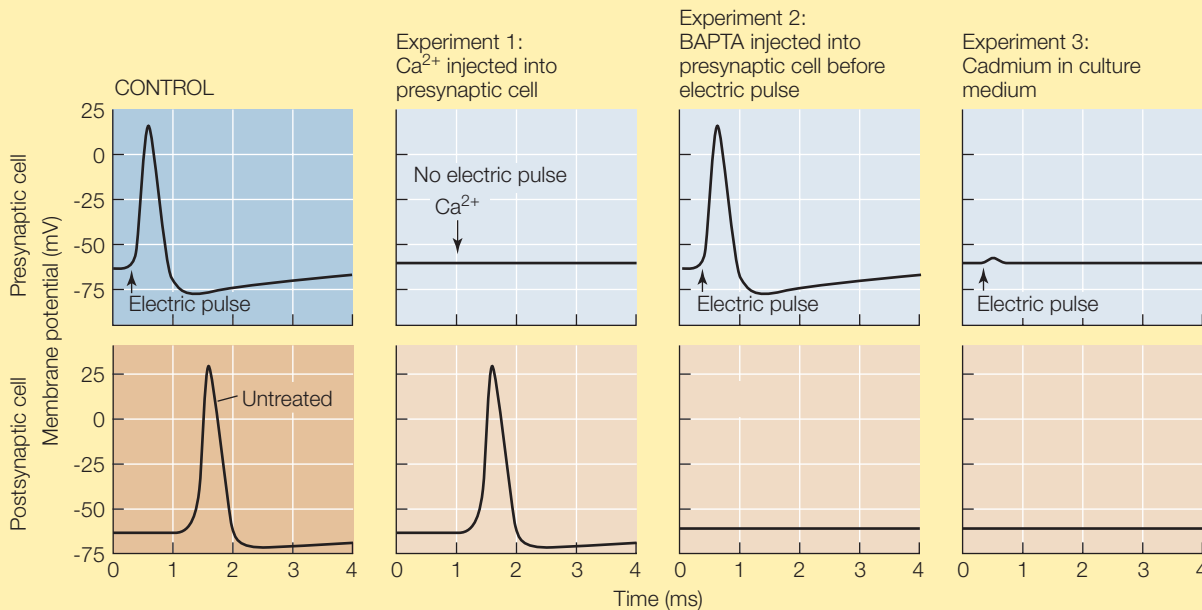

APPLY THE CONCEPT

Neurons communicate with other cells at synapses

How do we know that Ca^{2+} influx into the presynaptic nerve ending causes the release of neurotransmitter? Because the squid giant axon and its nerve endings are so large, they are a convenient system for experiments. It is possible to inject substances into both the presynaptic and postsynaptic cells near the synapse. Some of the substances that can be injected are Ca^{2+} ions and BAPTA, a substance that binds Ca^{2+} ions. Also, channel blockers can be added to the culture medium. For example, cadmium blocks Ca^{2+} channels. Shown below are the results of a series of experiments using these substances.

1. What is happening during the delay between the pre- and postsynaptic membrane events in the control condition?
2. Explain the postsynaptic response in the absence of a presynaptic response in experiment 1.
3. Explain why there is a presynaptic but no postsynaptic response in experiment 2.
4. Why are there no pre- or postsynaptic responses in experiment 3?

dopamine, norepinephrine, and serotonin; and peptides such as endorphins.

In addition to the multitude of neurotransmitters, each neurotransmitter may have multiple receptor types, which may have different effects on postsynaptic cells. For example, ACh has two receptor types: *nicotinic receptors*, which tend to be excitatory, and *muscarinic receptors*, which tend to be inhibitory. The action of a neurotransmitter ultimately depends on the receptor to which it binds.

Where do neurotransmitter molecules come from? The enzymes required for ACh synthesis are produced in the cell body of the motor neuron and are transported along microtubules down the axon to the terminals. In other types of neurons, neurotransmitters may be produced in the cell body, packaged into membrane-bound vesicles by the Golgi apparatus, and then transported down the axon.

Certain drugs can interfere with neurotransmitter release, as can many naturally occurring toxins. Toxins from *Clostridium* bacteria, for example, destroy several of the proteins necessary for the binding of vesicles to the presynaptic membrane. These toxins cause botulism and tetanus, frequently fatal diseases that involve muscle impairment due to loss of neurotransmitter release.

Synapses can be fast or slow depending on the nature of receptors

Most neurotransmitter receptors induce changes in postsynaptic cells by opening or closing ion channels. How they do so is the basis for grouping receptors into two general categories:

- **Ionotropic receptors** are ion channels themselves. Neurotransmitter binding to an ionotropic receptor causes a direct change in ion movement across the plasma membrane of the postsynaptic cell. These proteins enable fast, short-lived responses.
- **Metabotropic receptors** are not ion channels, but they induce signaling cascades in the postsynaptic cell that secondarily lead to changes in ion channels. Postsynaptic cell responses mediated by metabotropic receptors are generally slower and longer-lived than those induced by ionotropic receptors.

The ACh receptor of the motor end plate is an example of an ionotropic receptor. It consists of five subunits, each of which extends through the plasma membrane. When assembled, the subunits create a central pore that allows ions to pass through. Of several different kinds of subunits, only one kind has the ability to bind ACh. Each functional receptor has two of the ACh-binding subunits and three other subunits.

Metabotropic receptors are also transmembrane proteins, but instead of acting as ion channels, they initiate an intracellular signaling process that can result in the opening or closing of an ion channel. These receptors have seven transmembrane domains, and they are linked to G proteins. When a neurotransmitter binds to the extracellular domain of a metabotropic receptor, the intracellular domain activates a G protein that initiates a second-messenger cascade, which in turn opens

an ion channel. Because metabotropic receptors act through a sequence of cellular reactions, their responses are slower, but they can last longer.

Do You Understand Concept 34.3?

- List the sequence of events at a neuromuscular junction, starting with the firing of an action potential of the presynaptic neuron and ending with contraction of the muscle cell.
- Compare chemical and electrical synapses. Why do you think electrical synapses are more predominant in invertebrates than in vertebrates?
- Dendrites can extend quite a distance from the cell body. Synapses can form at all locations on the dendrites and on the cell body itself. Which synapses do you think will have a stronger effect on the firing rate of the cell? Why?
- Some forms of learning involve physical and chemical changes in the postsynaptic cells. Do you think such synapses are more likely to be ionotropic or metabotropic, and why?

We have seen how neurons use ion pumps and ion channels to generate action potentials and how action potentials trigger neurotransmitter release, allowing neurons to communicate with each other and with other cells. Next we'll look at how neurons form a complex nervous system.

concept 34.4 The Vertebrate Nervous System Has Many Interacting Components

As we saw in Concept 34.1, nervous systems range from simple to highly complex. Here we focus on the complex system of humans. Although it represents an extremely high level of complexity, the human nervous system shares the basic structure of all vertebrate nervous systems.

In vertebrates, most cells of the nervous system are found in the brain and the **spinal cord**. The brain and spinal cord together are called the **central nervous system (CNS)**. Information is transmitted from sensory cells to the CNS, and from the CNS to effectors, via neurons that extend or reside outside the brain and the spinal cord; these neurons and their supporting cells are called the **peripheral nervous system (PNS)**. **FIGURE 34.12** illustrates the major avenues of information flow through the nervous system.

The *afferent* portion of the PNS carries sensory information to the CNS. The *efferent* portion of the PNS carries information from the CNS to the muscles and glands of the body. Efferent pathways can be further divided into a voluntary division, which executes our conscious movements, and an involuntary, or *autonomic*, division. An additional division of the nervous system exists in the gut (the enteric nervous system, discussed in Chapter 39).

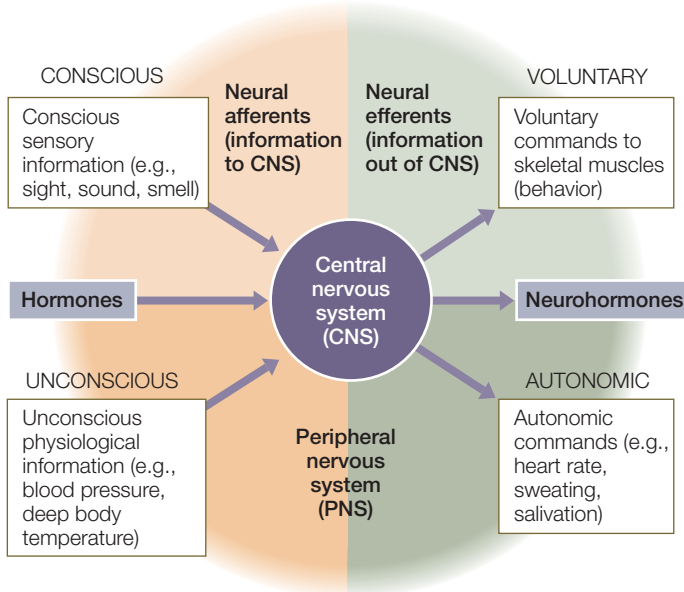

FIGURE 34.12 Organization of the Nervous System The peripheral nervous system (beige and green) carries information both to (afferent) and from (efferent) the central nervous system (purple). The CNS also receives hormonal inputs and produces hormonal outputs (lavender).

The autonomic nervous system controls involuntary physiological functions

The **autonomic nervous system**, or **ANS**, comprises the output pathways of the CNS that control involuntary functions that are crucial to homeostasis, such as heart rate, sweating, and some functions of the gut. The ANS has two divisions, **sympathetic** and **parasympathetic**, that frequently work in opposition to each other (FIGURE 34.13). Generally, the sympathetic division produces the fight-or-flight response: increased heart rate, blood pressure, and cardiac output (see Concept 30.2). The sympathetic division prepares the body for emergencies and reduces less urgent activities such as digestion. In contrast, the parasympathetic division slows the heart, lowers blood pressure, and increases digestion; its actions have been characterized as “rest and digest.”

Whether sympathetic or parasympathetic, every autonomic efferent pathway begins with a *preganglionic neuron* that has its cell body in the CNS (see Figure 34.13). Axons of preganglionic neurons lead to a ganglion (a collection of neurons) outside the CNS, where they synapse with *postganglionic neurons*. Most of the ganglia of the sympathetic division are lined up in two chains, one on either side of the spinal cord. In contrast, the parasympathetic ganglia are close to the target organs. In both divisions, axons of the postganglionic neurons lead to the target organs, where they synapse with target cells.

The postganglionic neurons of the sympathetic division are *noradrenergic*, meaning they release norepinephrine as their neurotransmitter. In contrast, the postganglionic neurons of the parasympathetic division are *cholinergic* neurons, meaning they release acetylcholine. In organs that receive both sympathetic and parasympathetic input, the target cells respond in

opposite ways to norepinephrine and to ACh. This happens, for example, in a region of the heart called the *pacemaker*, which generates the heartbeat. Stimulating the sympathetic nerve to the heart or dripping norepinephrine onto the pacemaker cells increases their firing rate and causes the heart to beat faster. In contrast, stimulating the parasympathetic nerve to the heart or dripping acetylcholine onto the pacemaker cells decreases their firing rate and causes the heart to beat more slowly.

The sympathetic and parasympathetic divisions of the ANS can also be distinguished by anatomy. The preganglionic neurons of the parasympathetic division come from the brainstem and the *sacral* region of the spinal cord; those of the sympathetic division come from the *thoracic* and *lumbar* regions of the spinal cord (see Figure 34.13).

The spinal cord transmits and processes information

The spinal cord has afferent and efferent tracts of axons communicating between the brain and the body’s organs. It also integrates much of the information coming from the PNS and responds to that information by issuing motor commands.

A cross section of the spinal cord reveals a central area of gray matter in the shape of a butterfly, surrounded by an area of white matter (see Figure 34.14). Remember that **gray matter** is rich in neural cell bodies, whereas **white matter** is rich in myelinated axons. The gray matter of the spinal cord contains the cell bodies of the spinal neurons; the white matter contains the axons that conduct information up and down the spinal cord.

Spinal nerves extend from the spinal cord at regular intervals on each side. Each spinal nerve has two roots, one connecting with the *dorsal horn* of the gray matter, the other with the *ventral horn*. The afferent (sensory) axons in a spinal nerve enter the spinal cord through the *dorsal root*, and the efferent (motor) axons leave through the *ventral root*.

The spinal cord is capable of some simple reactions to certain stimuli without involving the brain. These reactions are called **spinal reflexes**. The simplest type of spinal reflex circuit has only two neurons with one synapse between them, and is therefore called a **monosynaptic reflex**. An example is the knee-jerk reflex (FIGURE 34.14). When a physician taps your knee with a little hammer, the tap stretches the patellar tendon connecting the extensor muscle (quadriceps) in your upper leg to the femur in your lower leg. Modified muscle fibers in the quadriceps called “muscle spindles” form stretch receptors that are innervated by sensory neurons. Stretching the muscle spindle generates action potentials in that sensory neuron. The axon of that sensory neuron travels to the spinal cord, enters the dorsal horn, and continues to the ventral horn where it synapses onto a motor neuron. This synapse is excitatory and causes the motor neuron to fire action potentials that travel in the axon of that motor neuron back out to the quadriceps, causing it to contract. The result is that your lower leg kicks forward.

Most spinal reflexes are more complex than this monosynaptic reflex, and may involve additional muscles and more neurons. But the basic principle is the same: information enters

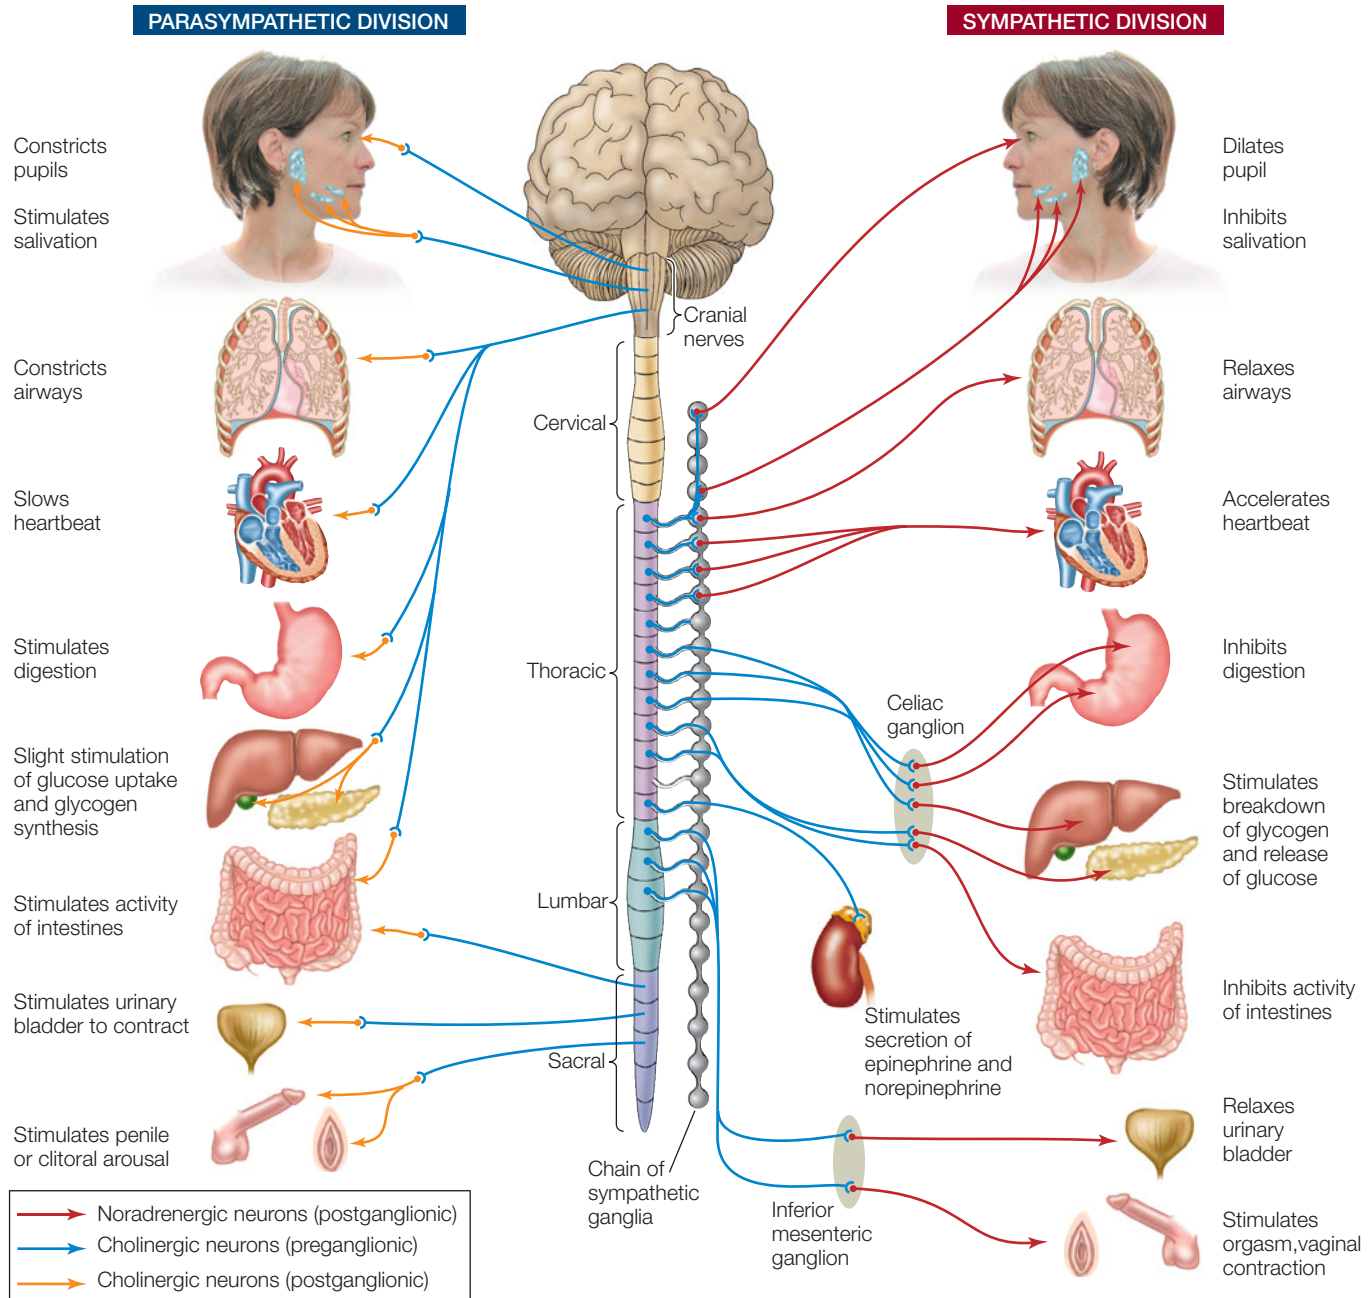

FIGURE 34.13 The Autonomic Nervous System The autonomic nervous system is divided into the sympathetic and parasympathetic divisions. The two divisions work in opposition to each other in their effects on most organs; one results in an increase and the other a decrease in activity.

the spinal cord from sensory neurons, and commands leave the spinal cord through motor neurons — all without any involvement of the brain. Spinal reflexes allow rapid responses to certain simple stimuli and are important in maintaining posture and balance.

Interneurons coordinate polysynaptic reflexes

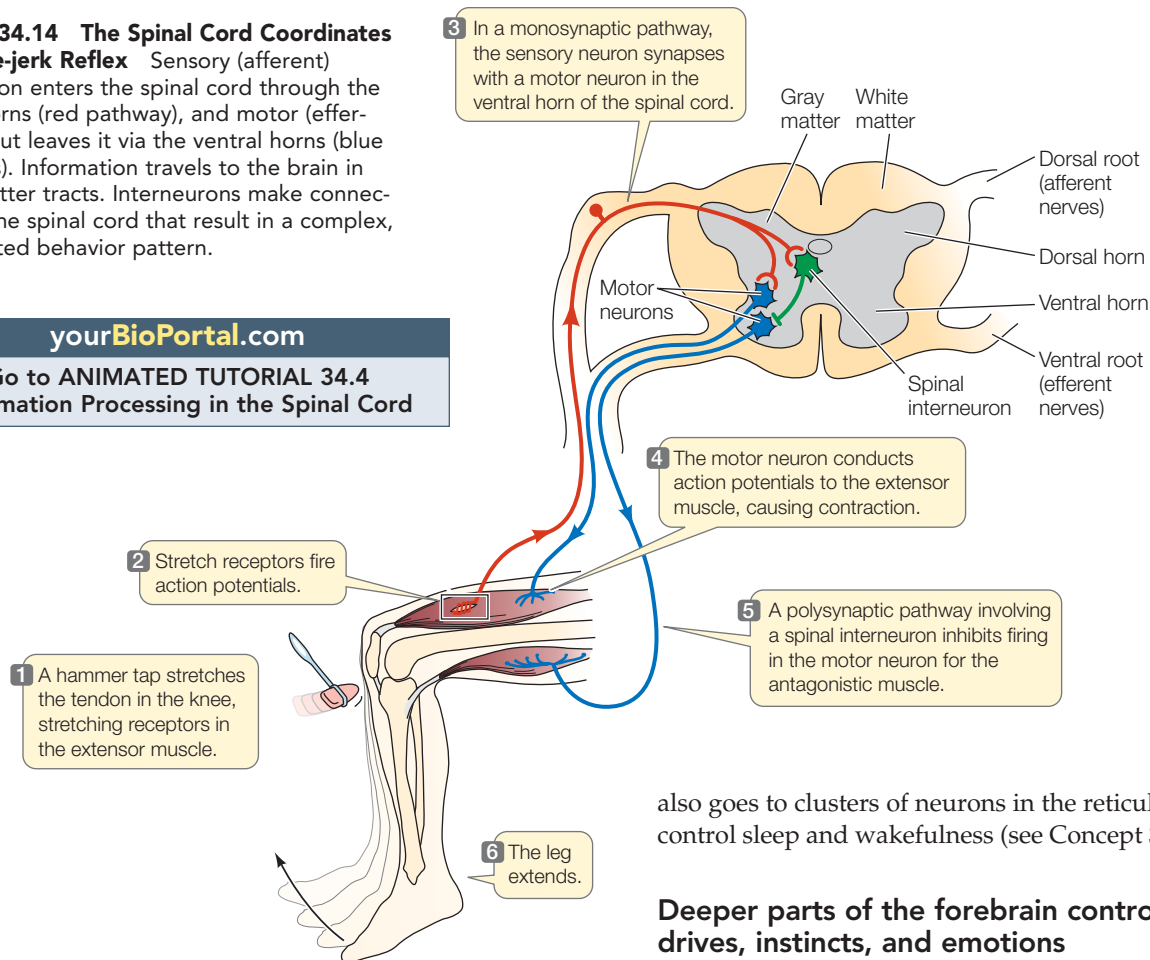

Even a monosynaptic reflex involves additional neurons. Muscles of the limbs are organized in antagonistic pairs of *flexors* and *extensors* (see Concept 36.3). Thus if a muscle such as the quadriceps is going to contract, its antagonistic muscle has to relax. The sensory neurons coming from the quadriceps stretch

receptors also synapse onto *interneurons* in the spinal cord (see Figure 34.14). Those interneurons make *inhibitory* synapses onto the motor neurons of the flexor of the lower leg, allowing it to move forward when the quadriceps contracts.

Now think about your reflex movements when you step on something sharp. You immediately withdraw the foot generating the painful sensation, and at the same time shift your weight to your other leg, making many small adjustments in

FIGURE 34.14 The Spinal Cord Coordinates the Knee-jerk Reflex Sensory (afferent) information enters the spinal cord through the dorsal horns (red pathway), and motor (efferent) output leaves it via the ventral horns (blue pathways). Information travels to the brain in white matter tracts. Interneurons make connections in the spinal cord that result in a complex, coordinated behavior pattern.

Information Processing in the Spinal Cord

muscles to maintain your balance. What you experience is a *polysynaptic reflex* mediated by interneurons in the spinal cord.

The brainstem transfers information between the brain and spinal cord

The embryonic neural tube in vertebrates forms three anterior swellings that become the *hindbrain*, *midbrain*, and *forebrain* (see Figure 33.13). From the hindbrain come the *medulla*, *pons*, and *cerebellum*. The medulla and pons contain distinct groups of neurons involved in controlling physiological functions such as breathing and circulation, while the cerebellum is involved in coordinating muscle activity and maintaining balance. The midbrain gives rise to certain structures that process aspects of visual and auditory information.

All information traveling between the spinal cord and higher brain areas must pass through the pons, the medulla, and the midbrain, which are collectively known as the **brainstem**. Many sensory axons give off branches in the brainstem that form synapses with a network of brainstem neurons called the **reticular system**. Information from joints and muscles, for example, is directed to areas of the reticular system that are involved in balance and coordination. Sensory information

also goes to clusters of neurons in the reticular formation that control sleep and wakefulness (see Concept 34.5).

Deeper parts of the forebrain control physiological drives, instincts, and emotions

The forebrain includes a central region called the **diencephalon** and a surrounding structure called the **telencephalon**. The diencephalon, in turn, consists of an upper structure, the *thalamus*, and a lower structure, the *hypothalamus*. The thalamus is the final relay station for sensory information going to the telencephalon. The hypothalamus regulates many physiological functions and biological drives such as hunger and thirst; it receives a lot of physiological information of which we are not conscious.

LINK The roles of the hypothalamus in homeostatic regulation and sensory integration are detailed in Concepts 29.5 and 30.3

Surrounding the diencephalon of all vertebrates are phylogenetically older structures of the telencephalon called the **limbic system** (FIGURE 34.15). The limbic system is responsible for many basic functions such as instinctive reactions, fear, pleasure, pain, rage, and memory formation. If a rat is given the opportunity to stimulate the pleasure centers of the limbic system by pressing a switch, it will ignore food, water, and even sex, pushing the switch until it is exhausted. An oval-shaped structure called the **amygdala** (Latin, “almond”), part of the limbic system, is the brain’s center for the fear reactions and fear memories. Another limbic structure, the **hippocampus**, is necessary for the transfer of short-term memory to long-term memory, as we will see in Concept 34.5.

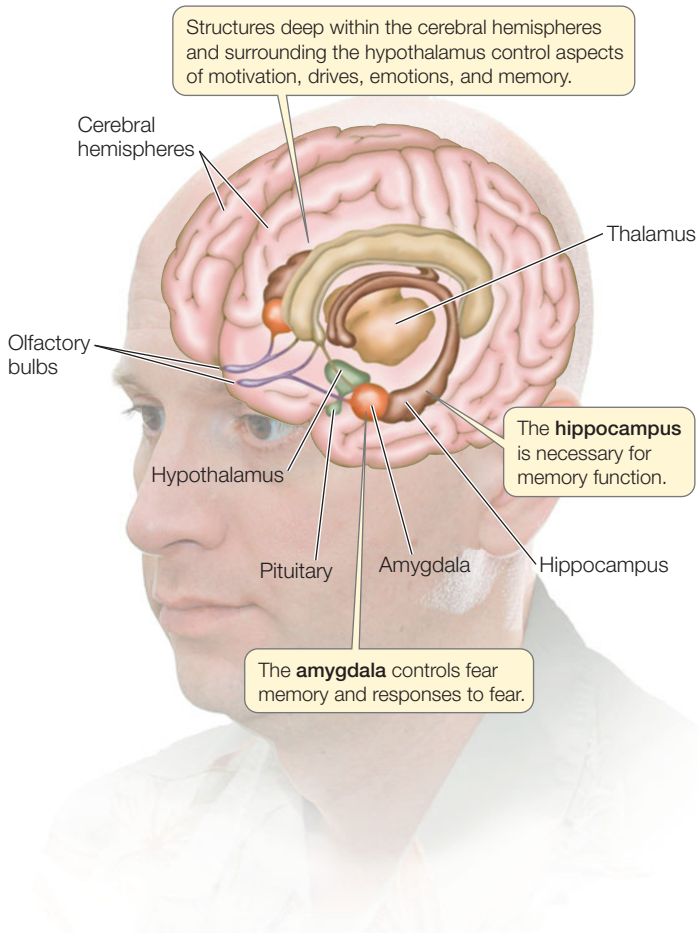

FIGURE 34.15 The Limbic System The evolutionarily primitive parts of the telencephalon are referred to as the limbic system. The hippocampus is involved in forming long-term memory. The amygdala triggers fear emotions and fear memories (see p. 693).

the **cerebral cortex**, a thin layer rich in cell bodies. The cerebral cortex is only about 4 millimeters thick, but it is folded into ridges, or *convolutions*, that increase its surface area.

The cerebral cortex plays a major role in sensory perception, learning, memory, and conscious behavior. Different regions of the cerebral cortex have specific functions (**FIGURE 34.16B**). Some of those functions are easily defined, such as receiving and processing sensory information or generating motor commands, but most of the cortex is involved in higher-order information processing that is less easy to define. These latter areas are given the general name of **association cortex**, so named because they integrate, or *associate*, information from different sensory modalities and from memory.

Humans (and, interestingly, dolphins) have much bigger brains than would be predicted from their body size, primarily because of an unusually large telencephalon. The telencephalon is by far the largest part of the human brain. Humans also have the greatest degree of convolution of the cerebral cortex. The percentage of human cerebral cortex that is association cortex (devoted to the integration of information) is greater than in other species. It is these evolutionary changes, primarily in the cortex, that provide the resources for the great intellectual capacity of humans—a topic to which we will return at the end of the chapter.

Regions of the telencephalon interact to produce consciousness and control behavior

The outer part of the telencephalon—and the dominant structure of the mammalian brain—is the **cerebrum**, with its left and right **cerebral hemispheres** (**FIGURE 34.16A**). In humans, the cerebral hemispheres cover all other parts of the brain except the cerebellum. The outermost layer of the cerebrum is

FIGURE 34.16 The Human Cerebrum (A) Each cerebral hemisphere is divided into four lobes. (B) Different functions are localized in particular areas of the cerebral lobes.

yourBioPortal.com

Go to **WEB ACTIVITY 34.2**
The Human Cerebrum

A curious feature of the human nervous system is that the left side of the body is served (in both sensory and motor aspects) mostly by the right side of the brain, and vice versa. Thus sensory input from the right hand goes to the left cerebral hemisphere, and sensory input from the left hand goes to the right cerebral hemisphere. The exception is the head, where the left side is controlled by the left cerebral hemisphere and the right side by the right cerebral hemisphere.

Each cerebral hemisphere has four lobes

Each cerebral hemisphere consists of four lobes: the **temporal lobe**, **frontal lobe**, **parietal lobe**, and **occipital lobe** (see Figure 34.16A).

THE TEMPORAL LOBE The upper region of the temporal lobe receives and processes auditory information. The lower regions are involved in visual processing. The association areas of this lobe are involved in recognizing, identifying, and naming objects. Damage to the temporal lobe results in disorders called *agnosias*, in which the individual is aware of an object but cannot identify it. For example, damage to a certain area of the temporal lobe results in the inability to recognize faces. The temporal lobe also contains areas involved in language (see Concept 34.5).

THE FRONTAL LOBE This is the largest of the brain lobes in humans. Its association areas are involved with feeling and

planning, and contribute significantly to what we consider our “personality.” People with frontal lobe damage have drastic alterations of personality and difficulty planning future events.

The strip of the frontal lobe cortex that is just anterior to the parietal lobe is called the **primary motor cortex** (FIGURE 34.17A). The neurons in this region control muscles in specific parts of the body. Regions of the body with fine motor control, such as the face and hands, have disproportionate representation in the primary motor cortex.

THE PARIETAL LOBE A major association function of the parietal lobe is attending to complex stimuli. The parietal lobe also helps translate visual information into a perception of objects being located in a three-dimensional space surrounding the body. Just behind the primary motor cortex of the frontal lobe is a similar strip of parietal lobe called the **primary somatosensory cortex** (FIGURE 34.17B). This area receives touch and pressure information relayed from the body through the thalamus. Just as with the primary motor cortex, the entire body surface can be mapped onto the primary somatosensory cortex. Areas of the body that are capable of making fine discriminations in touch (such as the lips and fingers) have disproportionately large representation.

THE OCCIPITAL LOBE The occipital lobe receives and processes visual information. The association areas of the occipital cortex are essential for making sense of the visual world and translating visual experience into language. For example, in one case a woman with limited damage to the occipital lobe was unable to see motion. Her vision was intact, but she could see a waterfall only as a still image, and an approaching car only as a series of stationary objects at different distances.

FIGURE 34.17 The Body Is Represented in Primary Motor and Primary Somatosensory Cortices Neurons in the primary motor cortex (A) control muscles in specific parts of the body, while neurons in the primary somatosensory cortex (B) receive information from specific parts of the body. The locations of these neurons in the cortex correspond to “maps” on which regions of the body are represented in proportion to the amount of primary cortical area devoted to them.

Do You Understand Concept 34.4?

- Describe the sympathetic, parasympathetic, central, autonomic, and peripheral nervous systems and explain how they relate to one another.
- What senses do you think would be most affected if a person's occipital and temporal lobes were damaged? Where would you expect to find the major cortical area involved in reading?
- The activity of different brain regions can be imaged as a person is shown different pictures. When a picture of a familiar, pleasant place is viewed, the activity of the hippocampus increases. When a picture of a place associated with a traumatic event is shown, the activities of the hippocampus and the amygdala increase. How would you interpret these findings?

So far this chapter has described the cellular components of the nervous system and how these cells are organized into networks that send, receive, and process information. We have described regions of the human brain that epitomize the information-processing ability of the vertebrate nervous system. Next let's see how these regions are responsible for the most complex of abilities and behaviors.

concept 34.5 Specific Brain Areas Underlie the Complex Abilities of Humans

The following discussion addresses several of the most complex functions of the human brain, including our ability to extensively use and manipulate language; our ability to learn and remember, both of which significantly surpass similar abilities in other primates; and finally, research into the functions of sleep and dreaming, as well as the nature of consciousness. These areas are still not completely understood, but neuroscientists are making fascinating progress.

Language abilities are localized in the left cerebral hemisphere

No aspect of brain function is as integrally related to human consciousness and intellect as language. Therefore, brain mechanisms that underlie the acquisition and use of language are extremely interesting to neuroscientists. A curious observation about language ability is that it resides in one cerebral hemisphere—which in about 85 percent of people is the left hemisphere. This phenomenon is referred to as **lateralization** of language functions.

Individuals who suffer damage to the left hemisphere are frequently left with some form of **aphasia**, a deficit in the ability to use or understand words. PET scans of people reading or speaking have revealed heightened activity of the same areas in the left hemisphere (**FIGURE 34.18**), thus identifying several *language areas*:

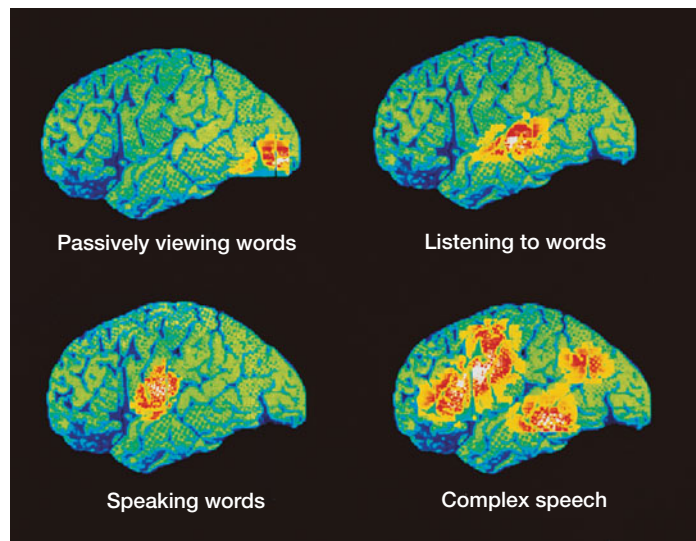

FIGURE 34.18 Imaging Techniques Reveal Active Parts of the Brain Positron emission tomography (PET) scanning reveals the brain regions activated by different aspects of language use. Radioactively labeled glucose is given to the subject. Brain areas take up radioactivity in proportion to their metabolic use of glucose. The PET scan visualizes levels of radioactivity in specific brain regions when a particular activity is performed. The red and white areas are the most active; green and blue the least active.

- **Broca's area**, located in the frontal lobe (see Figure 34.16B), is essential for production of language. Damage to Broca's area results in halting, poorly articulated speech or complete loss of speech, as well as loss of the ability to write. Patients can still read and can understand speech.
- **Wernicke's area**, located in the temporal lobe (see Figure 34.16B), is essential for understanding language. Damage to Wernicke's area results in loss of the ability both to read and to understand speech. Patients may still produce fluent-sounding, but nonsensical, speechlike sounds.

Normal language ability depends on the flow of information among these and several other areas of the left cerebral cortex.

Some learning and memory can be localized to specific brain areas

Learning is the modification of behavior by experience. *Memory* is the ability of the nervous system to retain what is learned and experienced. Even very simple animals can learn and remember, but these two abilities are most highly developed in humans.

LEARNING Learning that leads to long-term memory must involve long-lasting synaptic changes. One phenomenon that is involved in long-term synaptic changes is **long-term potentiation (LTP)**. In LTP, high-frequency electrical stimulation of certain neuronal circuits makes these circuits more sensitive to subsequent stimulation.

Several kinds of learning exist. A form that is widespread among animal species is **associative learning**, in which two unrelated stimuli become linked to the same response. The simplest example of associative learning is the **conditioned reflex**, described by the Russian physiologist Ivan Pavlov. Pavlov observed that a dog salivates at the sight or smell of food—a simple autonomic reflex. He discovered that if he rang a bell just before food was presented to the dog, after a few trials the dog would salivate at the sound of the bell, even if no food followed. The salivation reflex was “conditioned” to be associated with the sound of a bell, a stimulus that normally is unrelated to feeding and digestion.

More complex forms of learning, often referred to as *observational learning*, are the foundation of human intelligence. The general pattern of successful observational learning has three elements:

- We pay attention to another person’s behavior.
- We retain a memory of what we have observed.
- We try to copy or use that information.

A key to this scheme of learning is the way in which we create and recall memories.

MEMORY You experience several forms of memory everyday. Memory of facts—people, places, and events that you can consciously recall and describe—is **declarative memory**. **Procedural memory**, in contrast, is the memory of how to perform a motor task. When you learn to ride a bicycle or use a computer keyboard, you form procedural memories.

Declarative memory lasts varying lengths of time. You have *immediate memory* for events that are happening right now. Immediate memory is virtually photographic, but it is retained for only seconds. *Short-term memory* contains less information but lasts longer—10 to 15 minutes. If you are introduced to a group of new people, you may remember most of their names for a few minutes, but you will have forgotten them in an hour or so if you have not written them down or used them in a conversation. Repetition facilitates the transfer of short-term memory to *long-term memory*, which can last for days, months, or a lifetime.

Where in the brain does memory reside? Electrical stimulation of small areas of association cortex (those areas devoted to the integration of sensory information) elicits recall of vivid memories. Destroying a small area does not completely erase a memory, however, so memory may be distributed over many brain regions. Additional clues come from observations of persons who have lost parts of the limbic system, notably the hippocampus. A famous case is that of the man identified as H.M., whose hippocampus on both sides of the brain was removed in 1953 in an effort to control severe epilepsy. After the surgery, H.M. was unable to transfer information to long-term memory. If someone was introduced to him and then left the room for several minutes, when that person returned, H.M. did not recognize him. Up until his death 55 years later, H.M. remembered events that happened before his surgery but could not remember postsurgery events for more than a few minutes.

Although H.M. was incapable of forming declarative memories, he could form procedural memories. When taught a motor

task day after day, he could not consciously recall the lessons of the previous day, yet his performance steadily improved. Thus procedural memory must involve mechanisms different from those used in declarative memory.

There are two different states of sleep

All vertebrates (and many invertebrates) sleep, even those that must take considerable risks to do so, such as prey animals and marine mammals (which risk drowning when they sleep, yet sleep anyway). We humans spend one-third of our lives sleeping. Lack of sleep results in a progressive decline in alertness and function, impaired learning, immune system suppression, hormonal changes, hypothermia, and many other pathological changes.

How we fall asleep and what happens in our brains while we sleep have been the subject of a great deal of research in recent years. A primary tool of sleep researchers is the *electroencephalogram*, or EEG, where electrodes are placed at different locations on the subject’s scalp. Rather than recording the activity of single neurons, the EEG characterizes the electrical activity of entire brain regions, primarily those of the cerebral cortex. EEG studies have revealed that, in birds and mammals, there are two very different sleep states: **rapid eye movement (REM) sleep** and **non-REM sleep** (FIGURE 34.19A).

When we are awake, clusters of neurons with specific neurochemical characteristics (called *nuclei*, but unrelated to the nuclei of cells) in different regions of the brainstem are continuously active. Their axons project broadly to the forebrain, where they release depolarizing neurotransmitters. These neurotransmitters keep the resting potentials of the neurons of the thalamus and cortex close to threshold and sensitive to synaptic inputs, thereby maintaining the responsiveness of the brain that characterizes being awake.

With the onset of sleep, these brainstem neurons release less neurotransmitter. As a result, the resting potentials of the cells of the thalamus and cortex become more negative (hyperpolarized) and are less sensitive to excitatory synaptic input. Their processing of information is inhibited, and consciousness is lost. This state is non-REM sleep. As non-REM sleep deepens, neurons over broad areas of the cerebral cortex begin to fire action potentials in slow, synchronized bursts (see Figure 34.19A, Stages 3 and 4). Because an EEG records these bursts as large deflections with a slow wavelength, this stage of non-REM sleep is called *slow-wave sleep*.

After some time in non-REM sleep, a dramatic change occurs. Some of the brainstem neurons that were inactive suddenly become active again, causing a general depolarization of cortical neurons. The synchronized bursts of firing cease, and the EEG resembles that of the awake brain (see Figure 34.19A, REM). Because the resting potentials of the neurons return to near-threshold levels, the cortex can again process information. This is the state of REM sleep, so named because the eyes—even behind closed eyelids—move rapidly during this stage. Vivid dreams occur during REM sleep.

During REM sleep, the brain inhibits both afferent (sensory) and efferent (motor) pathways. In other words, during REM

FIGURE 34.19 Stages of Sleep (A) Electrical activity in the cerebral cortex is detected by electrodes that are placed on the scalp and record changes in voltage between the electrodes through time. The resulting record is an electroencephalogram, or EEG. (B) Humans cycle through different stages of sleep throughout the night.

sleep our active brains are isolated from the external sensory world, and we are paralyzed (which is why we may have trouble awakening ourselves from a nightmare even when we realize we are dreaming). The bizarre nature of dreams may be due to the lack of sensory information—the cortex is functioning but is out of touch with reality. The muscle paralysis prevents the acting out of dreams. (Sleepwalking occurs during non-REM sleep.)

After a period of REM sleep, we return to non-REM sleep. We cycle repeatedly between non-REM and REM sleep, and similar sleep cycles occur in other mammals (**FIGURE 34.19B**).

Why do we have two sleep states with very different neurophysiological characteristics? Why does non-REM sleep always occur first? Why do the two states cycle? Understanding the cellular mechanisms of sleep has not yet answered these questions. We know sleep is essential for life, but we don't know why. Various hypotheses hold that sleep may be necessary for proper immune function, for the maintenance and repair of neural connections, and for the neural changes involved in learning and memory. The last hypothesis is supported by experiments showing that performance of a learned task is impaired if sleep is prevented, and is enhanced following a period of sound sleep.

We still cannot answer the question “What is consciousness?”

Even with all of our current knowledge of the human brain, we still cannot answer the question “What is consciousness?” Consciousness is the sense of being mentally aware of yourself, your environment, events going on around you, and your past, in such a way that you can plan for future events and make decisions.

The central requirement for consciousness is a perception of self that can be integrated with information from the environment and from past experience. A perception of self could, in theory, be derived from the afferent (sensory) information that comes from all parts of the body. Generally, this afferent

information goes to appropriate areas in the brainstem and forebrain. Visual information goes to the visual cortex, somatosensory information goes to the somatosensory cortex, and so on. However, all sensory information also goes to an area deep within the forebrain called the *insular cortex*, or *insula*. The insula appears to integrate information from all over the body to create a sensation of how the body “feels.”

In humans, great apes, and a few other mammals (e.g., dolphins and elephants), the insula is greatly expanded and has types of neurons not seen in other animals. The circuitry of the insula has also expanded to communicate with parts of the brain that are involved in planning and decision making. In imaging studies, the insula is seen to be active in a great diversity of situations that involve strong feelings, be they pleasure, disgust, humor, pain, lust, guilt, or empathy. Damage to the insula results in apathy, loss of ability to enjoy music or good food, and loss of sexual response. Fascinatingly, the few species that have expanded insulas and the unusual neurons are also the only species that are able to recognize themselves in a mirror. Could it be that this tiny part of our brains contains the neurobiological bases for self-awareness and conscious experience?

Do You Understand Concept 34.5

- Read this sentence out loud. Then name the brain areas you used to perform the feat of seeing a printed sentence, understanding it, saying it out loud, and finally hearing your own voice.
- Compare and contrast slow-wave sleep and REM sleep. Which one is more similar to the “awake” state?
- Birds that store seeds for the winter in hidden locations often have a very well developed hippocampus. Why?

The next two chapters will encompass two major aspects of the nervous system: the sensory neurons and connections that receive and process information from the environment; and the musculoskeletal system that makes behavior possible.

How can a small brain tumor so dramatically affect personality and behavior?

ANSWER Charles Whitman's brain tumor was just below his thalamus and was about the size of a walnut. It was pressing on his hypothalamus and parts of his limbic system, notably the *amygdala* (FIGURE 34.20). The amygdala is involved with intense emotions such as fear. When the neurons of the amygdala are activated and fire action potentials, you experience fear. If you are faced with a threatening situation, your amygdala is activated.

People with a damaged amygdala frequently have trouble engaging in normal social relationships. They cannot "read" the nature, mood, or intentions of other people by looking at their faces. This loss of the ability to assess the possible negative consequences of one's actions is effectively the loss of the ability to perceive fear. Without an amygdala, you would never be frightened—and not being frightened could be hazardous to your health. Conversely, studies in which the amygdalas of animals and humans have been stimulated electrically produce intense expressions of fear and rage.

FIGURE 34.20 Source of the Fear Response Frightening situations—or even memories of such a situation—activate a brain region called the amygdala, as shown in this functional magnetic resonance image (fMRI) of the brain of a person experiencing fear.

The pressure on Charles Whitman's amygdala might have been a factor in the emotions that drove him to mass murder. This sad case is a vivid example of how the actions of neurons in certain parts of the brain underlie the core of who we are—our individual behaviors and personalities. Understanding these brain systems and how they function in health and disease is critical to the development of improved therapies for psychiatric illnesses.

34

SUMMARY

concept
34.1

Nervous Systems Consist of Neurons and Glia

- The cells of the nervous system are either **neurons** or **glia**. Neurons generally receive information via their **dendrites** and transmit information via their **axon**. **Review Figure 34.1**
- Glia include **Schwann cells** and **oligodendrocytes**, both of which generate **myelin** sheets on axons. Glia also include **astrocytes**, which contribute to the **blood-brain barrier**. **Review Figure 34.2**
- Neurons are organized in networks with sensory inputs (**afferent neurons**), outputs (**efferent neurons**), and integration (**interneurons**). These networks may be simple or complex. **Review Figure 34.3**

concept
34.2

Neurons Generate and Transmit Electrical Signals

- Neurons have an electric charge difference across their plasma membranes, called the **membrane potential**. The membrane potential is created by ion transporters and channels. In inactive neurons, the membrane potential is called the **resting potential**.

Review Figures 34.4 and 34.5 and ANIMATED TUTORIAL 34.1

- The **sodium-potassium pump** concentrates K^+ on the inside of a neuron and Na^+ on the outside. Potassium channels allow K^+ to diffuse out, causing the resting potential to be negative. **Review Figure 34.5**
- The **Nernst equation** can be used to calculate the equilibrium potential of a single ion. **Review WEB ACTIVITY 34.1**
- When ion channels open or close, the plasma membrane can become **depolarized** or **hyperpolarized**. This causes a **graded membrane potential**. **Review Figure 34.6**
- An **action potential** is a rapid reversal in charge across a portion of the plasma membrane resulting from the opening and closing of **voltage-gated channels** of Na^+ and K^+ . These voltage-gated channels open when the plasma membrane depolarizes to a **threshold** level. **Review Figure 34.7 and ANIMATED TUTORIAL 34.2**
- Action potentials are all-or-none, self-regenerating events. They are conducted down axons because local current flow depolarizes adjacent regions of membrane and brings them to threshold.

- In myelinated axons, action potentials jump between **nodes of Ranvier**, patches of membrane that are not covered by myelin. **Review Figure 34.8**

concept 34.3 Neurons Communicate with Other Cells at Synapses

- Neurons communicate with each other and with other cells by transmitting information over **chemical synapses** (with neurotransmitters) or **electrical synapses**.
- The **neuromuscular junction** is a well-studied chemical synapse between a motor neuron and a skeletal muscle cell. Its neurotransmitter is acetylcholine (ACh). **Review Figure 34.9**
- When an action potential reaches an axon terminal, it causes the release of neurotransmitters, which diffuse across the **synaptic cleft** and bind to receptors on the postsynaptic membrane. **Review Figures 34.9 and 34.10, ANIMATED TUTORIAL 34.3, and INTERACTIVE TUTORIAL 34.1**
- Synapses between neurons can be either **excitatory** or **inhibitory**. A postsynaptic neuron integrates information by summation of excitatory and inhibitory postsynaptic potentials in both space (**spatial summation**) and time (**temporal summation**). **Review Figure 34.11**
- There are many different neurotransmitters and types of receptors. The action of a neurotransmitter depends on the receptor to which it binds.
- Synapses can be fast or slow, depending on the nature of their receptors. **Ionotropic receptors** are ion channels and generate fast, short-lived responses. **Metabotropic receptors** initiate second-messenger cascades that lead to slower, more sustained responses.

concept 34.4 The Vertebrate Nervous System Has Many Interacting Components

- The brain and **spinal cord** make up the **central nervous system (CNS)**; neurons that extend or reside outside the brain and the spinal cord, together with their supporting cells, make up the **peripheral nervous system (PNS)**. **Review Figure 34.12**
- The **autonomic nervous system (ANS)** is the part of the PNS that controls involuntary physiological functions. Its **sympathetic** and **parasympathetic** divisions differ in anatomy, neurotransmitters, and effects on target tissues. **Review Figure 34.13**
- The spinal cord communicates information between the brain and the rest of the body. It can issue some commands to the body

without input from the brain (reflexes). **Review Figure 34.14 and ANIMATED TUTORIAL 34.4**

- The embryonic brain consists of a hindbrain, midbrain, and forebrain. The forebrain develops into the **cerebral hemispheres** (the **telencephalon**, or **cerebrum**) and the underlying thalamus and hypothalamus (which together compose the **diencephalon**). The midbrain and hindbrain develop into the **brainstem** and the **cerebellum**.
- The **reticular system** is a complex network in the brainstem that controls various autonomic functions and transmits sensory information to the forebrain.
- The **limbic system** is an evolutionarily primitive part of the telencephalon that is involved in emotions, physiological drives, instincts, and memory. **Review Figure 34.15**
- The cerebral hemispheres are the dominant structures of the human brain. Their surfaces are layers of neurons called the **cerebral cortex**. **Review Figure 34.16**
- Each cerebral hemisphere can be divided into temporal, frontal, parietal, and occipital lobes. Many motor functions are localized in the **frontal lobe**. Information from many sensory receptors projects to the **parietal lobe**. Visual information goes to the **occipital lobe**, and auditory and visual information goes to the **temporal lobe**. **Review Figure 34.16 and WEB ACTIVITY 34.2**

concept 34.5 Specific Brain Areas Underlie the Complex Abilities of Humans

- Language abilities are localized mostly in the left cerebral hemisphere, a phenomenon known as **lateralization**. Different areas of the left hemisphere are responsible for the production and understanding of language. **Review Figure 34.18**
- Complex memories can be elicited by stimulating small regions of association cortex. Damage to the hippocampus can destroy the ability to form long-term **declarative memory** but not **procedural memory**.
- Most animals, including humans, have a daily cycle of sleep and waking. Sleep can be divided into **rapid-eye-movement (REM) sleep** and **non-REM sleep**. **Review Figure 34.19**
- A sense of the physiological state of the body may be created in the insular cortex. Evolution of this integrative function could be the basis for conscious experience.

See WEB ACTIVITY 34.3 for a concept review of this chapter.

On moonless, pitch-black nights in the desert, kangaroo rats move silently about to forage and to seek mates. When two kangaroo rats meet, they immediately identify each other's gender and behave accordingly—males fight with other males and try to court females. We may not be able to observe their behavior in total darkness, but they can easily identify each other, interact, and also gather food. However, other denizens of the desert can observe the kangaroo rats and attempt to capture them for food.

If a kangaroo rat chances to hop near a coiled rattlesnake, the snake can detect the rat, accurately fix its location, and with a lightning fast strike attempt to nail the rat. But even as the strike of the rattlesnake is in process, the kangaroo rat senses it and can make a giant leap that usually saves it from the deadly fangs. Another predator of kangaroo rats comes silently from the air. Also in total darkness, an owl can swoop down, flare its wings and extend its talons just above the ground, and accurately seize an unlucky kangaroo rat.

Similar dramas play out overhead. Moths fly about seeking mates as well as night-blooming, nectar-producing plants. Bats pursue the moths and are amazingly accurate in detecting and capturing them in flight. Frequently, however, the moths use a very specific behavior to escape. As a bat is closing in, the moth suddenly dives straight down, and the bat misses its prey.

These feats of detection and identification of individuals of the same or different species in total darkness, and these feats of prey capture and predator avoidance, are remarkable. The kangaroo rat distinguishes when another kangaroo rat is a male or a female. The rattlesnake and the

owl detect potential prey at a distance and accurately attack. The kangaroo rat senses the lightning fast strike of the snake and avoids it. The bats accurately home in on fluttering moths, and the moths sense the incoming bat and take evasive action.

A human being would not even be able to observe any of these nighttime dramas without the benefit of special technologies. We may have impressive sensory capabilities of our own, such as excellent color vision during the daytime, but in a nighttime desert, we would be humbled by the remarkable sensory capabilities of the animals that live there.

How do kangaroo rats, rattlesnakes, owls, bats, and moths “see in the dark”?

The acute senses of this barn owl (*Tyto alba*) have enabled it to detect and capture its kangaroo rat prey.

KEY CONCEPTS

- 35.1** Sensory Systems Convert Stimuli into Action Potentials
- 35.2** Chemoreceptors Detect Specific Molecules or Ions
- 35.3** Mechanoreceptors Detect Physical Forces
- 35.4** Photoreceptors Detect Light

concept 35.1 Sensory Systems Convert Stimuli into Action Potentials

Sensory receptor cells, sometimes simply called *sensors* or *receptors*, transduce (convert) sensory stimuli such as light, sound, and touch into changes in membrane potential that cause in these cells or in neighboring cells the generation of action potentials (see Concept 34.2). These action potentials convey the sensory information to the central nervous system for processing and interpretation. In the first step in this process, a sensory cell must somehow respond to a certain type of stimulus with a change in membrane potential.

Sensory transduction involves changes in membrane potentials

Sensory transduction typically begins with a **receptor protein** that opens or closes ion channels in response to a specific stimulus, such as heat or light. The resulting change in ion flow alters the receptor cell's membrane potential. A change in the membrane potential of a receptor cell in response to a stimulus is called a **receptor potential**. Receptor potentials are *graded membrane potentials* that spread over only short distances. To travel long distances in the nervous system, receptor potentials must generate action potentials, which they can do in two ways:

- The receptor potential may trigger action potentials in the receptor cell itself.
- The receptor potential may cause the receptor cell to release neurotransmitters that can induce a postsynaptic neuron to generate action potentials.

A good model of how a receptor cell generates action potentials can be seen in the *stretch receptor* of a crayfish (**FIGURE 35.1**). Stretching of the muscle to which the stretch receptor is attached causes receptor potentials. These receptor potentials spread to the base of the cell's axon, where they generate action potentials that travel down the axon to the CNS. The rate at which action potentials are fired depends on the magnitude of the receptor potential; that magnitude, in turn, depends on how much the muscle is stretched.

In receptor cells that do not fire action potentials (such as the photoreceptors in the retina), the receptor potential induces the release of neurotransmitter. The intensity of the stimulus influences how much neurotransmitter is released.

LINK Review the mechanics of graded membrane potentials and action potentials in Concept 34.2 and of synaptic transmission in Concept 34.3

Different sensory receptors detect different types of stimuli

Different types of sensory receptor proteins respond to particular types of environmental energy. *Mechanoreceptors* detect physical forces, such as pressure (touch) and variations

FIGURE 35.1 Stimulating a Sensory Cell Produces a Receptor Potential Signal transduction in the stretch receptor of a crayfish can be investigated by measuring the membrane potential at different places on the stretch receptor neuron while stretching the muscle innervated by that sensory neuron.

in pressure (sound waves); the crayfish cell described above contains mechanoreceptors in its dendrites. *Thermoreceptors* respond to temperature. *Electrosensors* are directly sensitive to changes in membrane potential. *Chemoreceptors* respond to the presence or absence of certain specific chemicals, and *photoreceptors* detect light. All of these receptor proteins respond to the appropriate stimulus by causing changes in ion flow (i.e., by directly or indirectly causing ion channels to open or close; **FIGURE 35.2**). These changes in ion flow result in a receptor potential.

Some sensory receptor cells are assembled with other types of cells into *sensory organs*, such as eyes, ears, and noses, that enhance the ability of the sensory cells to collect, filter, and amplify stimuli. A **sensory system** consists of sensory cells, the associated structures, and the neural networks that process the information.

Sensation depends on which neurons receive action potentials from sensory cells

All sensory systems, no matter what type of stimulus they detect, convey information in the form of action potentials. But the sensations we perceive—such as heat, pressure, light, smell, and sound—differ because the messages from different kinds of sensory cells arrive at different places in the CNS. Action potentials arriving in the visual cortex of the brain are interpreted as light, in the auditory cortex as sound, in the olfactory bulb as odors, and so forth. Action potentials arriving from the various

FIGURE 35.2 Sensory Receptor Proteins Respond to Stimuli by Opening or Closing Ion Channels Some receptor proteins are themselves ion channels. Others initiate signal transduction cascades that eventually open or close ion channels.

sensory neurons in a patch of skin may be perceived as heat, cold, itch, pressure, or pain, depending on which neuron is involved and which pathways of the CNS are stimulated. The intensity of the sensation, meanwhile, is coded as the frequency of action potentials.

Some sensory cells transmit information about internal conditions in the body, but we may not be consciously aware of that information. The brain continuously receives information about body temperature, blood carbon dioxide and oxygen concentrations, arterial pressure, muscle tension, and the positions of the limbs—all of which are important for homeostasis. All of this sensory information goes to the CNS, but it does not always result in conscious sensation.

Many receptors adapt to repeated stimulation

Some sensory cells give gradually diminishing responses to maintained or repeated stimulation. This phenomenon is known as **adaptation**, and it enables an animal to ignore background or unchanging conditions while remaining sensitive to changes or to new information. (Note that this use of the term “adaptation” is different from its application in an evolutionary context.) When you dress, you feel each item of clothing touch your skin, but the sensation of clothes touching your skin soon fades from awareness. You are immediately aware, however, of new sensations, such as someone touching your back.

Some sensory cells adapt very little or very slowly, such as pain receptors and the mechanoreceptors for balance. You shouldn’t ignore pain, because it is signaling that something is wrong in your body, and to maintain equilibrium you must continuously know (albeit unconsciously) the tensions and forces on all of your joints and muscles.

Do You Understand Concept 35.1?

- An ice cube held in your fingertips causes the sensation of cold, whereas a pinprick to the same finger causes the quite different sensation of pain. How can action potentials from the same patch of skin result in such different sensations?
- We have stretch receptors in our skeletal muscles (see Figure 34.14). Would you expect them to adapt to a prolonged stretch? Why or why not?
- A cell on a mosquito’s foot responds to heat, letting the mosquito know if it has landed on a warm body. Another cell on its antennae detects the CO_2 exhaled by other animals. What types of sensory receptor proteins do these cells probably contain?

The remainder of this chapter will discuss specific types of sensory receptors and their associated sensory systems. We will begin with chemosensation, the basis of smell and taste.

concept 35.2 Chemoreceptors Detect Specific Molecules or Ions

A colony of corals responds to a small amount of meat extract in seawater by extending bodies and tentacles and searching for food; a solution of a single amino acid can stimulate this response. Conversely, a small amount of seawater in which corals were crushed will stimulate a defensive retraction of the coral polyps. Humans react strongly to certain chemical stimuli. When we smell freshly baked bread, we salivate and feel hungry; when we smell rotting meat, we feel nauseated.

All animals receive information about chemical stimuli through **chemoreceptors**, which are receptor proteins that bind to certain molecules. Chemoreceptors are also responsible for

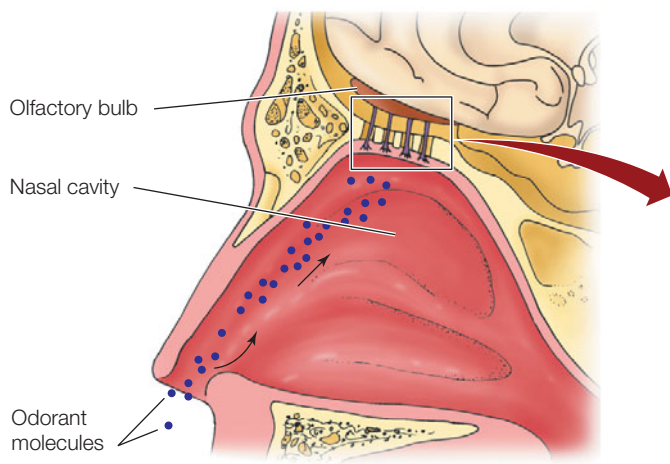

FIGURE 35.3 Olfactory Receptors Communicate Directly with the Brain The receptor cells of the human olfactory system are embedded in epithelial tissues lining the nasal cavity and send their axons to the olfactory bulb of the brain.

monitoring some aspects of the internal environment, such as the level of carbon dioxide in the blood.

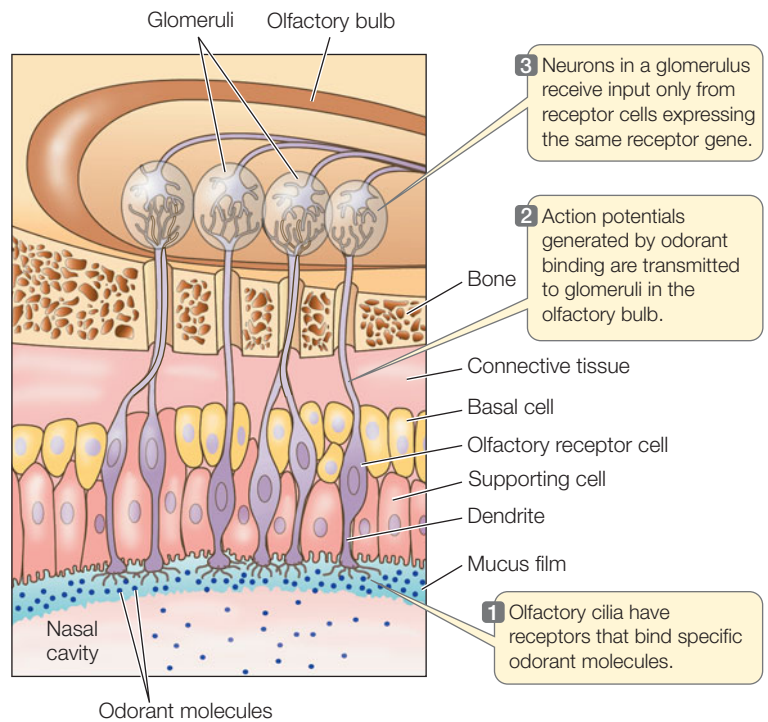

Olfaction is the sense of smell

In vertebrates, the sense of smell, **olfaction**, depends on olfactory sensors—chemoreceptive neurons—embedded in a layer of epithelial tissue at the top of the nasal cavity (**FIGURE 35.3**). The axons from these neurons extend to the olfactory integration area of the brain (the *olfactory bulb*), whereas their dendrites end in olfactory cilia on the surface of the nasal epithelium. A protective layer of mucus covers the epithelium. Molecules from the environment must diffuse through the mucus to reach the receptor proteins on the olfactory cilia. When you have a cold, the amount of mucus in your nose increases and the epithelial tissue swells; this is why you can temporarily lose your sense of smell.

The olfactory world has an enormous number of odors and a correspondingly large number of olfactory receptor proteins. In the 1990s, Linda Buck and Richard Axel discovered a family of about 1,000 genes in mice (about 3 percent of the mouse genome) that code for olfactory receptor proteins (a discovery that won them a Nobel Prize). Each receptor protein is found in a limited number of receptor cells in the olfactory epithelium, and each cell expresses just one type of receptor protein. Each receptor can bind to a set of similar molecules called **odorants**.

When an odorant binds to a receptor, it activates a G protein. The G protein in turn activates an enzyme that causes an increase of a second messenger (cAMP in vertebrates) in the cytoplasm (see the chemoreceptor panel in Figure 35.2). The second messenger causes an influx of Na^+ , depolarizing the olfactory neuron.

LINK G protein-linked receptors are involved in many sensory mechanisms and are described in Concept 5.5; see especially Figure 5.14

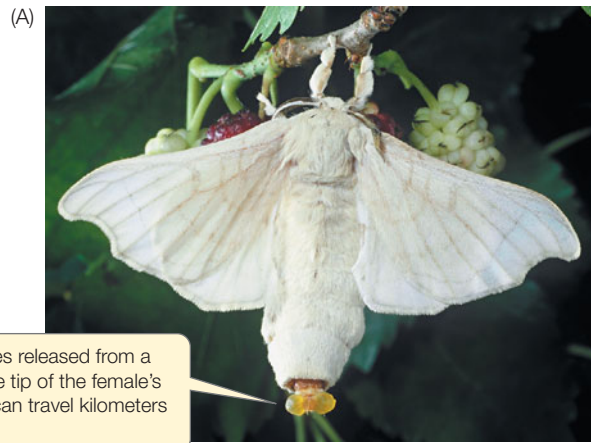

The next stage of processing olfactory information is in the olfactory bulb, where axons from neurons expressing the same receptor protein cluster together on the dendrites of olfactory bulb neurons, forming structures called *glomeruli* (singular *glomerulus*; see Figure 35.3). A complex odorant molecule may bind to several different types of receptor proteins, and thus can activate a unique combination of glomeruli in the olfactory bulb. Therefore an olfactory system with hundreds of different receptor proteins can discriminate an astronomically large number of smells. The more odorant molecules that bind to receptors, the greater the frequency of action potentials and the greater the intensity of the perceived smell.

Humans are unusual among mammals in that we depend more on vision than on olfaction. About two-thirds of the mammalian genes for olfactory receptor proteins are thought to be nonfunctional in humans, and our nasal anatomy reflects the reduced importance of olfaction. A typical dog's nasal epithelium is 15–20 times larger than a human's and has about 1 *billion* olfactory receptors, compared with about 20 million in humans. Dogs can detect some scents at concentrations 100 million times lower than humans can. The olfactory worlds of dogs, and of most mammals, are much richer than ours.

Some chemoreceptors detect pheromones

A specialized type of chemical signal used for communication among members of the same species is a **pheromone**. Many animals use pheromones to attract mates, and often these are detected by specialized chemoreceptors that are separate from the primary olfactory system.

Male moths have chemoreceptors in their antennae, which are used to detect the presence of female moths (**FIGURE 35.4**).

Pheromones released from a gland at the tip of the female's abdomen can travel kilometers downwind.

A male moth detects this pheromone in the air passing over his antennae, which are covered with chemo-sensitive hairs.

FIGURE 35.4 Some Scents Travel Great Distances Mating in silkworm moths of the genus *Bombyx* is coordinated by pheromones released from the female.

In the silkworm moth *Bombyx mori*, for example, a female releases a blend of pheromone molecules from a gland at the tip of her abdomen; the male silkworm moth has receptors for these molecules on his antennae. Each feathery antenna carries about 10,000 pheromone-sensitive hairs. A single molecule of pheromone may be sufficient to generate action potentials in the antennal nerve. When approximately 200 hairs per second are activated, the male orients upwind in search of the female. Because the rate of firing in the male's sensory nerves is proportional to the pheromone concentration in the air, he can follow the airborne concentration gradient and home in on the signaling female.

Many vertebrates use pheromones, often detecting them with a specialized olfactory organ called the **vomer nasal**

organ, or **VNO**. The VNO is a small, paired tubular structure embedded deep within the nasal epithelium. When the animal sniffs, the VNO draws a sample of nasal fluid over the chemoreceptors embedded in its walls. The information from these chemoreceptors goes to an accessory olfactory bulb in the brain, and from there to brain regions involved in sexual and other instinctive behaviors. Some humans have a very small, vestigial VNO that is probably nonfunctional.

Gustation is the sense of taste

In terrestrial vertebrates, the sense of taste, or **gustation**, depends on clusters of chemoreceptors in **taste buds** in the mouth. Some fishes have taste buds in their skin that allow them to find food without the use of vision. The duck-billed platypus, a prototherian mammal (see Figure 23.50A), has similar abilities as a result of taste buds on the sensitive skin of its bill.

APPLY THE CONCEPT

Chemoreceptors detect specific molecules or ions

If the vomeronasal organ of a male rodent is surgically removed, both his mating behavior toward females and aggressive behavior toward other males are impaired. One hypothesis to explain this finding is that the VNO is essential for detecting pheromones given off by sexually receptive females, and that these pheromones stimulate male mating behavior and aggression. Catherine Dulac and her students genetically engineered male mice so they lacked one of the VNO receptor ion channels, called TRPC2. Normal (TRPC2^{+/+}) and receptor-deficient (TRPC2^{-/-}) male mice were tested by placing castrated male mice or female mice into their cages and observing the behavior of the normal (control) and receptor-deficient (experimental) male mice. The experiments were repeated with the castrated male mice being swabbed with urine from intact males. Use the results shown in the table to answer the questions.

RESIDENT MOUSE GENOTYPE	INTRUDER MOUSE ^a			
	CASTRATED ♂	FEMALE	CASTRATED ♂, URINE-SWABBED	FEMALE, URINE-SWABBED
TRPC2 ^{+/+}	N	M	A	A
TRPC2 ^{-/-}	M	M	M	M

^aThe resident's behavior when confronted with different intruders was scored as neutral (N), aggressive (A), or mating attempted (M).

1. Do the results of these experiments support the hypothesis that TRPC2 receptors are essential for males to respond to female pheromones? Why or why not?
2. What function(s) can you hypothesize for the TRPC2 receptor?

The human tongue has approximately 10,000 taste buds, mostly embedded in the epithelium on the sides of papillae (FIGURE 35.5). (Look at your tongue in a mirror—the papillae make it look fuzzy.) Each taste bud has a pore that exposes the tips of sensory receptor cells. These sensory cells generate action potentials when they are exposed to certain chemicals. They synapse at their bases with sensory neurons that convey the information to the CNS.

Humans perceive at least five tastes—sweet, salty, sour, bitter, and *umami* (a savory, meaty taste). Much of our experience of taste is actually due to our olfactory receptors, which is why you lose much of your sense of taste when you have a cold.

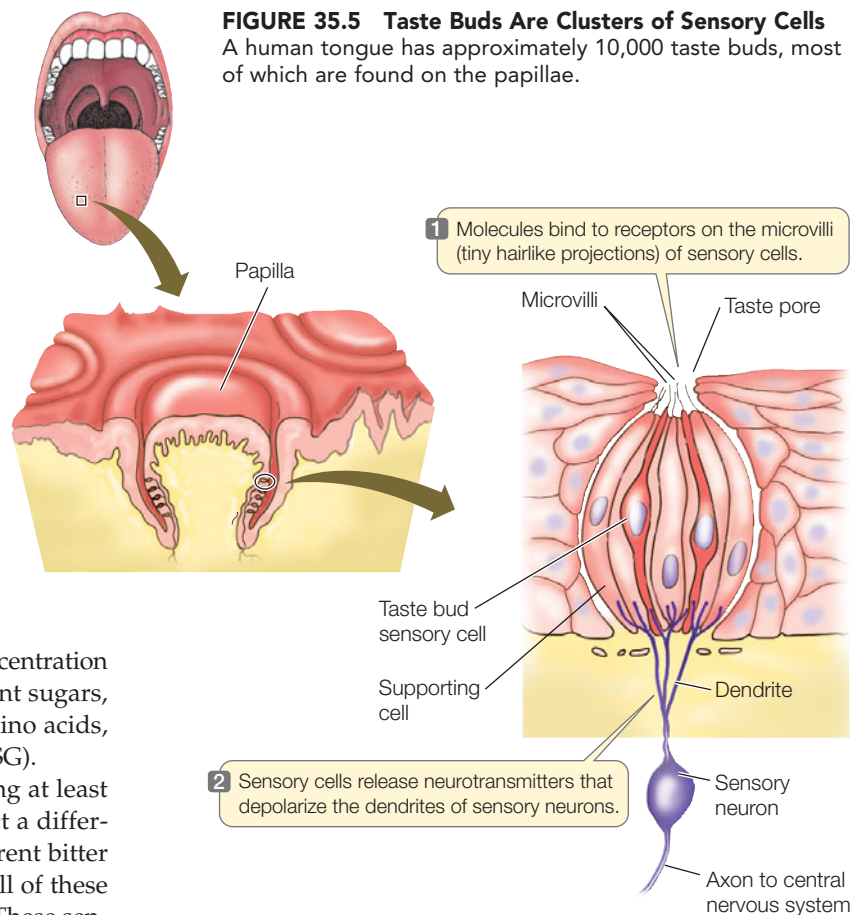

Research has identified the mechanism of action of all five taste perceptions. “Salty” receptors allow sodium to diffuse through open Na^+ channels, directly depolarizing the sensory cell. “Sour” receptors are in fact detecting acidity—that is, the concentration of H^+ . “Sweet” receptors bind to a variety of different sugars, and the umami receptor detects the presence of amino acids, such as the glutamate in monosodium glutamate (MSG).

Bitterness is the most complicated taste, involving at least 30 different taste receptors. Each of these can detect a different molecule at very low concentration. Many different bitter receptors may be present on the same cell, so that all of these different molecules evoke the same taste sensation. These sensitive “bitter” taste receptors probably evolved in response to toxic plant compounds such as quinine, caffeine, and nicotine. Plants produce many such toxic molecules because they repel herbivorous predators; the ability to detect these potentially dangerous molecules in the plants we consume is thus adaptive.

Do You Understand Concept 35.2

- Which sense, olfaction or gustation, has more types of chemoreceptor proteins?
- Explain why we have evolved dozens of different bitterness taste receptors but only one type of saltiness receptor.
- Most dogs can distinguish millions of different odors. Explain how this is possible when a dog’s nose contains only about 1,000 different types of olfactory receptors.

We’ve seen how chemoreceptors can give rise to the senses of smell and taste. We will turn next to mechanoreceptors, the sensory cells that respond to mechanical forces.

concept 35.3 Mechanoreceptors Detect Physical Forces

Mechanoreceptors are cells that detect a variety of physical forces. Physical distortion of a mechanoreceptor’s plasma membrane causes ion channels to open, creating a receptor potential that in turn can lead to the release of neurotransmitter or the generation of action potentials. A considerable diversity of mechanosensory cells and mechanisms has evolved. Involved in many sensory systems, their functions range from interpreting skin sensations to sensing blood pressure to hearing and maintaining balance.

Many different cells respond to touch and pressure

The most obvious sensory receptors in your skin are the many *free nerve endings* that detect heat, cold, and pain. Mammalian skin is also packed with diverse mechanoreceptors that generate varied sensations (FIGURE 35.6). The most important tactile receptors are *Merkel’s discs*, which adapt rather slowly and provide continuous information about things touching the skin. *Meissner’s corpuscles* are very sensitive but adapt rapidly, so they provide information about *changes* in objects contacting the skin. The rapid adaptation of Meissner’s corpuscles is why you roll a small object between your fingers (rather than

FIGURE 35.6 The Skin Feels Many Sensations Even a very small patch of skin contains a variety of sensory cells, making the skin a multimodal receptor that can sense temperature, pressure, texture, pain, touch, and itch.

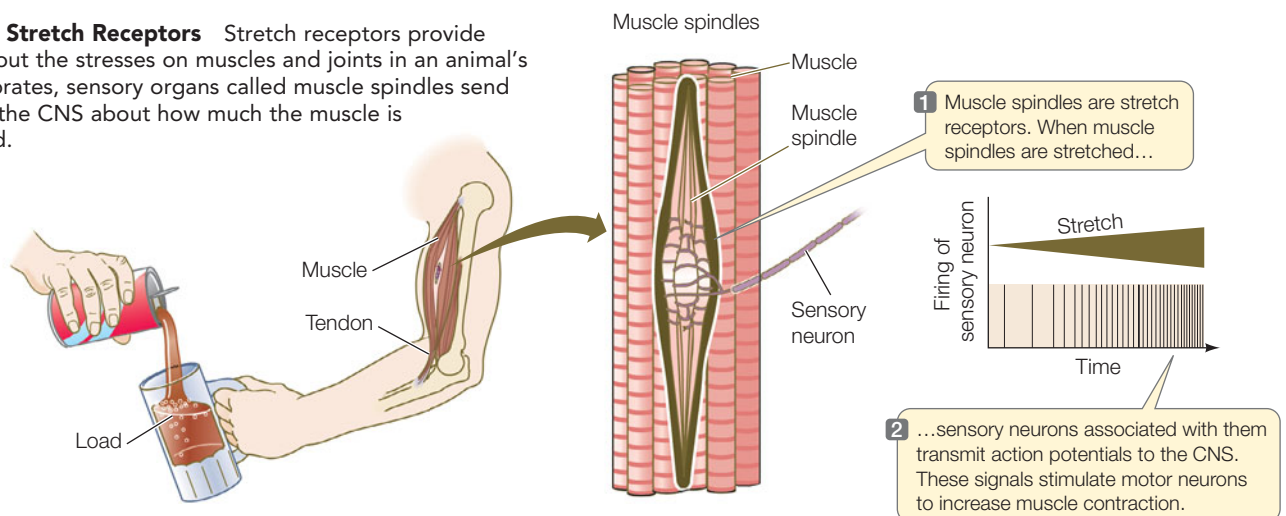

yourBioPortal.com

Go to INTERACTIVE TUTORIAL 35.1
Sensory Receptors

holding it still) to discern its shape and texture: as you roll it, the object continues to stimulate Meissner's corpuscles.

Two other kinds of mechanoreceptors are found deeper in the skin. *Ruffini endings* adapt slowly and are good at providing information about vibrating stimuli of low frequencies. *Pacinian corpuscles*, which adapt rapidly, provide information about high-frequency alternating stimuli, such as when you

FIGURE 35.7 Stretch Receptors Stretch receptors provide information about the stresses on muscles and joints in an animal's limbs. In vertebrates, sensory organs called muscle spindles send information to the CNS about how much the muscle is being stretched.

run your fingers over a rough surface. Even deeper in the skin, dendrites of sensory neurons wrap around hair follicles. When the surface hairs are displaced, as when a mosquito lands on your skin, those neurons are stimulated.

Mechanoreceptors are found in muscles, tendons, and ligaments

Mechanoreceptors also provide information about the position of the limbs and the stresses on muscles and joints. Though we are not consciously aware of this information, it is essential for postural control and the coordination of movements.

For example, skeletal muscle contains mechanoreceptor organs called *muscle spindles*. These contain **stretch receptors**, modified muscle cells that are innervated by sensory neurons. Whenever the muscle is stretched, the muscle spindles are also stretched, and the neurons transmit action potentials to the CNS. The CNS uses this information to adjust the strength of the muscle contraction to match the load put on the muscle (**FIGURE 35.7**). This enables you to hold a glass in a steady position as someone else pours liquid into it.

Another type of mechanoreceptor, the *Golgi tendon organ*, provides information about the force being applied to tendons and ligaments. If a tendon or ligament is loaded to an unusual degree, action potentials from the Golgi tendon organ inhibit the spinal cord motor neurons innervating that muscle, causing it to relax and protecting it from tearing.

Hair cells are mechanoreceptors of the auditory and vestibular systems

The mechanoreceptors of the auditory system are the highly specialized **hair cells**. **Stereocilia**—fingerlike extensions of the cell membrane stiffened by cross-linked actin filaments—project from the surface of each hair cell like a set of organ pipes (**FIGURE 35.8A**). Stereocilia bend in response to waves of pressure; bending of the stereocilia in one direction depolarizes the hair cell, and bending in the other direction hyperpolarizes it (**FIGURE 35.8B**).

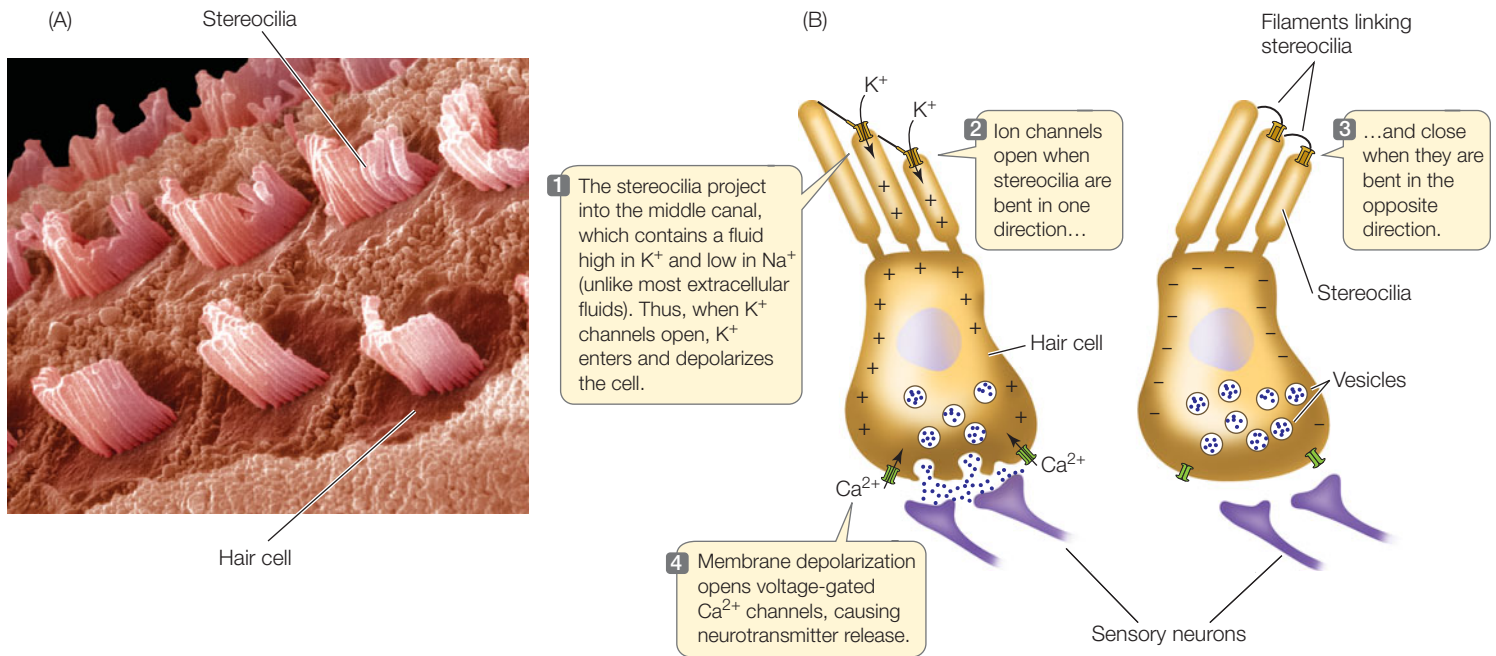

FIGURE 35.8 Hair Cells Have Mechanosensors on Their Stereocilia (A) Hair cells have stereocilia that are connected with each other by small filaments. (B) When a cilium is bent in one direction, the filament opens a mechanosensory ion channel at the tip of the neighboring cilium. The depolarized hair cell releases neurotransmitter onto a sensory neuron.

Measurements with microelectrodes have shown that bending of stereocilia causes local electric currents near their tip, indicating that ion channels near the tips must be opening or closing. Electron microscope images reveal minute filaments that connect the tip of each stereocilium to its taller neighbor. It is hypothesized that these filaments are fine molecular attachments to the ion channels, and that they act like springs that open the channels. If the taller neighboring stereocilium is bent away, the spring tightens and the ion channel is opened. If the taller neighbor bends toward its shorter neighbor, the spring is relaxed and the channel closes (see Figure 35.8B).

Hair cells are the mechanoreceptors for the vertebrate auditory (sound-perceiving) and vestibular (equilibrium-maintaining) systems. Both of these systems are housed in the complex structures of the vertebrate ear.

Auditory systems use hair cells to sense sound waves

Auditory systems use hair cells to convert pressure waves in air into receptor potentials that initiate the perception of sound. Special structures in the ear gather and amplify sound waves and direct them to the hair cells.

OUTER EAR The two prominent structures on the sides of our heads are the *pinnae*. A pinna collects sound waves and directs them into the *auditory canal* (FIGURE 35.9A). The eardrum, or **tympanic membrane**, covers the end of the auditory canal and vibrates in response to sound waves.

MIDDLE EAR The middle ear is an air-filled cavity containing three delicate bones called **ossicles**, individually named the *malleus* (Latin, “hammer”), *incus* (“anvil”), and *stapes* (“stirrup”) (FIGURE 35.9B). Together, the ossicles act as a lever that amplifies vibrations of the tympanic membrane into much more forceful vibrations of another flexible membrane called the **oval window**. Behind the oval window lies the fluid-filled inner ear.

The middle ear is connected to the throat via the **eustachian tube**, allowing air pressure to equilibrate between the middle ear and the outside world. If a eustachian tube becomes blocked because of a respiratory infection, changes in external air pressure can cause the tympanic membrane to stretch or even rupture. If you have ever taken an airplane flight when you had a bad cold, you might have experienced this painful phenomenon.

INNER EAR The inner ear consists of two sets of fluid-filled canals. One is the organ of balance, the **vestibular system**, and the other is the organ of hearing, the **cochlea**. The cochlea (Latin and Greek, “snail” or “spiral shell”) is a long, tapered, coiled canal. A cross section of the cochlea reveals that it is composed of three parallel canals separated by two membranes: **Reissner’s membrane** and the **basilar membrane** (FIGURE 35.9C). Sitting on the basilar membrane is the **organ of Corti**, which transduces pressure waves into action potentials. The organ of Corti contains hair cells with stereocilia. The tips of the longest stereocilia are embedded in a gelatinous overhanging shelf called the *tectorial membrane* (FIGURE 35.9D).

Because their tips are attached to the more rigid tectorial membrane, the stereocilia are bent when the basilar membrane flexes. The response of the hair cell is a graded membrane potential. Hair cells do not fire action potentials themselves, but they release neurotransmitter onto sensory neurons, which transmit action potentials to the brain.

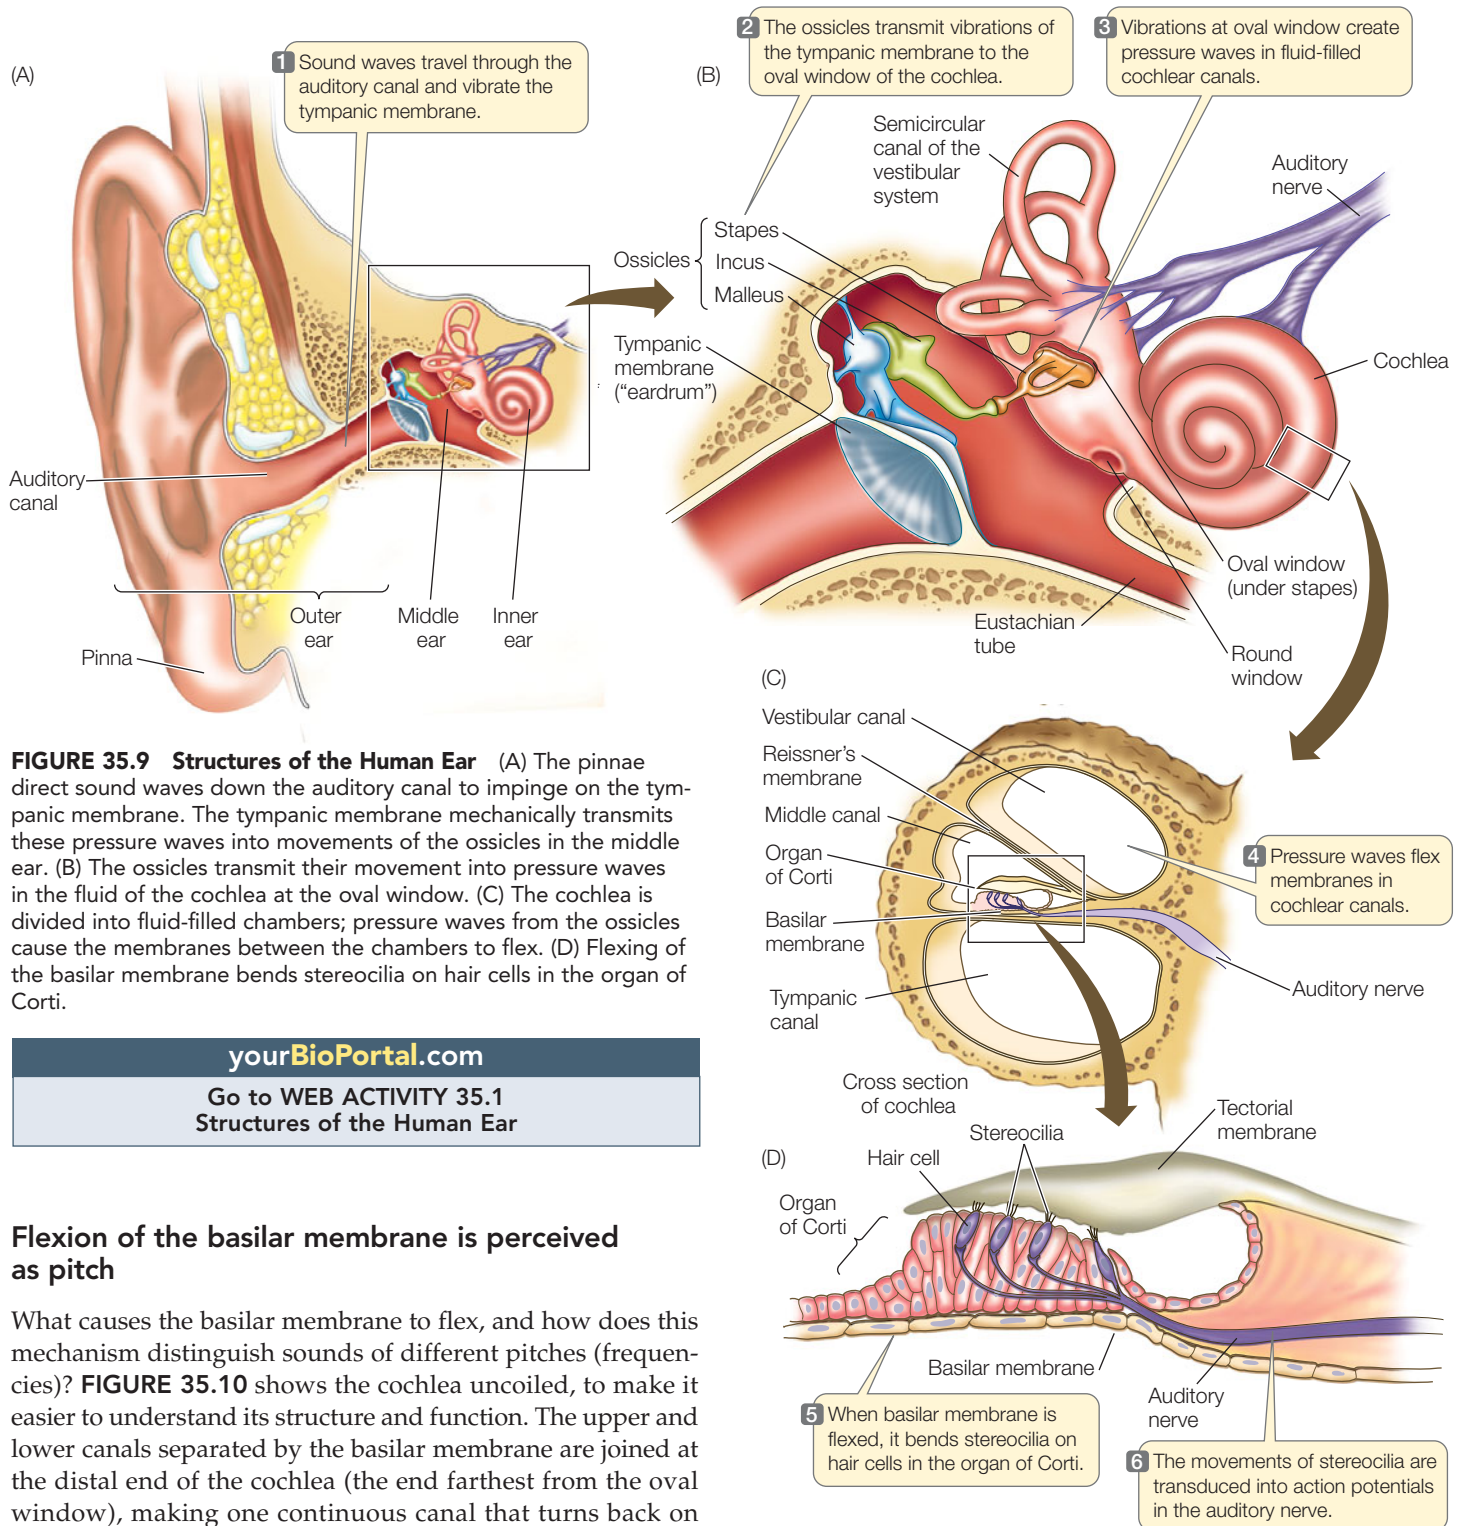

FIGURE 35.9 Structures of the Human Ear (A) The pinnae direct sound waves down the auditory canal to impinge on the tympanic membrane. The tympanic membrane mechanically transmits these pressure waves into movements of the ossicles in the middle ear. (B) The ossicles transmit their movement into pressure waves in the fluid of the cochlea at the oval window. (C) The cochlea is divided into fluid-filled chambers; pressure waves from the ossicles cause the membranes between the chambers to flex. (D) Flexing of the basilar membrane bends stereocilia on hair cells in the organ of Corti.

yourBioPortal.com

Go to WEB ACTIVITY 35.1
Structures of the Human Ear

Flexion of the basilar membrane is perceived as pitch

What causes the basilar membrane to flex, and how does this mechanism distinguish sounds of different pitches (frequencies)? **FIGURE 35.10** shows the cochlea uncoiled, to make it easier to understand its structure and function. The upper and lower canals separated by the basilar membrane are joined at the distal end of the cochlea (the end farthest from the oval window), making one continuous canal that turns back on itself. Just as the oval window is a flexible membrane at the beginning of the upper canal of the cochlea, the **round window** is a flexible membrane at the end of the lower canal.

Air is highly compressible but liquids are not. Therefore, a pressure wave can travel through air without much displacement of the air, whereas a pressure wave in an aqueous fluid displaces that fluid. When the stapes pushes on the oval window, the fluid in the upper canal of the cochlea is displaced. If this movement of the oval window occurs slowly, the cochlear fluid pressure wave travels down the upper canal, around the bend, and back through the lower canal. At the end of the

lower canal, the displacement pressure is dissipated by the outward bulging of the round window.

If the oval window vibrates in and out rapidly, the waves of fluid pressure create traveling waves in the basilar membrane. The basilar membrane is not uniform; it is thicker and stiffer at its base and wider and thinner at its apical end. Pressure waves in the cochlear fluid have different frequencies and set up different patterns of traveling waves. High-frequency waves cause maximal flexion at the basal end of the basilar membrane, whereas low-frequency pressure waves result in maximal flexion at its

FIGURE 35.10 Sensing Pressure Waves in the Inner Ear

Pressure waves of different frequencies flex the basilar membrane at different locations. Information about sound frequency is specified by which hair cells are activated. For simplicity, this representation illustrates the cochlea as uncoiled, and leaves out the middle ear.

Sound Transduction in the Human Ear

apical end. Thus different pitches of sound flex the basilar membrane at different locations and activate different sets of hair cells. Action potentials stimulated by the mechanoreceptors at different positions along the organ of Corti travel in the auditory nerve to different regions of the *auditory cortex*.

Various types of damage can result in hearing loss

There are two general types of hearing loss, or deafness. *Conduction deafness* is caused by the loss of function of the tympanic membrane or the ossicles of the middle ear. For example, the ossicles often stiffen with increasing age, resulting in a gradual loss of the ability to hear high-frequency sounds.

Nerve deafness is caused by damage to the inner ear or the auditory pathways. A common cause of nerve deafness is damage to the hair cells of the delicate organ of Corti by exposure to loud sounds. Consistent exposure to sounds above 85 decibels can damage hearing; this damage is cumulative and irreversible. For example, personal stereo earphones can reach 120 decibels, and people commonly use them at 100 decibels (equivalent to being at a rock concert).

FRONTIERS A recent study at Brigham and Woman's Hospital in Boston examined hearing in 5,000 adolescents ages 12 to 19. One fifth of the subjects had significant hearing loss. This represents a 30 percent increase in the incidence of hearing loss in this age group compared with an identical study done about 15 years earlier.

The vestibular system uses hair cells to detect forces of gravity and momentum

The mammalian vestibular system is a function of several bony structures in the cochlea of the inner ear. The working units of the vestibule are three **semicircular canals** and two chambers, the *saccul*e and the *utricle*. Hair cells in the vestibular system detect the position and movement of the head—information that is essential for maintaining balance (equilibrium) and for certain eye reflexes.

The canals and chambers of the vestibular system are filled with a fluid called endolymph. In the semicircular canals, the endolymph shifts when the head turns. Projecting into the base of each canal is a gelatinous swelling called a *cupula* (plural *cupulae*) that encloses a cluster of hair cell stereocilia. When the shifting endolymph pushes on the cupulae, it bends the stereocilia (**FIGURE 35.11A**). Since the three semicircular canals have different orientations, together they can detect rotational movement in any plane.

The stereocilia in the saccule and utricle are bent in a different way. These stereocilia are embedded in otolithic membranes, gelatinous structures covered with a layer of calcium carbonate crystals called *otoliths* (Latin, “ear stones”). When the head changes position or when it accelerates or decelerates, gravitational forces are exerted on the otoliths and bend the stereocilia (**FIGURE 35.11B**).

Do You Understand Concept 35.3?

- Explain how very tiny vibratory movements of the tympanum are translated into forces that bend the basilar membrane at different locations.
- Fish have lateral lines that are fluid-filled channels running down the sides of their bodies. In the channels are hair cells. What do you think the functions of these lateral-line hair cells are?
- Hair cell membrane potentials can respond to stimuli much faster than chemosensors can. What are the cellular mechanisms responsible for this difference?
- How is your auditory system able to distinguish a high-pitched sound from a low-pitched one?

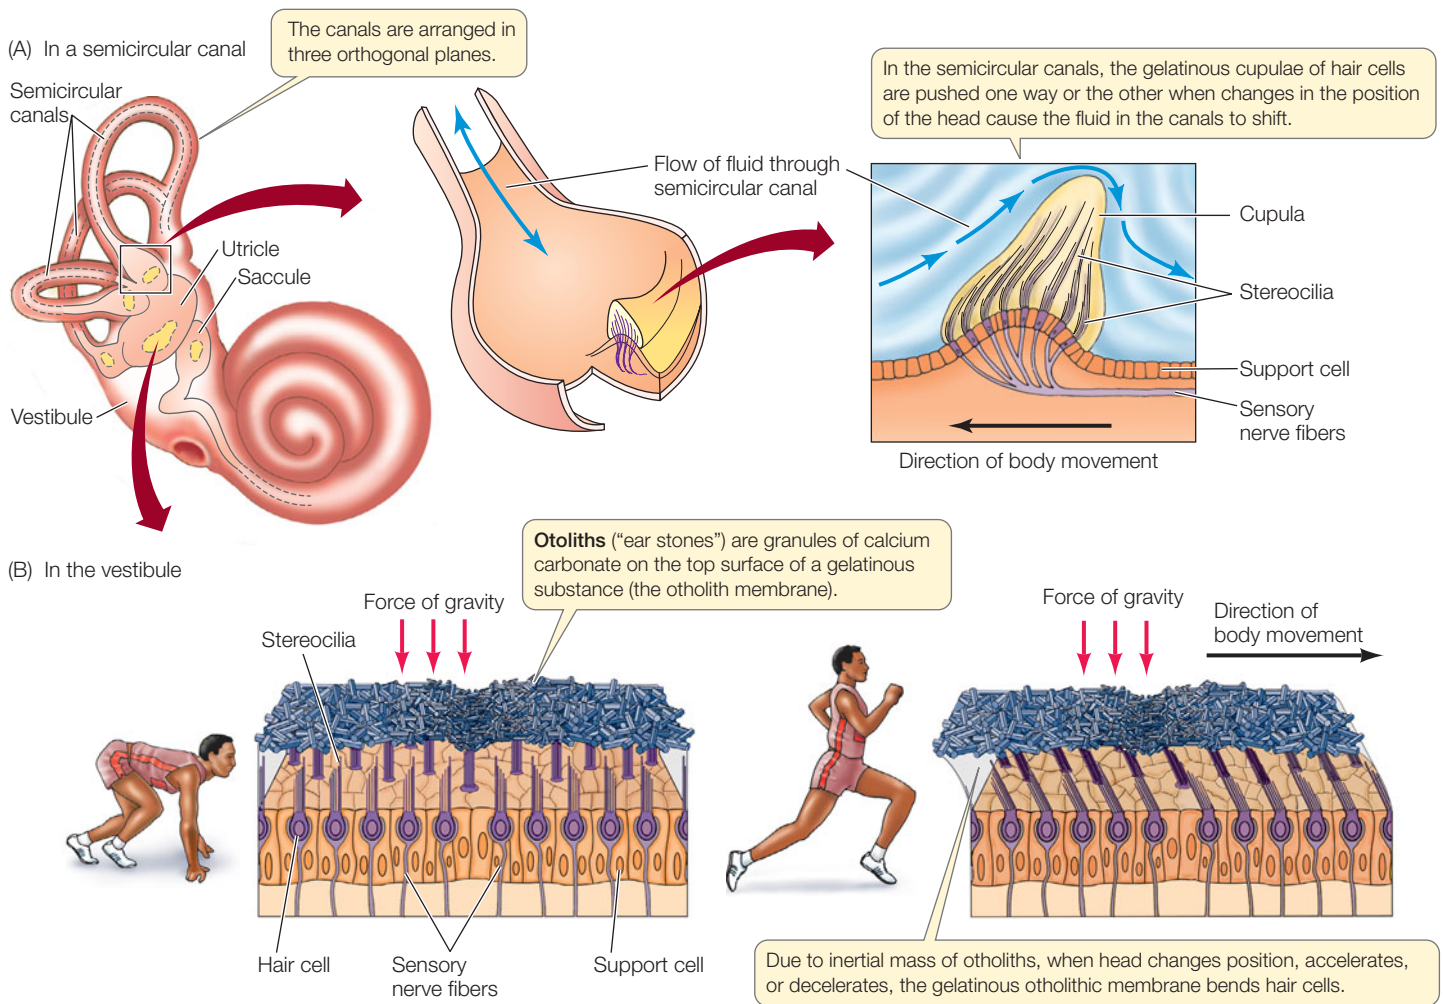

FIGURE 35.11 Organs of Equilibrium The vestibular system consists of bony chambers and fluid-filled canals. (A) Each semicircular canal has a cupula containing stereocilia. When fluid moves against the cupula, the stereocilia bend. (B) In the saccule and utricle, stereocilia are bent by gravitational forces on the otoliths.

We have seen how pressure and chemicals can be detected by sensory cells that give us the senses of smell, taste, touch, hearing, and balance. Now let's turn our attention to vision, which in humans is perhaps the most elaborate of the senses.

concept 35.4 Photoreceptors Detect Light

Sensitivity to light—**photosensitivity**—confers on the simplest animals the ability to orient to the sun and sky, and gives more complex animals rapid and extremely detailed information about objects in their environment. It is not surprising that both simple and complex animals can sense and respond to light. What is remarkable is that across the entire range of animal species, evolution has conserved the same basis for photosensitivity: a family of pigments called **rhodopsins**.

yourBioPortal.com

Go to ANIMATED TUTORIAL 35.2
Photosensitivity

Rhodopsins are responsible for photosensitivity

Photosensitivity depends on the ability of rhodopsins to absorb photons of light and to undergo a change in conformation. A rhodopsin molecule consists of a protein, **opsin** (which alone is not photosensitive), and an associated nonprotein light-absorbing group, **11-*cis*-retinal**, cradled in the center of the opsin and bound covalently to it. The entire rhodopsin molecule sits within the plasma membrane of a photoreceptor cell.

When 11-*cis*-retinal absorbs a photon of light energy, it changes into a different isomer of retinal, called all-*trans*-retinal. This change puts a strain on the bonds between retinal and opsin, changing the conformation of opsin. This change signals the detection of light. In vertebrate eyes, the retinal and the opsin eventually separate from each other—a process called **bleaching**, which causes the molecule to lose its photosensitivity. A series of enzymatic reactions is then required to return the all-*trans*-retinal to the 11-*cis* isomer, which then recombines with opsin so that it once again becomes the photosensitive pigment rhodopsin (FIGURE 35.12).

FIGURE 35.12 Light Changes the Conformation of Rhodopsin The light-absorbing molecule 11-*cis*-retinal bonds with the protein opsin to form the pigment rhodopsin, the molecular agent of photosensitivity.

INVESTIGATION

FIGURE 35.13 A Rod Cell Responds to Light The plasma membrane of a rod cell hyperpolarizes—becomes more negative—in response to a flash of light. Rod cells do not fire

action potentials, but in response to the absorption of light energy, the neuron experiences a change in membrane potential.

HYPOTHESIS

When a rod cell absorbs photons (light energy), its membrane potential changes in proportion to the strength of the light stimulus.

METHOD

1. Record membrane potentials from the inner segment of a rod cell.
2. Stimulate the rod cells with light flashes of varying intensity and record the results.

RESULTS

CONCLUSION

The membrane potential of rod cells is depolarized in the dark and hyperpolarizes (becomes more negative) in response to light.

ANALYZE THE DATA

In related experiments, researchers measured the effect of light on the current across the rod cell membrane. The figure shows a series of recordings of membrane currents (inward currents of positive ions) in rod cells when they are illuminated with lights of varying intensities. Zero on this scale represents the condition of the cell when it is in total darkness. The light flash is given at time 0, and the intensity of the flashes is indicated on the right side of the response curves.

- A. If instead of an outward current, you measured membrane potential, how would the resulting recordings differ from this one?
- B. Why is there no difference between the maximum currents induced by flashes of light at 7.8 and 16 photons per square micrometer?
- C. Why does a rod maintain its maximum current for longer in response to a flash of light at 16 photons per square micrometer than it does to one at 7.8 photons per square micrometer?

For more, go to Working with Data 35.1 at yourBioPortal.com.

FIGURE 35.14 Light Absorption Closes Sodium Channels The absorption of light by rhodopsin initiates a signaling cascade that hyperpolarizes the rod cell. In the dark, Na^+ channels in the plasma membrane of the rod cell's outer segment are held open by cGMP, allowing positive charges to enter the cell (step 1). When the rod cell is stimulated by light, it activates transducin (steps 2 and 3). Transducin activates a molecule of phosphodiesterase (PDE), which catalyzes the breakdown of cGMP to GMP and results in closure of the Na^+ channels and hyperpolarization of the cell (step 4).

How does the conformational change of rhodopsin transduce light into a cellular response? After retinal is converted from the 11-*cis* to the all-*trans* form, it triggers a cascade of reactions involving a G protein signaling mechanism that results in the alteration of membrane potential. As an example, let's look at one type of vertebrate photoreceptor cell, the rod cell.

Rod cells respond to light

The **rod cell**, named for its shape, is a modified neuron that has an outer segment, an inner segment, and a synaptic terminal (**FIGURE 35.13**). The outer segment contains a stack of discs of plasma membrane densely packed with rhodopsin. The function of the discs is to capture photons of light passing through the rod cell. The inner segment contains the cell nucleus, mitochondria, and other organelles. Rod cells do not generate their own action potentials, but they can alter how much neurotransmitter they release at the synaptic terminal, where they synapse with other neurons.

From what we have learned about other types of sensory receptors, we might expect that stimulation of the rod cell by light would make its membrane potential *less* negative (i.e., depolarized). But the opposite is true—it becomes *more* negative (hyperpolarized).

When a rod cell is kept in the dark, Na^+ continually enters the outer segment of the cell—a flow of Na^+ ions called the **dark current** (**FIGURE 35.14, STEP 1**). This keeps the rod cell depolarized, and it continually releases large amounts of neurotransmitter. When light is flashed on the dark-adapted rod cell, its membrane potential becomes more negative—that is, it

hyperpolarizes—and its release of neurotransmitter decreases.

How does light cause hyperpolarization? Light photoexcites rhodopsin, which activates a G protein called *transducin* (**FIGURE 35.14, STEPS 2 AND 3**; see Figure 5.14). Activated transducin in turn activates a phosphodiesterase (PDE; see Figure 5.18). Activated PDE converts cyclic GMP (cGMP) to GMP, which causes the Na^+ channels to close, and the cell hyperpolarizes (**FIGURE 35.14, STEP 4**).

This mechanism may seem like a roundabout way of doing business, but its advantage is its enormous amplification ability. Each molecule of photoexcited rhodopsin can activate several hundred transducin molecules, thus activating a large number of PDE molecules, each of which can hydrolyze several hundred molecules of cGMP per second. The bottom line is that a single photon of light can cause a huge number of Na^+ channels to close.

FRONTIERS Algae have a form of rhodopsin (called channel rhodopsin) that opens a cation channel when it is stimulated by blue light. Neurobiologists use channel rhodopsin in a new technique called optogenetics. A channel rhodopsin gene is combined with the promoter for a gene—such as a gene encoding a neurotransmitter—that is uniquely expressed in a particular class of neurons. This genetic construct is then transferred into a target tissue, such as a region of the brain. The channel rhodopsin is expressed only in the cells that normally activate the promoter used in the construct. Those cells can then be excited by blue light, giving the scientists the ability to turn specific types of neurons on and off at will.

Animals have a variety of visual systems

Photoreceptors using rhodopsin are incorporated into a variety of visual systems, from simple to complex. One of the simplest systems is the paired bilateral **eye cups** of flatworms. Eye cups cannot produce detailed images, but the arrangement of

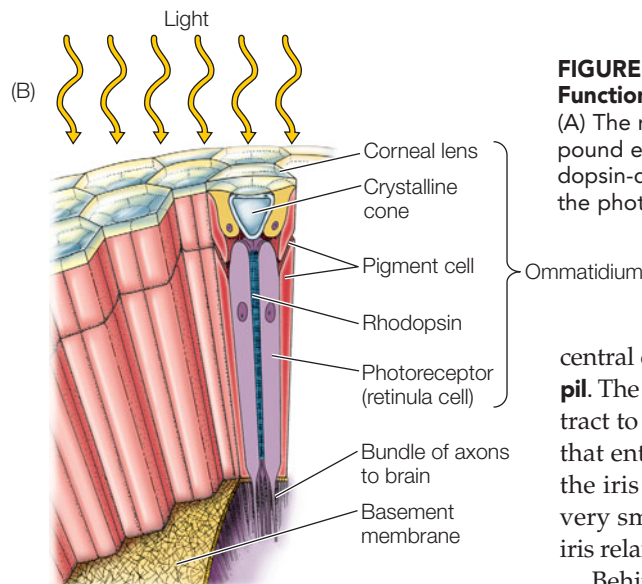

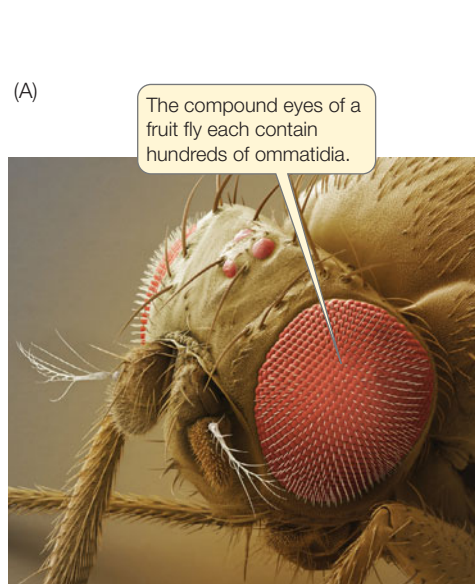

FIGURE 35.15 Ommatidia: The Functional Units of Insect Eyes
(A) The micrograph shows the compound eye of a fruit fly. (B) The rhodopsin-containing retinula cells are the photoreceptors in ommatidia.

central opening of the iris is the **pupil**. The iris is a muscle that can contract to control the amount of light that enters the eye. In bright light, the iris constricts and the pupil is very small. As light levels fall, the iris relaxes and the pupil enlarges.

Behind the iris is the crystalline protein **lens**, which makes fine adjustments in the focus of images

falling on the photosensitive layer—the **retina**—at the back of the eye. The retina is organized into five layers of neurons, including the photoreceptors (rods and cones) at the back (**FIGURE 35.16B**). The various cells of the retina receive and process visual information, then transduce these visual signals to the brain. The layer of photoreceptor cells sends information to a layer of *bipolar cells*, which sends information to a layer of *ganglion cells*. The axons of ganglion cells conduct information to the brain.

The other two cell layers, the *horizontal cells* and *amacrine cells*, communicate laterally across the retina, so that photoreceptors and bipolar cells can communicate with their neighbors. Horizontal cells help sharpen the perception of contrast between light and dark. Amacrine cells have several functions, including detecting motion and adjusting visual sensitivity to the overall level of light. Ultimately, all of this information converges onto the ganglion cells.

The function of these retinal cross-connections was explored in a series of classic experiments by Stephen Kuffler in 1953. Kuffler used electrodes to record the activity in the axons of single ganglion cells of cat eyes. His experiments revealed that each ganglion cell has a well-defined circular **receptive field** composed of a group of photoreceptors. Individual photoreceptors contribute to the receptive fields of multiple ganglion cells, so receptive fields overlap. Some ganglion cells are excited by light falling on the center of the receptive field and are inhibited if light falls in the periphery (surround) of the receptive field. Other ganglion cells are the reverse; they are inhibited by light falling in the center and are stimulated by light falling on the surround. The result of this complex circuitry is that ganglion cells can communicate information to the brain about simple visual patterns such as spots, edges and areas of contrast.

What further processing happens in the brain itself? In the 1960s, another series of classic experiments by David Hubel and Torsten Wiesel demonstrated that neurons in the visual cortex, like retinal ganglion cells, have receptive fields. These neurons each receive input from multiple ganglion cells, in

yourBioPortal.com

Go to **INTERACTIVE TUTORIAL 35.2**
Visual Receptive Fields

pigments and photoreceptors in the eyes means that the photoreceptors on the two sides of the animal are unequally stimulated unless the animal is facing directly toward or away from a light source. The resulting directional information enables the flatworm to move away from light.

Arthropods have elaborate **compound eyes**, so called because each eye consists of many optical units called **ommatidia** (singular *ommatidium*), each with its own narrow-angle lens that directs light onto photoreceptor (retinula) cells (**FIGURE 35.15**). The inner borders of the photoreceptors are covered with microvilli (tiny hairlike projections) that contain rhodopsin and trap light. Axons from the photoreceptors send the light information to the nervous system.

Each ommatidium of a compound eye is directed at a slightly different part of the visual world. The more ommatidia in the eye, the higher the resolution of the image compiled by the CNS, rather like the pixel density in a computer monitor. The number of ommatidia in a compound eye varies from only a few in some ants to 800 in fruit flies and to 30,000 in some dragonflies.

Visual information is processed by the retina and the brain

Vertebrates have *image-forming eyes*. Like a camera, an image-forming eye has a lens that focuses images on an internal surface that is sensitive to light. (Cephalopod mollusks, including squid and octopus, also have image-forming eyes, which evolved independently from the vertebrate eye.)

The vertebrate eye—exemplified by the human eye illustrated in **FIGURE 35.16A**—is a fluid-filled structure bounded by a tough connective tissue layer called the *sclera*. At the front of the eye, the sclera forms the transparent **cornea**, through which light enters the eye. Just inside the cornea is the colored **iris**. The

FIGURE 35.16 The Human Eye (A) The human eye, like that of other vertebrates, has a lens that focuses images on layers of photoreceptor cells. (B) The retina consists of five layers of neurons at the back of the eye that receive and process visual information. The rods and cones are photoreceptors.

analyzing edges in patterns of light and dark. Each retina sends a million axons to the brain, but there are *hundreds of millions* of neurons in the visual cortex. The action potentials from one retinal ganglion cell are received by hundreds of cortical neurons, each responsive to a different combination of orientation, position, color, and movement of contrasting lines in the patterns of light and dark falling on the retina. The end result is that before visual information is sent on to different parts of the brain (for example, the parts that can recognize faces, written words, or the shapes of objects), the information has already been highly analyzed by both the retina and the visual cortex to highlight patterns such as spots, lines, and certain shapes and motions.

1 Light travels through layers of transparent neurons—ganglion, amacrine, bipolar, and horizontal cells...

2 ...and is absorbed by the rods and cones (the photoreceptive layer) at the back of the retina.

such a way that they are maximally stimulated by bars of light with a particular orientation. Cortical receptive fields from the center of the retina are small and contribute to high-acuity vision, while receptive fields from the periphery of the retina are large and provide low-acuity vision. Also, most cells in the primary visual cortex respond well to motion, and many are directionally selective. Hubel and Wiesel received a Nobel Prize for their work in 1981.

The concept that emerges from these experiments is that the brain assembles a mental image of the visual world by

Structure of the Human Eye
Structure of the Human Retina

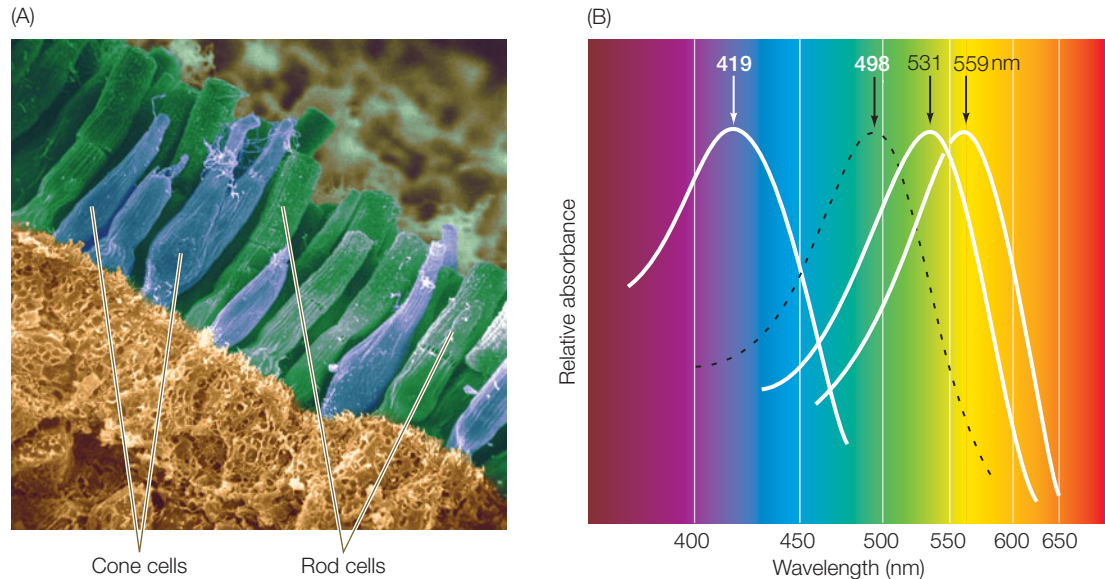

Color vision is due to cone cells

Our discussion so far has focused on rod cells. **Cone cells**, also named for their shape, constitute the other major class of vertebrate photoreceptors (FIGURE 35.17A). Whereas rod cells are highly sensitive to light and are responsible for vision at low light levels, cone cells are responsible for high-acuity color vision. The human retina has about 5 million cones and about 100 million rods, but their densities are not even across the entire retina.

Light coming from the center of the visual field falls on the **fovea** (see Figure 35.16A), where the density of cone cells is highest. The human fovea has about 160,000 cones per square millimeter. The fovea of a hawk has almost twice that number, making the hawk's vision much sharper than ours. Hawks also have *two* foveae in each eye. One receives light from straight ahead, the other from a more lateral field of vision. The hawk's forward-looking foveae make binocular vision possible, while the lateral-looking foveae provide high-acuity vision that is directed toward the sides.

Cones have low sensitivity to light and contribute little to night vision. Night vision depends mostly on rod cells; vision in dim light is mostly in shades of gray, and acuity is low. You may have trouble seeing a small object such as a keyhole at night when you are looking straight at it—that is, when its image is falling on your fovea. If you look a little to the side, so that the image falls on a rod-rich area of the retina, you see the object better (astronomers looking for faint objects in the night sky learned this trick a long time ago).

FIGURE 35.17 Rods and Cones (A) This scanning electron micrograph of photoreceptors in the retina of a mud puppy (an amphibian) shows cylindrical rods and tapered cones. This micrograph has been artificially colored and does not show the actual color of the rod and cone cells. (B) The three types of cone cells in the human retina can detect different wavelengths of light. The dashed line shows the spectral sensitivity of rod cells.

The human retina has three kinds of cone cells, each containing slightly different opsin molecules. Although all opsins contain the same *11-cis*-retinal group, the three cone opsins differ in the wavelengths of light they absorb best (FIGURE 35.17B), because of molecular interactions between the retinal and the opsin. Therefore the brain can interpret the relative inputs from the three classes of cones to determine what wavelength—that is, what color—is being viewed.

Most mammals have two classes of cones, whereas most other vertebrates have at least four. Mammals tend to be nocturnal, and it appears that during their long evolutionary history of nocturnal living, they have lost much of the color vision capabilities found in other vertebrates.

In humans and a few other primates, a third opsin has evolved, by means of gene duplication of one of the opsin genes. This duplicated gene is nonfunctional in a substantial number of human males (about 10 percent of men of European descent), resulting in an inability to distinguish red from green. The gene in question is located on the X chromosome, and the condition, known as red–green color blindness, is inherited as a sex-linked trait.

Do You Understand Concept 35.4?

- Would you expect a nocturnal animal such as a flying squirrel to have a high or low density of cones in its retinas? How about a diurnal animal such as a gray squirrel? Explain.
- How do opsins produce light-sensitive responses when opsin molecules themselves are not affected directly by light?
- If you record action potentials from single retinal ganglion cells, they only respond optimally to circular spots of light. However, if you record from neurons in the visual cortex, they can respond optimally to bars of light in specific orientations. Explain how information coming to the cortex from the retinal ganglion cells could result in a linear receptive field.

We have seen how sensory receptors detect a wide variety of sensory information and transmit it to the central nervous system. In response, the CNS analyzes the sensory information and sends out an appropriate command to a muscle, gland, or other *effector cell*. In the next chapter, we will discuss how these effectors work.

How do kangaroo rats, rattlesnakes, owls, bats, and moths “see in the dark”?

ANSWER Kangaroo rats have large eyes that give them maximal visual sensitivity even in very dim light, but that is not the only sense that enables them to function on moonless nights. Their long whiskers enable them to use tactile information to explore their environments. Their olfactory sensitivity enables them to locate and identify other kangaroo rats, both as to the identity of familiar individuals and the gender of unfamiliar ones. The acute auditory sensitivity of the kangaroo rat enables it to hear the air disturbance caused by the strike of the rattlesnake and to jump reflexively.

The rattlesnake can “see” the kangaroo rat and other small mammals by the infrared radiation (heat) they emit. These snakes have pit organs lateral to their nostrils, and their eyes have high densities of infrared-sensitive neurons. Because the pits have overlapping fields of “view,” they give the snake a three-dimensional perspective. Information from the pit organs goes to the same region of the brain as information from the eyes, so rattlesnakes actually do see the world in infrared. Their prey literally glows in the dark.

Bats detect their flying prey with their voices and ears. Bats emit remarkably loud, brief sound pulses at higher sound frequencies than we can hear. Between the pulses, the bat listens for echoes of these sounds bouncing off objects in the environment. The bat’s brain analyzes the delays of the echoes with such accuracy that it gives the bat information about the distance to the moth, the moth’s trajectory, and

even the moth's size, shape, and wingbeat frequency. The moth, of course, can also hear the bat's sound pulses and can respond with a reflexive avoidance behavior that sometimes allows it to escape.

Our senses are our windows on the world, but we sense only a limited range of the information available. Animals with different ranges of sensitivity perceive the world quite differently.

35

SUMMARY

concept 35.1 Sensory Systems Convert Stimuli into Action Potentials

- Sensory receptor cells, also known as sensors or receptors, transduce information about an animal's external and internal environment into action potentials.
- Receptor potentials can spread to regions of the cell's plasma membrane that generate action potentials. Some sensors do not fire action potentials but release neurotransmitter onto sensory neurons that do fire action potentials. **Review Figure 35.1**
- Sensory receptor cells have **receptor proteins** that cause ion channels to open or close, affecting the cells' membrane potential. This causes a graded membrane potential called a receptor potential. **Review Figure 35.2**
- The interpretation of action potentials as particular sensations depends on which neurons in the CNS receive them.
- **Adaptation** enables the nervous system to ignore irrelevant or continuous stimuli while remaining responsive to relevant or new stimuli.

concept 35.2 Chemoreceptors Detect Specific Molecules or Ions

- **Chemoreceptors** are responsible for **olfaction**, **gustation**, and the sensing of **pheromones**.
- Mammalian olfactory sensors project directly to the olfactory bulb of the brain. Sensors for the same **odorant** project to the same area of the olfactory bulb.
- Each olfactory receptor cell expresses one receptor protein that can bind to a set of similar odorant molecules. **Review Figure 35.3**
- Pheromones are detected with chemoreceptors that are usually separate from the main olfactory system. In vertebrates, pheromones are detected with the **vomeronasal organ**. **Review Figure 35.4**
- In vertebrates, **taste buds** in the mouth cavity are responsible for gustation. The five basic tastes are sweet, salty, sour, bitter, and umami. **Review Figure 35.5**

concept 35.3 Mechanoreceptors Detect Physical Forces

- The skin contains a variety of **mechanoreceptors** that respond to touch and pressure. **Review Figure 35.6**
- **Stretch receptors** in muscle spindles and Golgi tendon organs inform the CNS of the loads on muscles and tendons. **Review Figure 35.7 and INTERACTIVE TUTORIAL 35.1**
- **Hair cells** are mechanoreceptors in the mammalian inner ear. Physical bending of their **stereocilia** alters their membrane

potentials. Hair cells are found in the **cochlea** and **semicircular canals** and function in the auditory and vestibular systems. **Review Figures 35.8 and 35.9**

- In mammalian auditory systems, ear pinnae collect and direct sound waves into the auditory canal, where the **tympanic membrane** vibrates in response to sound waves. The movements of the tympanic membrane are amplified through a chain of **ossicles** that conduct the vibrations to the **oval window**. Movements of the oval window create pressure waves in the fluid-filled **cochlea**. **Review Figure 35.9 and WEB ACTIVITY 35.1**
- The **basilar membrane** running down the center of the cochlea is distorted by pressure waves at specific locations that depend on the frequency of the waves, generating information we interpret as the pitch of sound. These distortions cause the bending of hair cells in the **organ of Corti**. **Review Figures 35.9 and 35.10 and ANIMATED TUTORIAL 35.1**

concept 35.4 Photoreceptors Detect Light

- **Photosensitivity** depends on the absorption of photons of light by **rhodopsin**, which consists of an **opsin** protein and a non-protein light-absorbing group called **11-cis-retinal**. Absorption of light by 11-cis-retinal leads to a change in the membrane potential of the photoreceptor cell. **Review Figure 35.12 and ANIMATED TUTORIAL 35.2**
- When excited by light, vertebrate photoreceptor cells hyperpolarize and release less neurotransmitter. They do not fire action potentials. **Review Figures 35.13 and 35.14 and WORKING WITH DATA 35.1**
- Visual systems range from the simple **eye cups** of flatworms, which sense the direction of a light source, to the **compound eyes** of arthropods, which detect shapes and patterns, to the image-forming eyes of vertebrates and cephalopods, which focus detailed images onto dense arrays of photoreceptors. **Review Figure 35.15**
- The vertebrate **retina** consists of five layers of neurons lining the back of the eye, including the light-absorbing photoreceptor cells at the back. Extensive processing of visual information occurs in the retina and also in the brain. **Review Figure 35.16, WEB ACTIVITIES 35.2 and 35.3, and INTERACTIVE TUTORIAL 35.2**
- Vertebrates have two types of photoreceptors, **rod cells** and **cone cells**. In humans, the **fovea** contains almost exclusively cone cells, which are responsible for color vision but are not very sensitive in dim light. Color vision in humans arises from three types of cone cells with different spectral absorption properties. **Review Figure 35.17**

The Olympic record for the women's long jump is 7.4 meters, set in 1988 by Jackie Joyner-Kersey. Another world-record long jump that still stands was set two years earlier by Rosie the Ribeter, who jumped 6.5 meters. Rosie was a frog competing in the Calaveras County Jumping Frog Contest. In some ways, Rosie's jump is more impressive: while Jackie's jump was about 5 times her body length (i.e., her height), Rosie's was about 20 times her body length.

Both jumps were powered by skeletal muscle. Muscles respond to commands from the nervous system. The cellular mechanisms of muscle contraction are essentially the same in the frog and the human, and in both the muscles accomplish their tasks by pulling on bones, so why is the frog's jump so much more impressive?

Another measure of performance is endurance. It would be hard to match the endurance capacity of a camel—the ship of the desert. Carrying a load that can be almost as heavy as its body mass, the camel can go for days and cover hundreds of kilometers of desert without food or water. The British Camel Corps recommends 200 kilograms as a load for a camel, but much greater loads are routinely imposed. In one study comparing the metabolic rates of walking camels with and without loads that amounted to a third of their body weights, there was only a slight but not significant difference in the cost of locomotion. Part of the camel's endurance is due to its adaptations to conserve water, but its highly efficient mode of locomotion is also important. What adaptations make the camel such an efficient long-distance traveler?

Still another measure of performance is efficiency. The camel's remarkable endurance is partly due to its efficiency of locomotion, but the kangaroo also puts in an impressive performance. Your experience

Jackie Joyner-Kersey set an Olympic record for the women's long jump at the Seoul Olympics in 1988.

will tell you that as you run faster, the number of strides you take per minute, and therefore the energy you expend, increases. Neither is true for the kangaroo. When moving at speeds from about 5 to 25 kilometers per hour, the kangaroo takes the same number of strides per minute, and its metabolic rate does not increase. How does the kangaroo achieve such remarkable speeds at such low metabolic cost?

Adaptations of musculoskeletal systems, the subject of this chapter, underlie the exceptional but different performance capabilities of humans, frogs, camels, and kangaroos.

How have musculoskeletal systems evolved to maximize force generation and do so at minimal metabolic cost?

concept
36.1 Cycles of Protein-Protein Interactions Cause Muscles to Contract

Most behavior and many physiological actions, such as beating of the heart and moving of food through the digestive tract, depend on muscle contraction. There are three types of vertebrate muscle:

- **Skeletal muscle** is responsible for all voluntary movements, such as running or playing a piano. It is also involved in some involuntary actions, such as breathing, shivering, and maintaining posture (**FIGURE 36.1**).
- **Cardiac muscle** is responsible for the beating of the heart.
- **Smooth muscle** is responsible for the movement in many hollow internal organs, such as the gut, bladder, and blood vessels, and is under the control of the autonomic (involuntary) nervous system.

FIGURE 36.1 The Structure of Skeletal Muscle The arrangement of the actin and myosin filaments gives skeletal muscle fibers their characteristic striated appearance.

yourBioPortal.com

Go to WEB ACTIVITY 36.1
The Structure of a Sarcomere

All three muscle types use the same contractile mechanism, and we begin our study of musculoskeletal movement by describing its underlying molecular mechanisms. We will use vertebrate skeletal muscle as our primary example. Later we will discuss the differences in cardiac and smooth muscle that adapt them to their particular functions.

Sliding filaments cause skeletal muscle to contract

Skeletal muscle is also called *striated muscle* because of its striped appearance:

Skeletal muscle cells, called **muscle fibers**, are large and have many nuclei. These multinucleate cells form during development through the fusion of many individual embryonic muscle cells called *myoblasts*. A muscle such as your biceps (which bends your arm) is composed of hundreds or thousands of muscle fibers bundled together by connective tissue (see Figure 36.1).

Muscle contraction is due to the interaction between the contractile proteins **actin** and **myosin**. Within muscle cells, actin and myosin molecules are organized into filaments consisting of many molecules. Actin filaments are also called *thin filaments*, and myosin filaments are *thick filaments*. The two kinds of filaments lie parallel to each other. When muscle contraction is triggered, the actin and myosin filaments slide past each other in a telescoping fashion.

LINK Actin and myosin are part of the cytoskeleton, which is responsible for other types of movement in cells; see Concept 4.4

What is the relationship between a skeletal muscle fiber (cell) and the actin and myosin filaments responsible for its contraction? Each muscle fiber is packed with **myofibrils**—bundles of thin actin and thick myosin filaments arranged in an orderly fashion. In most regions of the myofibril, each thick myosin filament is surrounded by six thin actin filaments, and each thin actin filament sits within a triangle of three thick myosin filaments (see cross section of myofibril in Figure 36.1).

A longitudinal view of a myofibril shows that it consists of repeating units called **sarcomeres**. Each sarcomere is made of overlapping filaments of actin and myosin, creating a distinct banding pattern (see Figure 36.1). Before the molecular nature of the muscle banding pattern was known, the bands were given names that are still used today. Each sarcomere is bounded by *Z lines* that anchor the thin actin filaments (*Z* is for German *zwischen*, “between”). Centered in the sarcomere is the *A band*, which contains all the myosin filaments. The *H zone* (*H* is for German *hell*, “bright”) and the *I band* appear light because the actin and myosin filaments do not overlap in these regions when the muscle is relaxed. The dark stripe in the *H zone* is called the *M band* (for middle); it contains proteins that help hold the myosin filaments in their regular arrangement.

The bundles of myosin filaments are held in a centered position within the sarcomere by a protein called **titin**. Titin is the largest protein in the body; it runs the full length of the sarcomere from *Z line* to *Z line*. Each titin molecule runs right through a myosin bundle. Between the ends of the myosin bundles and the *Z lines*, titin molecules are very stretchable, like bungee cords. In a relaxed skeletal muscle, resistance to stretch is mostly due to the elasticity of the titin molecules.

As the muscle contracts, the sarcomeres shorten and the band pattern changes. The *H zone* and the *I band* become much narrower, and the *Z lines* move toward the *A band* as the actin filaments slide into the *H zone*, the region occupied by the myosin filaments (**FIGURE 36.2**). This shortening of the sarcomeres is the basis of the *sliding filament contractile mechanism* of muscle contraction.

Muscle relaxed

Muscle contracted

FIGURE 36.2 Sliding Filaments The banding pattern of the sarcomere changes as it shortens. This shortening results from the sliding filament contractile mechanism of muscle contraction.

FIGURE 36.3 Actin and Myosin Filaments Overlap in Myofibrils Myosin filaments are bundles of molecules with globular heads and polypeptide tails; the protein titin holds these filaments centered within the sarcomeres. Actin filaments consist of two chains of actin monomers twisted together, along with two other proteins: tropomyosin and troponin.

yourBioPortal.com

Molecular Mechanisms of Muscle Contraction

Actin–myosin interactions cause filaments to slide

To understand how the sarcomere contracts, we must examine the structures of actin and myosin (**FIGURE 36.3**). A myosin molecule consists of two long polypeptide chains coiled together, each ending in a large globular head. A myosin filament is made up of many myosin molecules arranged in parallel, with their heads projecting sideways at each end of the filament.

An actin filament consists of actin monomers polymerized into long chains that look like two strands of pearls twisted together. Twisting around the actin chains is another protein, *tropomyosin*, and attached to tropomyosin at intervals are molecules of *troponin*. These molecules control the cycles of contraction and relaxation, as we will see in the next section.

The myosin heads can bind specific sites on actin, forming cross-bridges between the myosin and the actin filaments. Moreover, when a myosin head binds to an actin filament, the head's conformation changes, and it bends and exerts a tiny force that causes the actin filament to move 5–10 nanometers relative to the myosin filament (see Figure 36.6). The myosin heads also have ATPase activity; when they are bound to actin, they can bind and hydrolyze ATP. The energy released when this happens changes the conformation of the myosin head, causing it to release the actin and return to its extended position, from which it can bind to actin again.

Together, these details explain the cycle of events that cause the actin and myosin filaments to slide past each other and shorten the sarcomere. They also explain *rigor mortis*—the stiffening of muscles soon after death. ATP is needed to break the actin–myosin bonds, so when ATP production ceases with death, the actin–myosin bonds cannot be broken and the muscles stiffen. Eventually, however, the proteins begin to lose their integrity, and the muscles soften. The timing of these events helps a medical examiner estimate the time of death.

We have been discussing the cycle of contraction in terms of a single myosin head. Remember that each myosin filament has many myosin heads at both ends and is surrounded by six actin filaments; thus the contraction of the sarcomere involves a great many cycles of interaction between actin and myosin

molecules. These cycles of binding and release are not synchronized, so when a single myosin head breaks its contact with actin, other bridges are still connected and flexing, and the actin filaments do not slip backward.

Actin–myosin interactions are controlled by calcium ions

Like neurons, muscle cells are *excitable*: their plasma membranes can generate and conduct action potentials. In skeletal muscle fibers, action potentials are initiated by acetylcholine (ACh) released by motor neuron terminals at the *neuromuscular junction*. The axon terminals of motor neurons are generally highly branched and form synapses with hundreds of muscle fibers (**FIGURE 36.4**). A motor neuron and all of the fibers with which it forms synapses constitute a **motor unit**. The fibers of a motor unit contract simultaneously when its motor neuron fires. A muscle can consist of many motor units. Thus there are two ways to increase a muscle's strength of contraction: increase the firing rate of an individual motor neuron, or activate more motor neurons.

As described in Concept 34.3, when an action potential arrives at a neuromuscular junction, the neurotransmitter ACh is released from the motor neuron terminals, diffuses across the

FIGURE 36.4 The Neuromuscular Junction Axons branching from a single motor neuron end in terminals that innervate multiple skeletal muscle fibers.

APPLY THE CONCEPT

Cycles of protein–protein interactions cause muscles to contract

The ability of a muscle fiber to generate force depends on how many actin–myosin cross-bridges can form. This in turn depends on the degree of overlap between the actin and myosin filaments in the sarcomeres, which can vary considerably, as shown in Figure 36.2. When a muscle is stretched from its resting length, there is less overlap between the filaments; as the muscle contracts, there is more overlap between the filaments. We can hypothesize that the maximum force a muscle can produce during a given contraction will be a function of its length at the beginning of the contraction relative to its resting length. In an experiment, a bundle of muscle fibers can be attached at either end to an apparatus that can stretch the fibers and measure the force they generate when the motor neuron to those muscle fibers is stimulated. The results are shown in the table.

Plot these results with force generated on the y axis, and length of fibers at beginning of contraction on the x axis.

1. At what fiber length is a muscle's force generating capacity greatest?

LENGTH OF FIBERS AT BEGINNING OF CONTRACTION AS PERCENTAGE OF RESTING LENGTH	FORCE GENERATED AS PERCENTAGE OF MAXIMUM FORCE
35%	10%
75%	50%
100%	100%
115%	100%
130%	80%
150%	50%
175%	10%

2. At what percentages of the resting length do you predict that the muscle will not be able to generate any force?
3. Why does the force generating capacity of the muscle decrease at shorter lengths?
4. When you do a pull-up, what stages of the pull-up are most difficult?

synaptic cleft, binds to receptors in the postsynaptic membrane, and causes ion channels in the motor end plate to open (see Figures 34.9 and 34.10). Most of the ions that flow through these channels are Na^+ , and therefore the motor end plate is depolarized. The depolarization spreads to the surrounding plasma membrane of the muscle fiber, which contains voltage-gated sodium channels. When threshold is reached, the plasma membrane fires an action potential that is conducted rapidly to all points on the surface of the muscle fiber.

An action potential in a muscle fiber also travels deep within the cell because the plasma membrane is continuous with a distribution system of tubules that descend into the muscle fiber cytoplasm (also called the **sarcoplasm**). The action potential that spreads over the plasma membrane also spreads through this system of transverse tubules, or **T tubules** (FIGURE 36.5).

The T tubules are very close to the endoplasmic reticulum (ER) of the muscle cells. In muscle cells, the ER is called the **sarcoplasmic reticulum**, and it is a closed compartment surrounding every myofibril. Calcium pumps in the sarcoplasmic reticulum take up Ca^{2+} ions from the sarcoplasm. Therefore, when the muscle fiber is at rest, there is a higher concentration of Ca^{2+} in the sarcoplasmic reticulum and a lower concentration in the sarcoplasm.

Spanning the space between the membranes of the T tubules and the membranes of the sarcoplasmic reticulum are two proteins. One protein, the *dihydropyridine (DHP) receptor*, is located in the T tubule membrane; it is voltage-sensitive and changes its conformation when an action potential reaches it. The other protein, the *ryanodine receptor*, is located in the sarcoplasmic

reticulum membrane; it is a Ca^{2+} channel. These two proteins are physically connected. When the DHP receptor is activated by an action potential, it changes conformation, causing the ryanodine receptor to allow Ca^{2+} to leave the sarcoplasmic reticulum. Ca^{2+} ions diffuse into the sarcoplasm surrounding the actin and myosin filaments and trigger the interaction of actin and myosin and the sliding of the filaments. How do the Ca^{2+} ions do this?

An actin filament, as we have seen, is a helical arrangement of actin monomers. Twisted around the actin filament are two strands of the protein **tropomyosin** (FIGURE 36.6; see also Figure 36.3). At regular intervals, the filament also includes a globular protein, **troponin**. The troponin molecule has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

When the muscle is at rest, the tropomyosin strands are positioned so that they block the sites on the actin filament where myosin heads can bind. When Ca^{2+} is released into the sarcoplasm, it binds to troponin, changing its conformation. Because the troponin is bound to the tropomyosin, this conformational change twists the tropomyosin enough to expose the actin–myosin binding sites. Thus the cycle of making and breaking actin–myosin bonds is initiated, the filaments are pulled past each other, and the muscle fiber contracts. When the calcium pumps remove the Ca^{2+} ions from the sarcoplasm, the conformation of the tropomyosin returns to the state in which it blocks the binding of myosin heads to actin, and the muscle fiber returns to its resting condition. Figure 36.6 summarizes this cycle.

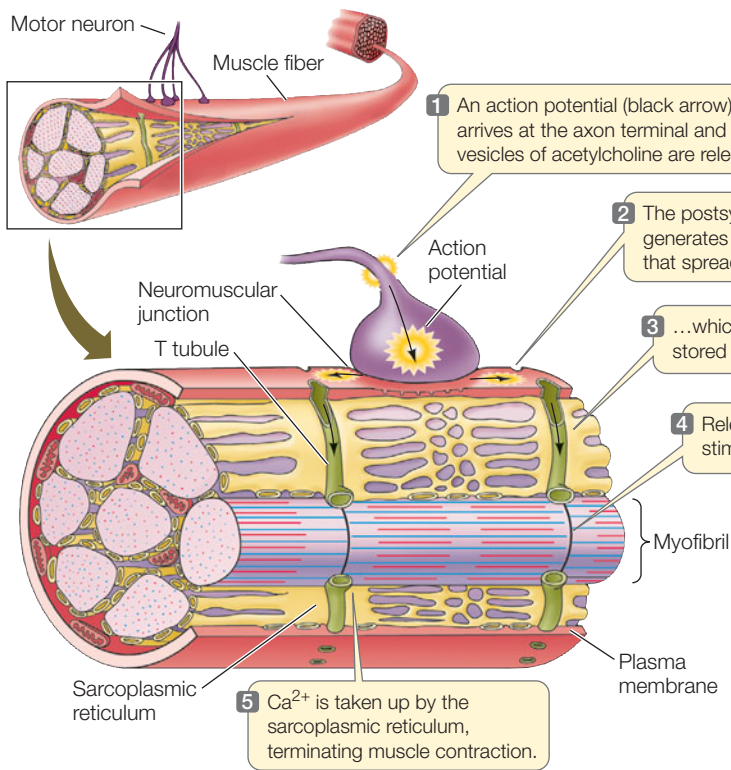

FIGURE 36.5 T Tubules Spread Action Potentials into the Fiber An action potential at the neuromuscular junction spreads throughout the muscle fiber via a network of T tubules, triggering the release of Ca^{2+} from the sarcoplasmic reticulum.

yourBioPortal.com
Go to WEB ACTIVITY 36.2
The Neuromuscular Junction

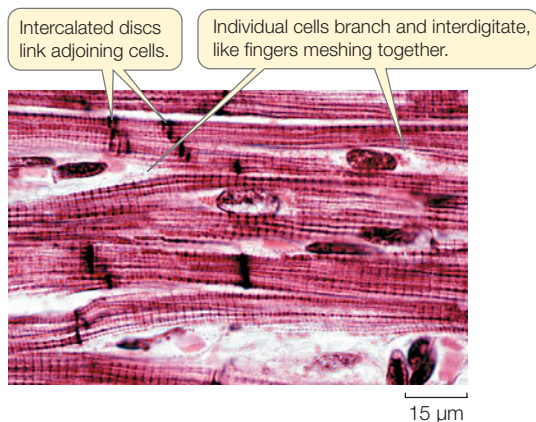

FIGURE 36.6 Release of Ca^{2+} from the Sarcoplasmic Reticulum Triggers Muscle Contraction When Ca^{2+} binds to troponin, it exposes myosin-binding sites on the actin. As long as binding sites and ATP are available, the cycle of actin and myosin interactions continues and the filaments slide past each other.

Cardiac muscle is similar to and different from skeletal muscle

Like skeletal muscle, cardiac muscle appears striated because of the regular arrangement of actin and myosin filaments into sarcomeres. The difference between cardiac and skeletal muscle is that cardiac muscle cells are much smaller and have only one nucleus each (*uninucleate*). Cardiac muscle cells branch, and the branches of adjoining cells interdigitate into a meshwork that is resistant to tearing:

As a result, the heart walls can withstand high pressures while pumping blood, without the danger of developing leaks. Adding to the strength of cardiac muscle are *intercalated discs* that provide strong mechanical and functional adhesions between adjacent cells. Gap junctions—protein structures that allow cytoplasmic continuity between cells—in the intercalated discs offer low-resistance pathways for ionic currents to flow between cells (see Figure 4.18 and Concept 34.3). Therefore, cardiac muscle cells are electrically coupled. An action potential initiated at one point in the heart spreads rapidly through a large mass of cardiac muscle, resulting in an integrated contraction.

Certain cardiac muscle cells are specialized for generating and conducting electrical signals. These *pacemaker* and *conducting cells* have a low density of actin and myosin filaments, but they initiate and coordinate the rhythmic contractions of the heart. (The molecular basis for this pacemaking function is covered in Concept 38.3.) Pacemaker cells make the vertebrate heartbeat *myogenic*, meaning it is generated by the heart muscle itself. A heart removed from a vertebrate can continue to beat with no input from the nervous system; although input from the autonomic nervous system modifies the *rate* of the pacemaker cells, it is not essential for their continued rhythmic function.

The mechanism of excitation–contraction coupling in cardiac muscle cells is different from that in skeletal muscle cells. The T tubules in cardiac muscle cells are larger, and the voltage-sensitive DHP proteins in the T tubules are Ca^{2+} channels. These T tubule proteins are not physically connected with the ryanodine receptors in the sarcoplasmic reticulum. Instead, the ryanodine receptors are ion-gated Ca^{2+} channels that are sensitive to Ca^{2+} . When an action potential spreads down the T tubules, it causes the voltage-gated channels to open, allowing extracellular Ca^{2+} to flow into the sarcoplasm. This slight rise

in sarcoplasmic Ca^{2+} concentration opens the Ca^{2+} channels in the sarcoplasmic reticulum, which in turn causes a huge rise in sarcoplasmic Ca^{2+} concentration, resulting in fiber contraction. This mechanism is called *Ca^{2+} -induced Ca^{2+} release*.

Smooth muscle causes slow contractions of many internal organs

Smooth muscle provides the contractile force for most of our internal organs, which are under the control of the autonomic nervous system. Smooth muscle moves food through the digestive tract, controls the flow of blood through blood vessels, and empties the urinary bladder. Structurally, smooth muscle cells are the simplest muscle cells. They are smaller than skeletal muscle cells, usually long and spindle-shaped, and each has a single nucleus. They are “smooth” because the actin and myosin filaments are not as regularly arranged as they are in skeletal and cardiac muscle, and so the cells do not have a striated appearance:

Some smooth muscle tissue, such as that from the wall of the digestive tract, consists of sheets of cells that are all in electrical contact with one another through gap junctions, as the cells are in cardiac muscle. As a result, an action potential generated in one smooth muscle cell can spread to all the cells in the sheet of tissue. Thus the cells in the sheet contract in a coordinated fashion.

The plasma membranes of smooth muscle cells are sensitive to stretch, with important consequences. If the wall of the digestive tract is stretched in one location (as by a mouthful of food passing down the esophagus to the stomach), the membranes of the stretched cells depolarize, reach threshold, and fire action potentials, which cause the cells to contract. Thus smooth muscle contracts after being stretched, and the harder it is stretched, the stronger it contracts. This behavior of smooth muscle is important for moving food through the gut.

LINK The structure and function of the gut are detailed in Concept 39.3

The neural influences on smooth muscle come from the two divisions of the autonomic nervous system. The neurotransmitters of the sympathetic and parasympathetic postganglionic cells alter the membrane potential of smooth muscle cells. For example, in the digestive tract, acetylcholine causes smooth muscle cells to depolarize, making them more likely to fire action potentials and contract. Antagonistically, norepinephrine causes

INVESTIGATION

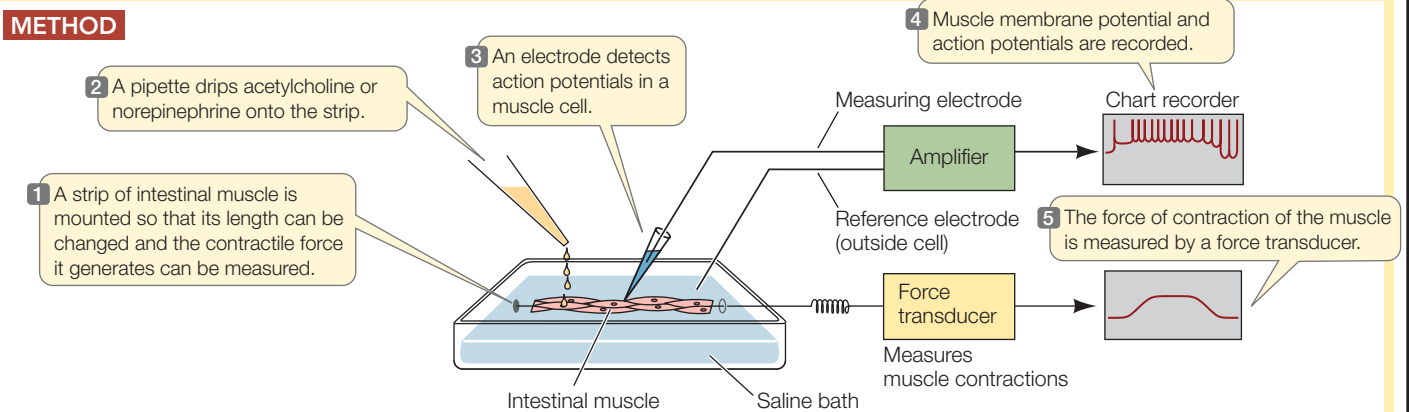

FIGURE 36.7 Neurotransmitters and Stretch Alter the Membrane Potential of Smooth Muscle Cells Several factors influence the motility of the gut. Motility increases after a meal when the ingested food stretches the walls of the gut. Activity of the autonomic nervous system also controls gut motility; the

sympathetic nervous system inhibits gut motility, and the parasympathetic nervous system stimulates it. The experimental setup below was used to study how stretching and autonomic neurotransmitters influence gut smooth muscle activity.

HYPOTHESIS

Neurotransmitters of the autonomic nervous system regulate contractions in the smooth muscles of the gut.

METHOD

RESULTS

CONCLUSION

ANS neurotransmitters can alter membrane resting potentials and affect the rate at which smooth muscle cells fire action potentials, thus controlling smooth muscle contraction.

ANALYZE THE DATA

In another experiment, the muscle strip was pulled to lengthen it, and the following data were collected:

Length of strip	Membrane potential	Firing rate	Contractile force
10 mm	-50 mv	0.8 hz	5 g
20 mm	-40 mv	1.2 hz	10 g
30 mm	-35 mv	1.6 hz	15 g

- What is the relationship between the amount the muscle was stretched and its membrane potential?
- What is the relationship between membrane potential and firing rate?
- How does firing rate influence the force of contraction?
- What would happen to your stomach motility if following a large meal you were confronted by a robber?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

these muscle cells to hyperpolarize and thus be less likely to fire action potentials and contract (FIGURE 36.7). In contrast, norepinephrine causes the smooth muscle in arteries serving the

gut to contract. Remember that the action of the neurotransmitters depends on the receptors and response mechanisms in the target tissues.

FIGURE 36.8 The Role of Ca^{2+} in Smooth Muscle Contraction When a smooth muscle cell is stimulated by neurotransmitter, Ca^{2+} enters the sarcoplasm and binds to calmodulin, which in turn activates an enzyme that phosphorylates the myosin heads, causing them to bind to actin. As long as the myosin remains phosphorylated, actin and myosin go through cycles of binding and release. Thus in smooth muscle, the Ca^{2+} -mediated change is on myosin, whereas in skeletal and cardiac muscle it is on the actin-tropomyosin filament.

Smooth muscle cell contraction is not controlled by the troponin–tropomyosin mechanism, but calcium still plays a critical role (FIGURE 36.8). A Ca^{2+} influx into the sarcoplasm of a smooth muscle cell can be stimulated by neurotransmitters, action potentials spreading from neighboring cells, hormones, or stretching. The Ca^{2+} that enters the sarcoplasm combines with a protein called *calmodulin*. The Ca^{2+} –calmodulin complex activates an enzyme called myosin kinase that phosphorylates myosin heads. When the myosin heads in smooth muscle are phosphorylated, they undergo cycles of binding and releasing actin, causing muscle contraction. As Ca^{2+} is removed from the sarcoplasm, it dissociates from calmodulin, and the activity of myosin kinase falls. An additional enzyme, myosin phosphatase, dephosphorylates the myosin to help reduce actin–myosin interactions.

concept 36.2 The Characteristics of Muscle Cells Determine Muscle Performance

The functions that different muscles perform place different demands on them. Some muscles, such as postural muscles, must sustain a load continuously over long periods of time. Other muscles, such as those that control your fingers, generally do not have to sustain long contractions, but they must be able to contract quickly. And, of course, muscles have to be able to contract in a graded manner to adjust to different loads placed on them.

Single skeletal muscle fibers can generate graded contractions

In skeletal muscle, the arrival of an action potential at a neuromuscular junction causes an action potential in a muscle fiber. The spread of that action potential through the muscle fiber's T tubule system causes a minimum unit of contraction, called a **twitch**. A twitch can be measured in terms of the *tension*, or force, it generates (FIGURE 36.9A). A single action potential stimulates a single twitch, but the ultimate force generated by an action potential can vary enormously depending on how many muscle fibers are in the motor unit it innervates. The level of tension an entire muscle generates depends on two factors:

- the number of motor units activated, and
- the frequency at which the motor units fire.

In muscles responsible for fine movements, such as those of the fingers, a motor neuron may innervate only one or a few muscle fibers, but in a muscle that produces large forces, such as the biceps, a motor neuron innervates a large number of muscle fibers.

At the level of a muscle fiber, a single action potential stimulates a single twitch. If action potentials reaching the muscle

Smooth Muscle Action

Do You Understand Concept 36.1?

- Explain how the cellular and subcellular structures of skeletal muscle cause muscle contraction. What role does ATP play?
- Explain the role of Ca^{2+} in the contractile mechanism of skeletal, cardiac, and smooth muscle.
- How does an action potential arriving at the neuromuscular junction cause the muscle to contract?
- A calcium ionophore is a chemical that allows calcium ions to cross membranes freely, without having to pass through a membrane channel. What do you think would happen in the experiment shown in Figure 36.7 if a calcium ionophore were added to the saline bath?

Now that we understand how the components of muscles generate force, let's look at what determines the characteristics of a muscle as a whole, and how individual muscles can change their characteristics with regular use and conditioning.

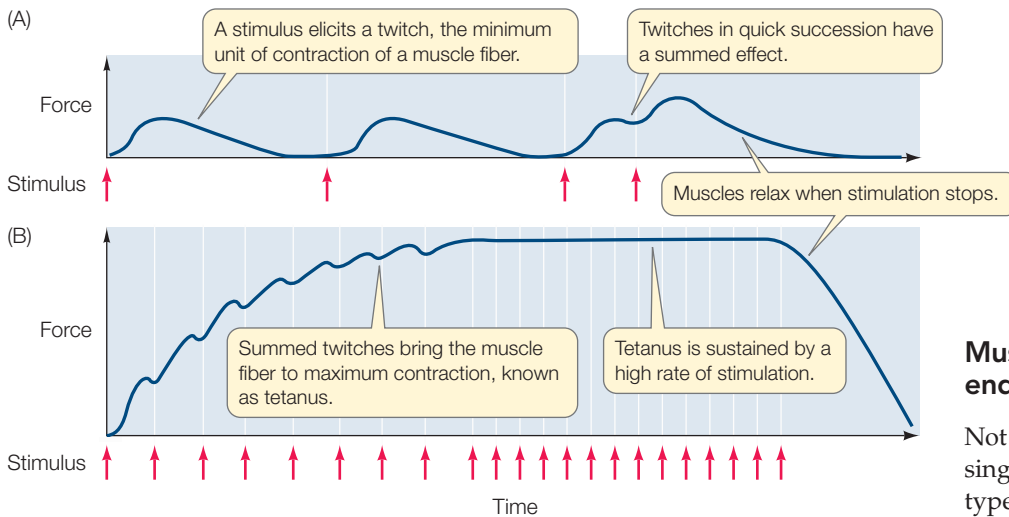

FIGURE 36.9 Twitches and Tetanus (A) Action potentials from a motor neuron cause a muscle fiber to twitch. Twitches in quick succession can be summed. (B) Summation of many twitches can bring the muscle fiber to tetanus.

Muscle fiber types determine endurance and strength

Not all skeletal muscle fibers are alike, and a single muscle often contains more than one type of fiber. The two major types of skeletal muscle fibers express different genes for

different myosin molecules, and these myosin variants have different rates of ATPase activity. Those with high ATPase activity can recycle their actin–myosin cross-bridges rapidly and are therefore called fast-twitch fibers. Slow-twitch fibers have lower ATPase activity; they develop tension more slowly but can maintain it longer.

Slow-twitch fibers are also called *oxidative* or *red muscle* because they contain the oxygen-binding protein *myoglobin*, have many mitochondria, and are well supplied with blood vessels. These characteristics both increase the fibers' capacity for oxidative metabolism and result in their red appearance. The maximum tension a slow-twitch fiber produces is low and develops slowly but is highly resistant to fatigue. Slow-twitch fibers have substantial reserves of fuel (glycogen and fat), so they can maintain steady, prolonged production of ATP as long as oxygen is available. Muscles with high proportions of slow-twitch fibers are good for long-term *aerobic* work (that is, work that requires oxygen). Long-distance runners, swimmers, cyclists, and other athletes whose activities require endurance have leg and arm muscles consisting mostly of slow-twitch fibers (**FIGURE 36.10**).

Some **fast-twitch fibers** are also called *glycolytic* or *white muscle* because, compared with slow-twitch fibers, they have few mitochondria, little or no myoglobin, and fewer blood vessels; thus they look pale. Fast-twitch glycolytic fibers can develop maximum tension more rapidly than slow-twitch fibers can, and that maximum tension is greater. However, fast-twitch fibers fatigue rapidly. The myosin of these fibers puts the energy of ATP to work very rapidly, but the fibers cannot replenish ATP quickly enough to sustain contraction for a long time. Fast-twitch fibers are especially good for short-term work that requires maximum strength. Weight lifters and sprinters have leg and arm muscles with high proportions of fast-twitch fibers. Rosie the Ribbeter in the opener to this chapter was using fast-twitch fibers in her jump. In fish, dark trunk muscle (slow-twitch) is used for steady, continuous swimming, whereas fast-twitch muscle is used for rapid spurts of activity such as escape or prey capture. When rapid contractions are necessary, as in hummingbird flight muscles or in sound generation by insects, fast-twitch muscles are involved.

fiber are adequately separated in time, each twitch is a discrete, all-or-none phenomenon. If action potentials are fired more rapidly, however, new twitches are triggered before the myofibrils have a chance to return to their resting condition. As a result, the twitches sum, and the tension generated by the fiber increases and becomes more sustained. Thus an individual muscle fiber can show a graded response to increased levels of stimulation by its motor neuron.

Twitches sum at high levels of stimulation because the calcium pumps in the sarcoplasmic reticulum are not able to clear the Ca^{2+} ions from the sarcoplasm between action potentials. Eventually a stimulation frequency can be reached that results in continuous presence of Ca^{2+} in the sarcoplasm at high enough levels to cause continuous activation of the contractile machinery—a condition known as **tetanus** (**FIGURE 36.9B**). (Do not confuse this condition with the disease called tetanus, which is caused by a bacterial toxin and is characterized by spastic contractions of skeletal muscles.)

How long a muscle fiber can maintain a tetanic contraction depends on its supply of ATP. Eventually the fiber will become fatigued. It may seem paradoxical that the *lack* of ATP causes fatigue, since the action of ATP is to break actin–myosin bonds. But remember that the energy released from the hydrolysis of ATP “re-cocks” the myosin heads, allowing them to cycle through another power stroke. When a muscle is contracting against a load, the cycle of making and breaking actin–myosin bonds must continue, to prevent the load from stretching the muscle. The situation is like rowing a boat upstream: you cannot maintain your position relative to the stream bank by just holding the oars out against the current; you have to keep rowing. Likewise, actin–myosin bonds have to keep cycling to maintain tension in the muscle.

Many muscles of the body maintain a low level of tension even when the body is at rest. For example, the muscles of the neck, trunk, and limbs that maintain our posture against the pull of gravity are always working, even when we are standing or sitting still. *Muscle tone* comes from the activity of a small but changing number of motor units in a muscle; at any one time, some of the muscle's fibers are contracting and others are relaxed. The nervous system is constantly readjusting muscle tone.

(A) Cross sections of leg muscles

(B)

FIGURE 36.10 Slow- and Fast-twitch Muscle Fibers (A) The skeletal muscles in the micrographs were stained with a reagent that shows slow-twitch fibers as dark and fast-twitch fibers as light. (B) Athletes in different sports show different percentages of slow-twitch muscles.

Muscle ATP supply limits performance

Muscles have three systems for supplying the ATP they need for contraction:

- The *immediate system* uses preformed ATP and a storage compound called *creatine phosphate (CP)*.
- The *glycolytic system* metabolizes carbohydrates to lactate and pyruvate.
- The *oxidative system* metabolizes carbohydrates or fats all the way to H_2O and CO_2 .

The capacity of these three systems and the rates at which they can produce ATP determine both work capacity and endurance (**FIGURE 36.11**).

ATP is present in muscles in very small amounts. However, muscle fibers also contain CP. This molecule stores energy in a phosphate bond, which it can transfer to ADP:

The total energy available in all the muscles of your body in the form of ATP and CP—the immediate energy system—is only about 10 kilocalories. When at rest, you metabolize 1 kilocalorie of energy in less than a minute. Even though the energy available from ATP and CP is limited, it is available immediately, and it enables fast-twitch fibers to generate a lot of force quickly. During burst activity, the immediate system is exhausted in seconds, but that is enough for a 100-meter sprint.

FIGURE 36.11 Supplying Fuel for High Performance Muscles have three systems for obtaining the ATP they need for contraction during exertion such as running.

The glycolytic system activates within a few seconds to replace the ATP depleted at the onset of muscle activity. The glycolytic enzymes are located in the cytoplasm of the muscle fiber, and therefore the ATP they generate is rapidly available to the myosin filaments. However, as noted in Chapter 6, glycolysis alone is an inefficient way to produce ATP, and it leads to the accumulation of lactic acid, which slows the process. Thus, the glycolytic system and the immediate system together can provide most of the energy for active muscles for less than a minute (see Figure 36.11).

Oxidative metabolism (which involves *oxidative phosphorylation*) becomes fully active in about a minute, producing relatively huge amounts of ATP because it can completely metabolize carbohydrates and fats. However, it requires many reactions (see Chapter 6), and it takes place in the mitochondria, so O_2 and substrate must diffuse into the mitochondria, and the formed ATP must diffuse from the mitochondria to the myosin filaments in the muscle. These processes are not instantaneous, so the rate at which oxidative metabolism can make ATP available to do work is slower than the rate at which the other two systems can supply ATP.

Do You Understand Concept 36.2?

- How do muscle fibers generate graded forces?
- Describe the differences between slow-twitch and fast-twitch fibers.
- It has recently been reported that pyruvate kinase, the enzyme that catalyzes the final step of glycolysis, is temperature sensitive. It is inactivated at high temperatures that can occur in muscles during heavy exercise. What would be the effect of inactivation of pyruvate kinase on muscle performance?

Regardless of how much force a muscle can generate, how long it can sustain a work load, or how fast it can contract and relax, a muscle needs something to pull on; otherwise it would just

be a lump of pulsating or quivering tissue. Let's look now at how skeletal systems help generate movement.

concept 36.3 Muscles Pull on Skeletal Elements to Generate Force and Cause Movement

Muscles can contract and exert force, or they can relax. To create significant movement, they must have something to pull on and something that stretches the muscle back to a longer position. In some cases, muscles pull on each other, as in the trunk of an elephant or the arms of an octopus. In most cases, however, **skeletal systems** are the rigid supports against which muscles pull to create directed movement. In this section we examine the three types of skeletal systems: hydrostatic skeletons, exoskeletons, and endoskeletons.

A hydrostatic skeleton consists of fluid in a muscular cavity

Cnidarians, annelids, and other soft-bodied invertebrates have **hydrostatic skeletons** consisting of a volume of fluid enclosed in a body cavity surrounded by muscle (see Concept 23.1). When muscles oriented in one direction contract, the fluid-filled body cavity bulges out in the opposite direction.

An earthworm uses its hydrostatic skeleton to crawl. The earthworm's body cavity is divided into many separate segments, each of which contains a compartment filled with extracellular fluid. The body wall surrounding each segment has two muscle layers: a circular layer and a longitudinal layer. Alternating contractions of the earthworm's circular and longitudinal muscles create waves of narrowing and widening, lengthening and shortening, that travel down the body (**FIGURE 36.12**). Bulging, shortened segments serve as anchors as

long, narrow segments project forward and longitudinal contractions pull other segments forward. Bristles help the widest parts of the body hold firm against the substrate.

Exoskeletons are rigid outer structures

An *exoskeleton* is a hardened, rigid outer surface to which muscles can be attached. Contractions of the muscles cause jointed segments of the exoskeleton to move relative to each other. Exoskeletons range from the relatively simple shells of mollusks (for example, clams and snails) to the complex, jointed *cuticles* of arthropods (for example, ants, spiders, and lobsters). The arthropod cuticle contains stiffening materials everywhere except at the joints, where flexibility must be retained. Muscles attached to the inner surfaces of the arthropod exoskeleton move its parts around the joints.

LINK The diverse structures and compositions of exoskeletons are detailed in Concept 23.3

A rigid exoskeleton can provide significant protection for the soft tissues of the body. However, a drawback of the arthropod exoskeleton is that it cannot expand. Therefore, if the animal is to become larger, it must *molt*, shedding its exoskeleton and forming a new, larger one.

Vertebrate endoskeletons consist of cartilage and bone

The **endoskeleton** of vertebrates is an internal scaffolding. Muscles are attached to it and pull against it. Endoskeletons are composed of rodlike, platelike, and tubelike bones connected to one another at a variety of joints that allow a wide range of movements.

The human skeleton consists of 206 bones, some of which are shown in **FIGURE 36.13**. It can be divided into an *axial skeleton*, which includes the skull, vertebral column, sternum, and ribs; and an *appendicular skeleton*, which includes the pectoral girdle, pelvic girdle, and bones of the arms, legs, hands, and feet.

The vertebrate endoskeleton consists of two kinds of connective tissue, *cartilage* and *bone*, which are produced by two kinds of connective tissue cells. *Cartilage cells* produce an extracellular matrix that is a tough, rubbery mixture of polysaccharides and proteins—mainly fibrous collagen. Collagen fibers run in all directions like reinforcing cords through the gel-like matrix and give it the well-known strength and resiliency of “gristle.” This matrix, called **cartilage**, is found in parts of the endoskeleton where both stiffness and resiliency are required, such as on the surfaces of joints where bones move against one another. Cartilage is also the supportive tissue in stiff but flexible structures such as the larynx (voice box), nose, and ear

FIGURE 36.12 A Hydrostatic Skeleton Alternating waves of muscle contraction move the earthworm through the soil. The red dot enables you to follow the changes in one segment as the worm moves forward.

FIGURE 36.13 The Human Endoskeleton Cartilage and bone make up the internal skeleton of a human being.

pinnae. Sharks and rays are called *cartilaginous fishes* because their skeletons are composed entirely of cartilage. In most other vertebrates, cartilage is the principal component of the embryonic skeleton, but during development most of it is gradually replaced by bone.

Bone also contains collagen fibers, but it gets its rigidity and hardness from an extracellular matrix of insoluble calcium phosphate crystals. Bone serves as a reservoir of calcium for the rest of the body and is in dynamic equilibrium with soluble calcium in the extracellular fluids of the body. This equilibrium is under the control of calcitonin, vitamin D, and parathyroid hormone (see Figure 30.11). If too much calcium is taken from the skeleton, the bones are seriously weakened.

The living cells of bone—*osteoblasts*, *osteocytes*, and *osteoclasts*—are responsible for the constant dynamic remodeling of bone (FIGURE 36.14). **Osteoblasts** lay down new matrix material on bone surfaces. These cells gradually become surrounded by matrix and eventually become enclosed within the bone, at which point they cease laying down matrix but

continue to exist within small lacunae (cavities) in the bone. In this state they are called **osteocytes**. Despite the vast amounts of matrix between them, osteocytes remain in contact with one another through long cellular extensions that run through tiny channels in the bone. Communication between osteocytes is important in controlling the activities of the cells that are laying down or removing bone.

The cells that resorb bone are the **osteoclasts**. They are derived from the same cell lineage that produces white blood cells. Osteoclasts erode bone, forming cavities and tunnels. Osteoblasts follow osteoclasts, depositing new bone. Thus the interplay of osteoblasts and osteoclasts constantly replaces and remodels the bones, allowing a bone to recover from damage and adjust to the forces placed on it.

FRONTIERS When astronauts spend long periods in a zero gravity environment, their bones decalcify and weaken. Conversely, in athletes, certain bones thicken during training, but if a bone is broken and immobilized in a cast, it thins. In some way that is not understood, placing stress on bones is necessary to keep them healthy. To learn more, animal physiologists are studying black bears; their bones do not thin as much as expected during their long hibernations, and they rebuild rapidly in the spring. An understanding of the mechanisms underlying the black bear's ability to maintain bone mass could help in the development of treatments for bone thinning caused by aging or inactivity.

Bones develop from connective tissues

Bones are divided into two types on the basis of how they develop. **Membranous bone** forms on a scaffold of connective tissue membrane. **Cartilage bone** forms first as a cartilaginous structure resembling the future mature bone, then gradually hardens, or

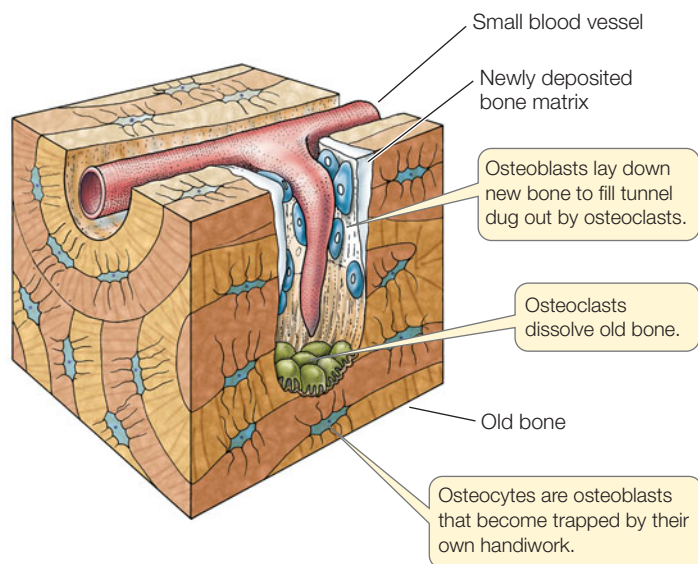

FIGURE 36.14 Bone Is Living Tissue Bones are constantly being remodeled by osteoblasts, which lay down bone, and osteoclasts, which resorb bone.

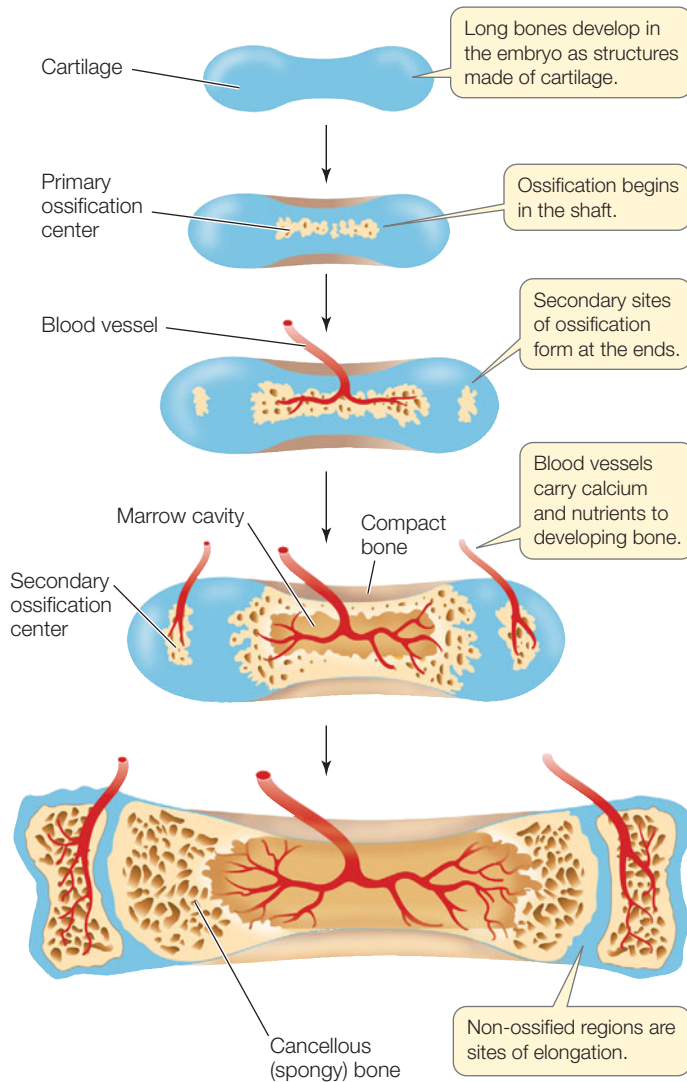

FIGURE 36.15 The Growth of Long Bones In the long bones of human limbs, ossification occurs first at the centers and later at each end.

ossifies, to become bone. The outer bones of the skull are membranous bones; the bones of the limbs are cartilage bones.

Cartilage bones can grow throughout the ossification process. The long bones of the legs and arms, for example, ossify first at the centers and later at each end (FIGURE 36.15). Growth can continue until these areas of ossification join. The membranous bones forming the skull cap grow until their edges meet. The soft spot on the top of a baby's head (the fontanelle) is the point at which the skull bones have not yet joined.

The structure of bone may be **compact** (solid and hard) or **cancellous** (having numerous internal cavities that make it appear spongy, although it is rigid). Most bones have both compact and cancellous regions. The shafts of the long bones of the limbs, for example, are cylinders of compact bone surrounding central cavities that contain the bone marrow, where the cellular elements of the blood are made. The ends of the long bones are cancellous (see Figure 36.15). Cancellous bone is lightweight because of its numerous cavities, but it is also strong because its internal meshwork constitutes a support system. It

can withstand considerable forces of compression. The rigid, tubelike shaft of compact bone can withstand compression and bending forces. Architects and nature alike use hollow tubes as lightweight structural elements.

Bones that have a common joint can work as a lever

Muscles and bones work together around **joints**, where two or more bones come together. Different kinds of joints allow motion in different directions (FIGURE 36.16), but muscles can exert force in only one direction. Therefore, muscles create movement around joints by working in antagonistic pairs: when one muscle contracts, the other relaxes. When both contract, the joint becomes rigid (which is important for maintaining posture, for example).

With respect to a particular joint, such as the knee, we refer to the muscle that bends, or flexes, the joint as the **flexor**, and the muscle that straightens, or extends, the joint as the **extensor**. The bones that meet at the joint are held together by **ligaments**, which are flexible bands of connective tissue. Other

FIGURE 36.16 Types of Joints The designs of joints are similar to mechanical counterparts and enable a variety of movements.

Go to **WEB ACTIVITY 36.3**
Joints

FIGURE 36.17 Joints, Ligaments, and Tendons A side view of the knee shows the interactions of muscle, bone, cartilage, ligaments, and tendons at this crucial and vulnerable human joint.

straps of connective tissue, called **tendons**, attach the muscles to the bones (**FIGURE 36.17**). In many kinds of joints, only the tendon spans the joint, sometimes moving over the surfaces of the bones like a rope over a pulley. The tendon of the quadriceps muscle traveling over the knee joint is what is tapped to elicit the knee-jerk reflex (see Figure 34.14).

Bones constitute a system of levers that are moved around joints by the muscles. A lever has an *effort arm* and a *load arm* that work around a *fulcrum* (pivot). The length ratio of the two arms determines whether a particular lever can exert a lot of force over a short distance or is better at translating force into large or fast movements. Compare the jaw and knee joints, for example (**FIGURE 36.18**). The effort arm of the jaw is long relative to the load arm, allowing the jaw to apply great force over a small distance. Think of the powerful jaws of carnivores that can easily crack bones. The effort arm of the lower leg, by contrast, is short relative to the load arm, so you can run fast, jump high, and deliver swift kicks.

Do You Understand Concept 36.3?

- How do the muscles and fluid-filled body cavity of an earthworm interact to enable the animal to crawl?
- Describe the differences between membranous and cartilaginous bone and between compact and cancellous bone.
- Wombats (groundhog-sized marsupials) are powerful digging animals, and kangaroos are powerful jumping animals. How do you think their leg structures compare in terms of their designs as lever systems?

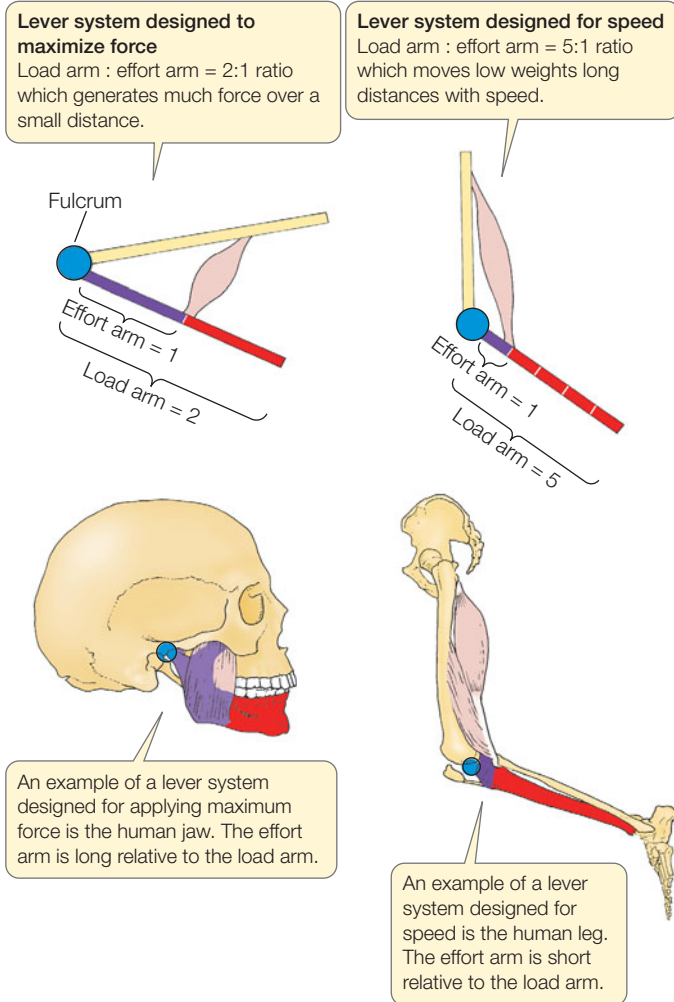

FIGURE 36.18 Bones and Joints Work Like Systems of Levers A lever system can be designed for maximizing either force or speed.

How have musculoskeletal systems evolved to maximize force generation and do so at minimal metabolic cost?

ANSWER Presumably both Jackie and Rosie the Ribeter have leg muscles that are rich in fast-twitch fibers, so that cannot explain the difference in their jumping abilities. The answer is to be found in the last topic covered in this chapter—leverage. The ratio of leg length to body mass is much greater in the frog than in the human (**FIGURE 36.19**). Thus frog legs are better at propelling a small mass a long distance, and human legs are better at propelling a large mass a short distance.

The camel has an amazing set of adaptations for efficient locomotion. The muscles that move its long legs are actually very small, and they reside mostly within or very close to the main mass of the body. Long tendons travel down the legs and insert on the bones of the legs and feet. The leverage that results is such that very small contractions of

FIGURE 36.19 Champion Jumpers Relative to their size, many animals have more impressive jumping skills than humans. This leopard frog (*Rana pipiens*) can leap distances up to 20 times its body length.

the muscles result in large-dimension movements of the legs. You might ask what about strength to carry such heavy loads? The camel does not need a lot of strength to move its legs because they have very little mass. And the gait of the camel is unusual—it paces. That means the two legs on one side of the body move forward at the same time while the weight of the camel is supported by the legs on the opposite side of the body. Thus the camel rocks from side to side as it walks, rather than moving the mass of its body up and down as most other mammals do.

The kangaroo takes advantage of elastic recoil of its tendons. When it hits the ground with its strong hindlimbs, the tendons in those limbs stretch and store part of the kinetic energy of the jump. The elasticity of those tendons then returns their stored energy to the next jump. As the kangaroo jumps faster, it takes the same number of jumps per minute, but they are longer. The longer jumps stretch the tendons more, creating more elastic energy that can help propel the next jump.

SUMMARY

concept
36.1

Cycles of Protein–Protein Interactions Cause Muscles to Contract

- **Skeletal muscle** consists of bundles of **muscle fibers**. Each skeletal muscle fiber is a large cell containing multiple nuclei.
- Skeletal muscles contain numerous **myofibrils**, which are bundles of **actin** and **myosin** filaments. The regular, overlapping arrangement of the actin and myosin filaments into **sarcomeres** gives skeletal muscle its striated appearance. **Review Figures 36.1 and 36.2 and WEB ACTIVITY 36.1**
- The molecular mechanism of muscle contraction involves the binding of the globular heads of myosin molecules to actin. Upon binding, the myosin head changes its conformation, causing the two filaments to move past each other (the sliding filament contractile mechanism). Release of the myosin heads from actin and their return to their original conformation requires ATP. **Review ANIMATED TUTORIAL 36.1**
- All the fibers activated by a single motor neuron constitute a **motor unit**. Each nerve ending of the motor neuron forms a synapse with the muscle cell membrane. When neurotransmitter is released at the synapse, the muscle cell membrane is depolarized and action potentials are generated. Action potentials spread across the plasma membrane and through the **T tubules**, causing Ca^{2+} to be released from the **sarcoplasmic reticulum**. **Review Figure 36.5 and WEB ACTIVITY 36.2**
- Ca^{2+} binds to **troponin** and changes its conformation, pulling the **tropomyosin** strands away from the myosin-binding sites on the actin filament. The muscle fiber continues to contract until the Ca^{2+} is returned to the sarcoplasmic reticulum. **Review Figure 36.6**

concept

The Characteristics of Muscle Cells Determine Muscle Performance

- In skeletal muscle, a single action potential causes a minimum unit of contraction called a **twitch**. Twitches occurring in rapid succession can be summed, thus increasing the strength of contraction. Maximum sustained tension is called **tetanus**. **Review Figure 36.9**
- **Slow-twitch fibers** facilitate extended, aerobic work; **fast-twitch fibers** generate maximum forces for short periods of time. **Review Figure 36.10**
- Muscle performance depends on a supply of ATP. Available ATP and creatine phosphate (CP) can fuel maximum tension instantaneously but are exhausted within seconds. Glycolysis can regenerate ATP rapidly but is limited by accumulation of lactic acid. Oxidative metabolism delivers ATP more slowly but can continue to do so for a long time. **Review Figure 36.11**

Gas Exchange in Animals

37

And so back up the gradual slopes, the wind behind me. A much greater effort this, stopping every few yards with a slight anxiety lest I should not make the distance. As I approached the tents, I was astonished to see a bird, a chough, strutting about on the stones near me.... During this day, too, Charles Evans saw what must have been a migration of small grey birds. Neither of us had thought to find any signs of life as high as this.

Sir John Hunt,
Ascent of Everest, 1953

The passage above comes from a book about the first successful climbing of Mount Everest, 8,850 meters high, and it describes an observation Hunt made at the last camp before the summit attempt. At that altitude, experienced and acclimated climbers are practically incapacitated if they do not breathe supplemental oxygen from pressurized bottles. Prior to the moment described in the passage, Hunt had gone a short distance downhill from his tent without supplemental oxygen.

Why do people have so much difficulty at high altitude? The atmosphere has the same percentage of oxygen at sea level and on top of Mount Everest—but there is less atmosphere the higher you go. A cubic meter of air atop Mount Everest has about one-third as much oxygen as an equivalent volume of air at sea level. Birds, however, are able to function normally and even fly under those conditions.

The champion for high-altitude flight is the bar-headed goose, which migrates over the Himalayan mountains. Migrating groups of bar-headed geese have been observed at 10,175 meters. There is so little oxygen at that altitude that kerosene

will not burn. Yet many species migrate at these high altitudes, as evidenced by radar signals, plane sightings (and collisions), and eyewitness accounts. These feats are all the more remarkable because the energetic costs of flapping flight are high—about the equivalent metabolic output of a well-trained human athlete engaged in a high-intensity activity that can be sustained for only minutes—yet the migrating birds can sustain it for hours and even days. Furthermore, the lungs of a bird are smaller than the lungs of a similar-sized mammal. Bird lungs are also less compliant—they do not inflate as much. Long-distance bird flight at high altitudes is the ultimate athletic performance.

How are bar-headed geese able to sustain the high metabolic cost of flight at altitudes higher than Mount Everest?

Bar-headed geese have adaptations that enable them to fly over high mountains.

KEY CONCEPTS

- 37.1** Fick's Law of Diffusion Governs Respiratory Gas Exchange
- 37.2** Respiratory Systems Have Evolved to Maximize Partial Pressure Gradients

- 37.4** Respiration Is under Negative Feedback Control by the Nervous System
- 37.5** Respiratory Gases Are Transported in the Blood

concept 37.1 Fick's Law of Diffusion Governs Respiratory Gas Exchange

The **respiratory gases** that animals must exchange are oxygen (O_2) and carbon dioxide (CO_2). Cells need O_2 from the environment to produce ATP by cellular respiration (see Chapter 6), and they must get rid of CO_2 , the end product of cellular respiration. Diffusion is the only way respiratory gases can be exchanged between an animal and the environment (air or water); there are no active transport mechanisms to move respiratory gases across biological membranes. Diffusion is a physical process, and knowing the physical factors that influence rates of diffusion helps us understand the diverse adaptations of gas exchange systems. In this concept we will discuss environmental factors that influence diffusion rates; we will then consider adaptations that facilitate the exchange of respiratory gases.

LINK Concept 5.2 discusses the diffusion of molecules in solution, and Concept 6.2 describes aerobic cellular respiration and the production of ATP

Diffusion is driven by concentration differences

Because diffusion results from the random motion of molecules, the net movement of molecules is always from an area of higher concentration to an area of lower concentration. Biologists express the concentrations of different gases in a mixture as the *partial pressures* of those gases. For air-breathing animals, the total pressure of the gas mixture they breathe is atmospheric pressure, or **barometric pressure**, and it is measured with a *barometer*. A classic barometer is a glass tube closed at one end, filled with mercury, and inverted over a pool of mercury with the open end under the surface of the mercury. In a total vacuum such as outer space, the mercury would just flow out of the tube, but on Earth it does not because of the pressure the atmosphere exerts on the pool of mercury. At sea level, the pressure exerted by the atmosphere supports, and is therefore equal to, a column of mercury about 760 mm high (depending on the weather):

Therefore barometric pressure (atmospheric pressure) at sea level is 760 mm of mercury (mm Hg). Because dry air is 20.9

percent O_2 , the **partial pressure of oxygen** (P_{O_2})—that is, the contribution of O_2 to the total air pressure—at sea level is 20.9 percent of 760 mm Hg, or about 159 mm Hg.

Describing the concentration of respiratory gases in a liquid such as water is a little more complicated because another factor is involved—the solubility of the gas in the liquid. The actual amount of a gas in a liquid depends on the partial pressure of that gas in the gas phase in contact with the liquid, as well as on the solubility of that gas in that liquid. So for fresh water close to $0^\circ C$ in equilibrium with the atmosphere at 760 mm Hg, the partial pressure of O_2 in both air and water is 159 mm Hg, but whereas the volume of O_2 in the air is about 200 ml/L, the volume of O_2 dissolved in the water is only 10 ml/L. The diffusion of the gas between the gaseous phase and the liquid depends on the partial pressures of the gas in the two phases, but the volume of gas that enters the liquid depends on its solubility.

Fick's law applies to all systems of gas exchange

Diffusion is a physical phenomenon that can be described with a simple equation called **Fick's law of diffusion**. All environmental variables that limit respiratory gas exchange and all adaptations that maximize respiratory gas exchange are reflected in one or more components of this equation. Fick's law is written as

$$Q = DA \frac{P_1 - P_2}{L}$$

where

- Q is the rate at which a gas such as O_2 diffuses between two locations.
- D is the *diffusion coefficient*, which is a characteristic of the diffusing substance, the medium, and the temperature. (For example, perfume has a higher D than motor oil vapor, and all substances diffuse faster at higher temperatures, as well as diffusing faster in air than in water.)
- A is the cross-sectional area across which the gas is diffusing.
- P_1 and P_2 are the partial pressures of the gas at the two locations.
- L is the path length, or distance, between the two locations.

Therefore $(P_1 - P_2)/L$ is a *partial pressure gradient*.

Animals can maximize D for respiratory gases by using air rather than water as their gas exchange medium whenever possible. All other adaptations for maximizing respiratory gas exchange must influence the surface area (A) for gas exchange or the partial pressure gradient $[(P_1 - P_2)/L]$ across that surface area.

Air is a better respiratory medium than water

Oxygen can be obtained more easily from air than from water for several reasons:

- The O_2 content of air is much higher than the O_2 content of an equal volume of water. A cascading freshwater stream has an O_2 content of less than 10 ml of O_2 per liter of water,

whereas the air over the stream has an O_2 content of about 200 ml of O_2 per liter of air.

- O_2 diffuses about 8,000 times more rapidly in air than in water.
- When an animal breathes, it does work to move water or air over its specialized gas exchange surfaces. More energy is required to move water than to move air because water is much more dense and viscous than air.

Even in air-breathing animals, the slow rate of O_2 diffusion in water limits the efficiency of O_2 distribution from gas exchange surfaces to the sites of cellular respiration. Eukaryotic cells carry out cellular respiration in their mitochondria, which are surrounded by aqueous cytoplasm. The cells themselves are bathed in extracellular fluid—also an aqueous medium. In addition, all respiratory surfaces must be protected from desiccation by a thin film of fluid. O_2 breathed in must diffuse through all of these aqueous compartments to get to the mitochondria.

Diffusion of O_2 in water is so slow that even animal cells with low rates of metabolism can be no more than a few millimeters away from a good source of environmental O_2 . Therefore most invertebrates that lack internal systems for distributing O_2 are very small or, like flat worms, have evolved a flat, thin body that maximizes surface area:

Pseudoceros ferrugineus

Others, such as sponges and cnidarians, have a thin body structure with a central cavity through which water circulates:

Callyspongia plicifera

A critical factor enabling larger, more complex animal bodies has been the evolution of specialized respiratory systems with large surface areas for enhancing respiratory gas exchange.

O_2 availability is limited in many environments

Environmental temperature can compromise the O_2 available for water-breathers. Warm water holds less O_2 per liter than does cold water. Furthermore, most animals that live in water are ectothermic, meaning their body temperature is the same as the temperature of the surrounding environment. This means that as water warms up, a fish warms up too, and that means its metabolic rate increases. As metabolic rate increases, the fish needs more and more O_2 —just when there is less and less O_2 available in the water. If the surrounding water becomes too warm, a fish will soon reach a point when it simply cannot obtain enough O_2 from the water to survive.

As discussed in the opening section of this chapter, O_2 availability for air-breathers decreases as altitude increases. Since O_2 's rate of diffusion depends on the P_{O_2} difference between the air and the body fluids, the drastically reduced P_{O_2} in the air at

APPLY THE CONCEPT

Fick's law of diffusion governs respiratory gas exchange

Water contains much less O_2 than an equal volume of air, and it requires more effort to move it over respiratory exchange surfaces. Other factors that affect respiration in water-breathing animals are changes in solubility of O_2 in water and the effect of temperature on their O_2 needs. Answer each of the following questions by constructing a graph from the data in the table. Use water temperature as your x axis.

1. How does water temperature influence the O_2 available to a water-breathing animal?
2. How does water temperature affect the O_2 demand of a water-breathing animal?
3. From the data, what is the evidence that O_2 availability is a limiting factor for metabolism in warm water?

WATER TEMPERATURE (°C)	O_2 CONTENT OF WATER (ML/L)	METABOLIC RATE OF INACTIVE FISH (ML O_2 /KG/HR)	METABOLIC RATE OF ACTIVE FISH (ML O_2 /KG/HR)
5	9.0	8	30
15	7.0	50	110
25	5.8	140	255
35	5.0	225	285

4. From this study, what general argument would you make about the effect of environmental warming on the viability of aquatic species?

high altitudes sharply reduces the rate of diffusion of O_2 from air to blood.

CO₂ is easily lost by diffusion

CO₂ diffuses out of the body as O₂ diffuses in. Since the amount of CO₂ in the atmosphere is extremely low (0.03%), air-breathing animals always have a large concentration gradient for diffusion of CO₂ from their bodies.

Getting rid of CO₂ is also not a problem for water-breathing animals. CO₂ is much more soluble in water than is O₂, so even in stagnant water, where the partial pressure of carbon dioxide (P_{CO₂}) is higher than in moving water, the lack of O₂ becomes a problem for an animal before CO₂ exchange difficulties arise.

Do You Understand Concept 37.1?

- Explain the phenomenon of diffusion and how it is influenced by each component of Fick's law.
- In many fishes, lungs or lunglike structures have evolved that allow the fish to gulp mouthfuls of air from the surface to supplement their O₂ intake. Predict whether this air-gulping ability has evolved more often in warm-water fishes or in cold-water fishes, and explain your reasoning.
- For each component of Fick's law, propose an adaptation that would improve respiratory gas exchange for an air-breathing and a water-breathing animal.

Now that we have an understanding of the physical factors that influence diffusion rates of respiratory gases between animals and their environments, let's look at some of the corresponding adaptations that have evolved for maximizing respiratory gas exchange.

concept 37.2

Respiratory Systems Have Evolved to Maximize Partial Pressure Gradients

Gas exchange systems are made up of gas exchange surfaces and the mechanisms that *ventilate* those surfaces with air or water, and *perfuse* those surfaces with blood or other body fluids. As you might expect from the components of Fick's law of diffusion, adaptations to maximize respiratory gas exchange can be categorized as those that:

- increase the surface area for gas exchange
- maximize the partial pressure difference driving diffusion
- minimize the diffusion path length
- minimize the diffusion processes that take place in an aqueous medium

Respiratory organs have large surface areas

A variety of anatomical adaptations maximize the specialized body surface area (A) over which respiratory gases can diffuse. Water-breathing animals generally have *gills*, and air-breathing animals have *tracheae* or *lungs*. **External gills** are highly branched extensions of the body surface that provide a large surface area for gas exchange with water (FIGURE 37.1A). External gills are found in larval amphibians and in many insect larvae. Because they consist of thin, delicate tissues, external gills minimize the path length (L) traversed by diffusing molecules of O₂ and CO₂. In many animals, protective body cavities for gills have evolved. Such **internal gills** are found in shelled mollusks such as clams, aquatic arthropods, and all fishes (FIGURE 37.1B).

Lungs are internal cavities for respiratory gas exchange with air (FIGURE 37.1C). Lungs have a large surface area because they are highly divided; and because they are elastic, they can be inflated with air and deflated.

Instead of lungs, insects have a network of air-filled tubes called **tracheae** that branch through all tissues of the insect's body (FIGURE 37.1D).

Partial pressure gradients can be optimized in several ways

Diffusion is driven by partial pressure gradient $[(P_1 - P_2)/L]$, so the larger the gradient, the greater the rate of gas exchange. Partial pressure gradients can be maximized in several ways:

- **Minimization of path length:** Very thin tissues in gills and lungs reduce the diffusion path length (L).
- **Ventilation:** Actively moving the external medium over the gas exchange surfaces (i.e., breathing) regularly exposes those surfaces to fresh respiratory medium containing maximum O₂ and minimum CO₂ concentrations. This maximizes $P_1 - P_2$.
- **Perfusion:** Actively moving the internal medium (e.g., blood) over the internal side of the exchange surfaces transports

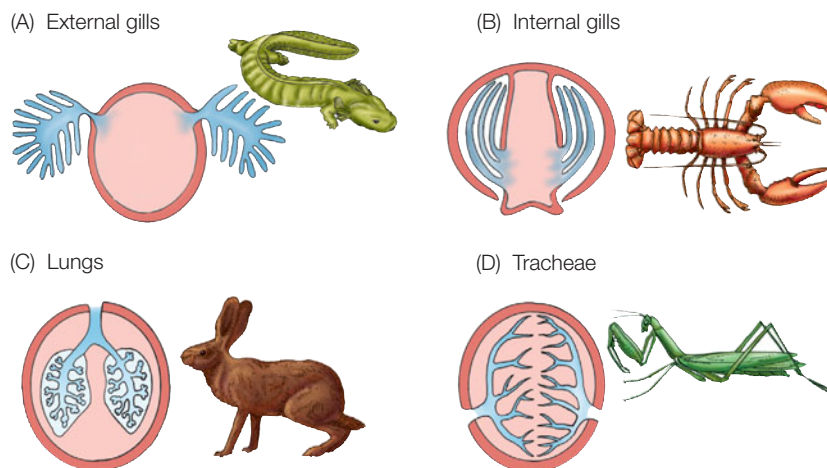

FIGURE 37.1 Gas Exchange Systems Large surface areas (blue in these diagrams) for the diffusion of respiratory gases are common features of animals. External (A) and internal (B) gills are adaptations for gas exchange with water. Lungs (C) and tracheae (D) are organs for gas exchange with air.

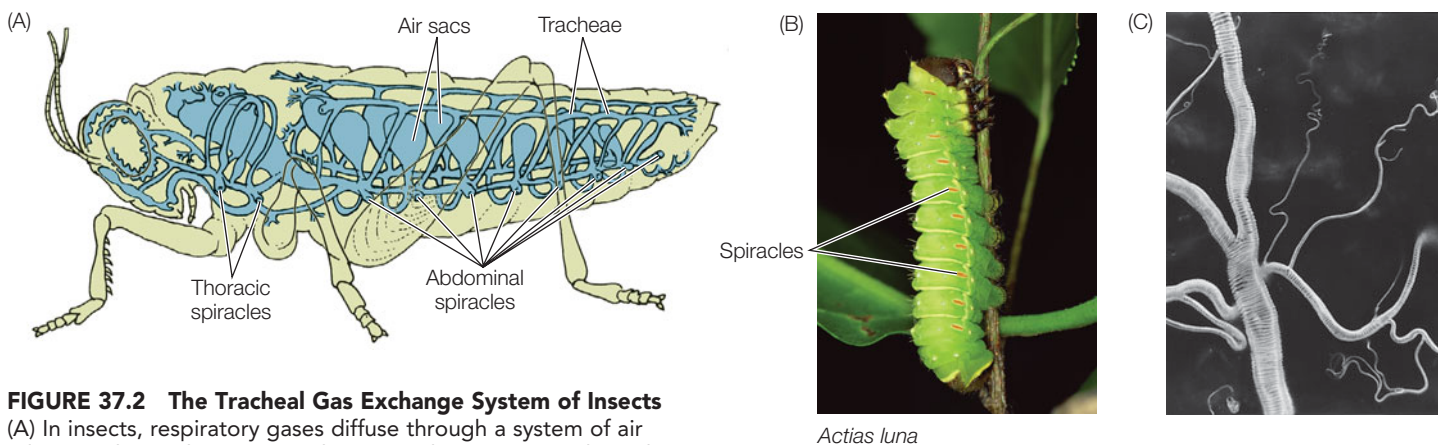

FIGURE 37.2 The Tracheal Gas Exchange System of Insects

(A) In insects, respiratory gases diffuse through a system of air tubes (tracheae) that open to the external environment through holes called spiracles. (B) The spiracles of a luna moth larva run down its sides. (C) A scanning electron micrograph shows an insect trachea dividing into smaller tracheoles and still finer air capillaries.

CO_2 to those surfaces and O_2 away from them. This also maximizes $P_1 - P_2$.

All gas exchange organs in animals rely on these basic principles, but the details vary in different animal groups. Below we will look at three examples: insect tracheae, fish gills, and lungs—in particular, avian lungs, which differ from those of other terrestrial vertebrates.

Insects have airways throughout their bodies

Rather than having a central respiratory organ like a lung or gill, insects have an extensive networking system of air tubes that bring air close to every cell. Thus respiratory gases diffuse through air most of the way to and from each cell. Air enters through openings called *spiracles* in the sides of the abdomen and thorax (FIGURE 37.2A AND B). The spiracles can close to decrease water loss. They connect to tubes called *tracheae* that branch into even finer tubes, or *tracheoles*, that end in tiny *air capillaries*, which are the gas exchange surfaces (FIGURE 37.2C). The terminal branches of these tubes are so numerous that they have an enormous surface area. In the insect's flight muscles and other highly active tissues, every mitochondrion is close to an air capillary. Rhythmic body contractions that promote ventilation throughout this network can be observed in some insects.

Fish gills use countercurrent flow to maximize gas exchange

The most efficient way for one solution (e.g., blood) to take up O_2 from another solution (e.g., an aqueous environment) is by **countercurrent exchange** (FIGURE 37.3). The structure and function of fish gills exemplify this principle. The internal gills of fishes are supported by *gill arches* that lie between the mouth cavity and the protective *opercular flaps* on the sides of the fish

just behind the eyes (FIGURE 37.4A). Water flows *unidirectionally* into the fish's mouth, over the gills, and out from under the opercular flaps. Thus the gills are continuously bathed with fresh water. This constant, one-way flow of water over the gills maximizes the P_{O_2} on the external gill surfaces. On the internal side of the gill membranes, the circulation of blood minimizes the P_{O_2} by sweeping O_2 away as rapidly as it diffuses across. Both of these features help maximize the partial pressure gradient for O_2 uptake.

Gills have an enormous surface area for gas exchange because they are so highly divided. Each gill consists of hundreds of ribbonlike *gill filaments* (FIGURE 37.4B). The upper and lower flat surfaces of each gill filament are covered with rows of evenly spaced folds, or *lamellae*. The lamellae are the actual gas exchange surfaces. Because the lamellae are exceedingly

FIGURE 37.3 Counter-current Exchange Is More Efficient In these models of concurrent and countercurrent gas exchange, the numbers represent the O_2 saturation percentages of blood and water. The thin black arrows represent the diffusion of O_2 molecules. (A) In a concurrent exchanger, the saturation percentages of blood and water reach equilibrium halfway across the exchange surface. (B) A countercurrent exchanger allows more complete gas exchange because the water is always more O_2 -saturated than the blood; thus a gradient of O_2 saturation is maintained.

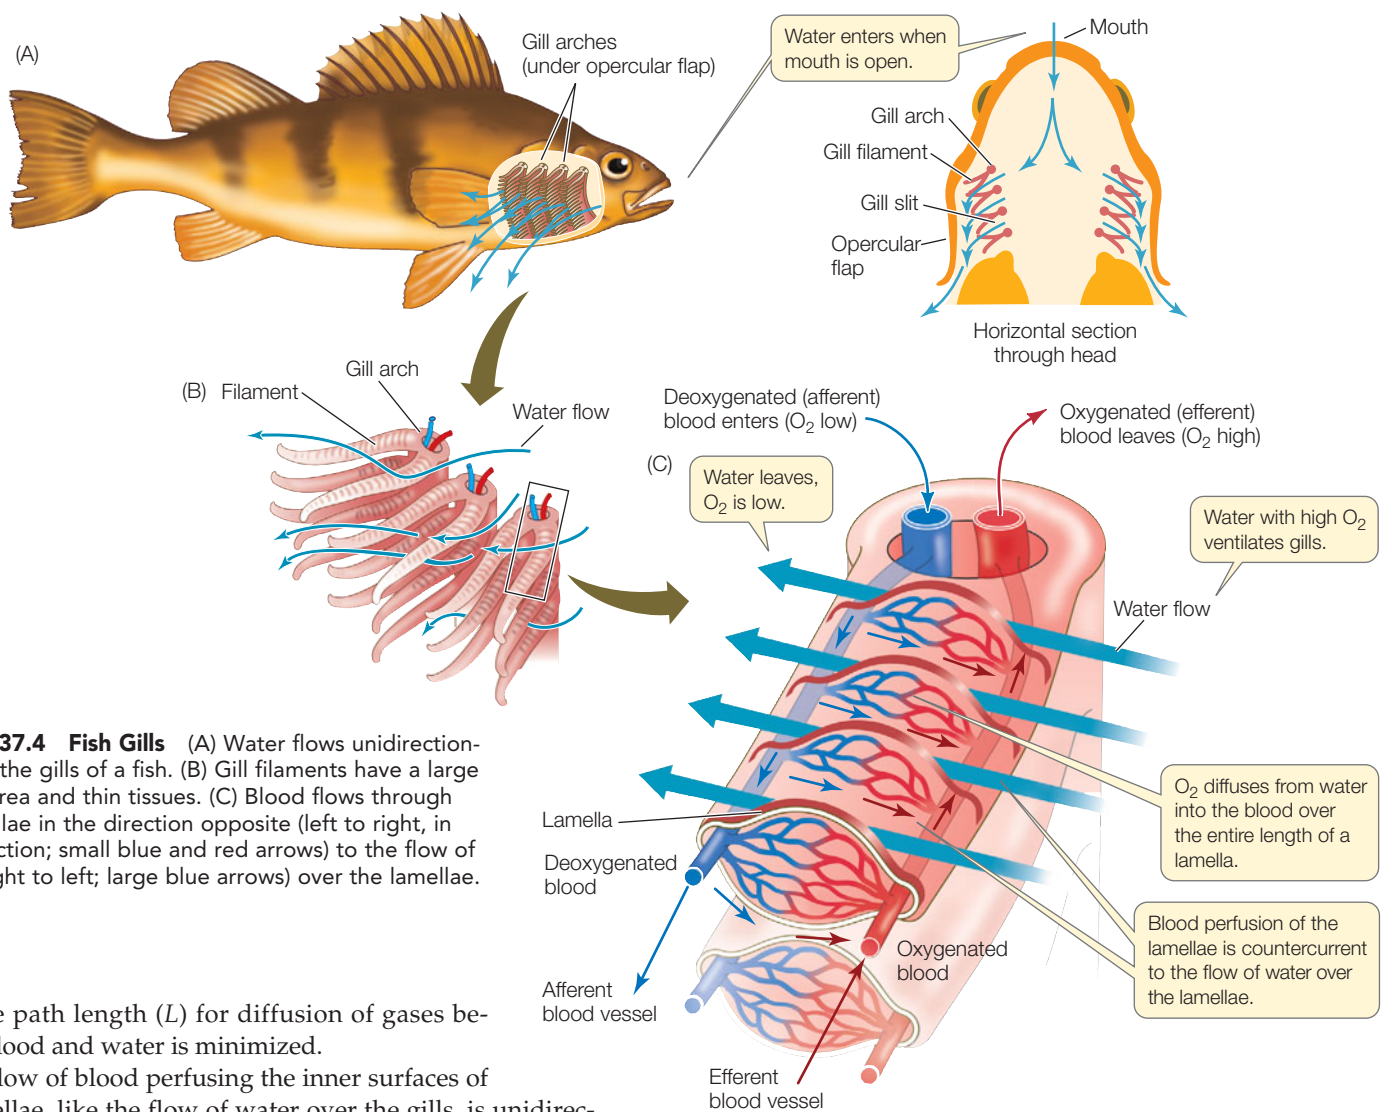

FIGURE 37.4 Fish Gills (A) Water flows unidirectionally over the gills of a fish. (B) Gill filaments have a large surface area and thin tissues. (C) Blood flows through the lamellae in the direction opposite (left to right, in this depiction; small blue and red arrows) to the flow of water (right to left; large blue arrows) over the lamellae.

thin, the path length (L) for diffusion of gases between blood and water is minimized.

The flow of blood perfusing the inner surfaces of the lamellae, like the flow of water over the gills, is unidirectional. *Afferent* blood vessels bring deoxygenated blood to the gills, while *efferent* blood vessels take oxygenated blood away from the gills (FIGURE 37.4C). Blood flows through the lamellae in the direction opposite to the flow of water over the lamellae. This *countercurrent flow* optimizes the P_{O_2} gradient between water and blood, making gas exchange more efficient than it would be in a system using concurrent (parallel) flow (see Figure 37.3).

LINK Countercurrent flow is also important for thermoregulation in some animals and in mammalian kidney function; see Figures 29.10 and 40.8

Some fishes, including anchovies, tuna, and some sharks, ventilate their gills by swimming almost constantly, thus forcing water into their open mouths and over their gills. Most fishes, however, ventilate their gills by means of a two-pump mechanism. Closing and contracting the mouth cavity pushes water over the gills, and the expansion of the opercular cavity prior to opening of the opercular flaps pulls water over the gills.

These adaptations for maximizing the surface area (A) for diffusion, minimizing the path length (L) for diffusion, and maximizing the P_{O_2} gradient allow fishes to extract an adequate supply of O_2 from meager environmental sources.

Most terrestrial vertebrates use tidal ventilation

Lungs evolved in the first “air-gulping” vertebrates as out-pocketings of the digestive tract. Although their structure has evolved considerably, lungs remain dead-end sacs in all air-breathing vertebrates except birds. Because of this, ventilation cannot be constant and unidirectional but must be **tidal**: fresh air flows in and exhaled gases flow out by the same route. Because of this two-way tidal flow, lungs and airways are never completely emptied of air. At the end of an exhalation they always contain some *dead space*, or **residual volume (RV)**, containing “stale” (low- O_2) air. On the next inhalation, fresh air entering the lungs mixes with the stale air that was already in the lungs. Therefore, the P_{O_2} in the mixed air that reaches the gas exchange surfaces is less than the P_{O_2} of the outside air. Tidal ventilation also precludes countercurrent exchange as a means of maximizing the partial pressure gradients. Amphibians, reptiles, and mammals all use tidal ventilation.

Mammals have high metabolic rates, and mammalian lungs have some evolved features that maximize the rate of gas exchange: an enormous surface area, a very short path length for diffusion, and a high ventilatory capacity (an ability to move a

(A) Avian air sacs and lungs

(B) Microscopic view of avian lung tissue

Air capillaries carry air from a parabronchus over blood capillaries, where O_2 is absorbed, and then out through the parabronchus.

large volume of air in and out of the lungs). These adaptations help mammals obtain enough O_2 to support their high metabolic rates. But what about the group of vertebrates that have the highest metabolic rates of all—the birds?

Birds have air sacs that supply a continuous unidirectional flow of fresh air

As discussed in the chapter opener, the ability of birds to sustain high metabolic rates at high altitudes is remarkable. Yet the lungs of birds are smaller than the lungs of similar-sized mammals, and during the breathing cycle, bird lungs do not change in volume as much as mammalian lungs do. And the most unusual feature of bird lungs is that they decrease in volume during inhalation and increase in volume during exhalation. How are birds able to fly in environments where the P_{O_2} is so low that a comparably sized mammal would pass out?

A lung structure evolved in birds that allows air to flow unidirectionally through the lungs (FIGURE 37.5). Air enters a bird lung from the posterior end and flows through the

FIGURE 37.5 The Respiratory System of a Bird (A) Air sacs and air spaces in the bones are unique to birds. (B) Air flows through bird lungs unidirectionally in parabronchi. Air capillaries, the site of gas exchange, branch off the parabronchi.

Airflow in Birds and
WORKING WITH DATA 37.1

lung in a series of tubes called *parabronchi*. Branching off the parabronchi are tiny *air capillaries*, which are the gas exchange surfaces. The air capillaries are so numerous that they provide an enormous surface area for gas exchange. The parabronchi coalesce into larger bronchi that take the air out of the anterior end of the lung. Since air leaves the lung by a different path than it entered, bird lungs have very little dead space, and fresh incoming air is not mixed with stale air. In this way, a high P_{O_2} gradient is maintained between the incoming air and the blood.

Bird lungs also receive fresh air continuously, even during exhalation. This is made possible by multiple **air sacs**, thin-walled air storage spaces that are not gas exchange organs. The air sacs are interconnected with each other, with the lungs, and with air spaces in some of the bones (see Figure 37.5A), and they can be divided into two groups: anterior and posterior. During inhalation the posterior air sacs receive the incoming air, and the anterior air sacs receive the air that was in the lungs. During exhalation the air in the posterior air sacs flows into the lungs, and the air in the anterior air sacs leaves the bird. Thus the air sacs work like bellows to create a continuous flow of fresh air through the lungs.

Do You Understand Concept 37.2?

- As we will discuss in the Chapter 38, insects do not have closed blood circulatory systems that could transport respiratory gases around their bodies, yet some insects are able to sustain high metabolic rates. Explain how this is possible.
- Compare the adaptations of fishes and birds that optimize the terms of Fick's law of diffusion. In what ways are they similar and in what ways different?
- Present-day reptiles are good at burst activity but not at long, sustained, high-metabolic efforts. Birds and other dinosaurs share a common reptilian ancestor (see Chapter 23). What feature would you look for in dinosaur fossils to support the hypothesis that dinosaurs were capable of sustained, high levels of metabolic activity like present-day birds?

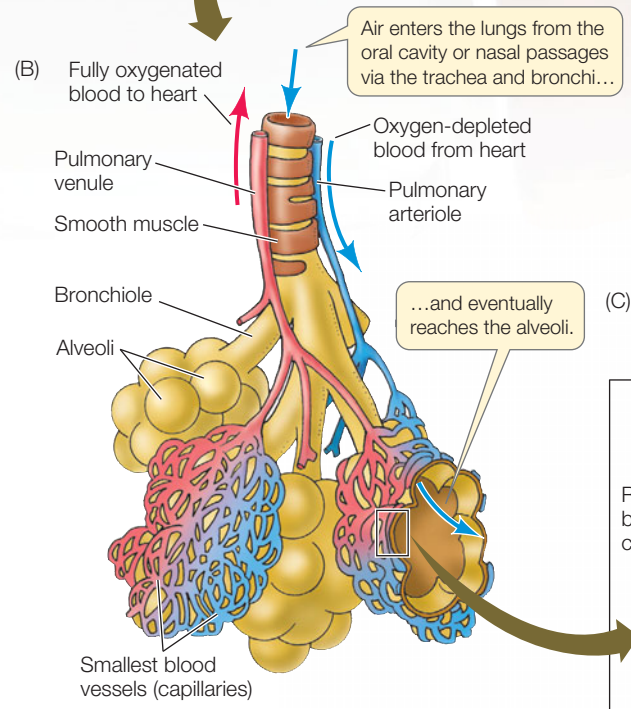

Let's take a closer look now at the anatomy and function of mammalian lungs, focusing on the human respiratory system as an example.

(A)

FIGURE 37.6 The Human Respiratory System The diagrams trace the hierarchy of human respiratory structures, from the airways to the minuscule alveoli.

The bronchi are the major air passageways of the lungs. They lead to the bronchioles, which are finely branched, as are the blood vessels.

The Human Respiratory System

concept 37.3 The Mammalian Lung Is Ventilated by Pressure Changes

In mammals, air enters the lungs through the oral cavity and the nasal passage, which join together in the *pharynx* (FIGURE 37.6A). Below the pharynx, the *esophagus* directs food to the stomach, and the *trachea* leads to the lungs. At the beginning of the trachea is the *larynx*, or voice box, which houses the vocal cords. The larynx is the “Adam’s apple” that you can see or feel on the front of your neck. The trachea’s thin walls are prevented from collapsing by bands of cartilage. If you run your fingers down the front of your neck just below your larynx, you can feel a few of these bands.

The trachea branches into two *bronchi*, one leading to each lung. Each bronchus branches repeatedly to generate a treelike structure of progressively smaller airways extending to all regions of the lungs. The smallest airways have no cartilage supports and are called **bronchioles**. The bronchioles branch a few more times, eventually leading to tiny, thin-walled air sacs, the **alveoli**. Alveoli are the sites of gas exchange (FIGURE 37.6B).

Human lungs have about 300 million alveoli. Although each alveolus is very small, their combined surface area for diffusion of respiratory gases is about 70 square meters—about one-fourth the size of a basketball court. Each alveolus is made of very thin cells. Between and surrounding the alveoli are networks of capillaries whose walls are also made up of exceedingly thin cells. Where capillary meets alveolus, very little tissue separates them (FIGURE 37.6C), so the length of the diffusion path between air and blood is less than 2 micrometers.

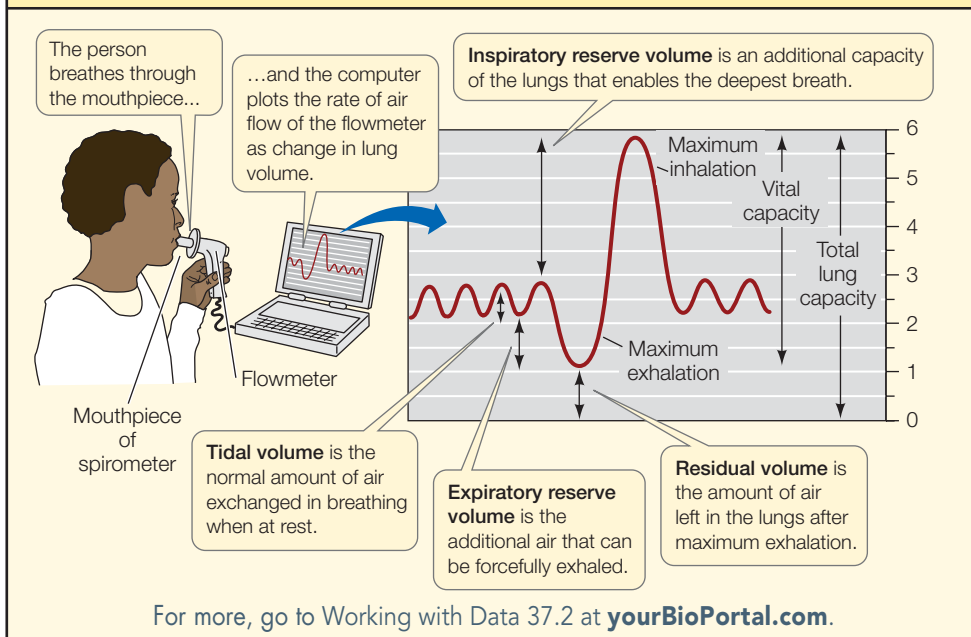

Secretions from lung tissues are not directly involved in gas exchange but are important for lung function. *Mucus* secreted in the airways helps capture inhaled particles and pathogens. Cilia in the bronchioles and bronchi continuously sweep the mucus and its trapped debris up to the pharynx where it can be swallowed. Nicotine in tobacco paralyzes these cilia, making it difficult to clear the airways and resulting in smoker’s cough.

Specialized cells in the alveoli secrete a fatty substance that serves as a *surfactant* to reduce the surface tension of the thin film of fluid that lines the inner surfaces of the alveoli. The work that must be done to inflate the lungs includes overcoming both the elasticity of the alveolar tissues and the surface tension. By reducing that surface tension, the surfactant decreases the effort required for inhalation.

FRONTIERS A baby that is born extremely prematurely—at 30 weeks of gestation or sooner—has lungs that are not fully developed and may not be producing lung surfactant. This makes it very difficult for the baby to inflate its lungs, resulting in Respiratory Distress Syndrome. If untreated, the baby gradually becomes exhausted from the breathing effort and can die in 2 to 7 days. A very successful treatment available today is application of artificial lung surfactant as an aerosol on the first day after birth. This treatment has reduced mortality from about 100 percent to 10 percent of cases. Among those 10 percent, however, are infants who are not extremely premature but are, for unknown reasons, resistant to treatment. Additional causes of failure of the lung surfactant system are being sought in the genes involved in surfactant synthesis and secretion.

RESEARCH TOOLS

FIGURE 37.7 Measuring Lung Ventilation A spirometer is a device that measures the volume of air a person breathes through a mouthpiece. The combined tidal volume, inspiratory reserve volume, and expiratory reserve volume are the lungs’ vital capacity.

At rest, only a small portion of the lung’s volume is exchanged

The amount of air that moves in and out per breath when a person is at rest is called the **tidal volume (TV)**. When we breathe in as much as possible, the additional volume is the **inspiratory reserve volume (IRV)**. Conversely, if we forcefully exhale as much air as possible, the additional amount of air expelled is the **expiratory reserve volume (ERV)**. The maximum capacity for air exchange in one breath, or the **vital capacity (VC)**, is the sum of TV + IRV + ERV (FIGURE 37.7). The vital capacity of an athlete is generally greater than that of a nonathlete, and vital capacity decreases with age because of stiffening of the lung tissues.

As noted in Concept 37.2, tidal ventilation involves a residual volume (RV) because the lungs and airways can never be completely emptied of air. The O_2 -poor RV dilutes the O_2 in the inhaled air. In most adult humans, TV averages about 500 ml, ERV is about 1,000 ml, and RV is 1,000 ml (see Figure 37.7). Thus the

air that reaches the alveoli with each breath consists of only 500 ml of fresh air diluted by 2,000 ml of stale air. The maximum P_{O_2} in this mixed air is thus much below the P_{O_2} of the outside air.

Any disease or condition that increases the RV compromises a person's respiratory ability. For example, *emphysema* is a condition in which inflammation damages and eventually destroys the walls of the alveoli, resulting in fewer but larger alveoli. The result is that RV increases. This diminishes the partial pressure gradient of O_2 , resulting in less O_2 diffusing to the blood. Emphysema is the fourth leading cause of death in the United States; the principal cause is smoking.

Lungs are ventilated by pressure changes in the thoracic cavity

Mammalian lungs are suspended in the **thoracic cavity**, which is bounded on the top by the shoulder girdle, on the sides by the rib cage, and on the bottom by a sheet of muscle called the **diaphragm**. Each lung is covered by a sheet of tissue called the **pleural membrane**, and the thoracic cavity is also lined by pleural membrane (see Figure 37.6A). There is a thin film of fluid in the pleural cavity between the pleural membranes of the lung and the thoracic cavity. This fluid lubricates the inner

surfaces of the pleural membranes so they can slip and slide against each other during breathing movements. However, because of the cohesive forces (hydrogen bonding) between water molecules, it is difficult to pull the pleural membranes apart. Think of two wet panes of glass or two wet microscope slides; you can slide them past each other, but it is difficult to separate them. Because the pleural membranes covering the cavity wall and the lung surface are stuck to each other by cohesive forces, any increase in volume of the thoracic cavity increases the tension between the pleural membranes, causing inflation of the lungs.

At rest, inhalation is initiated by contraction of the muscular diaphragm (**FIGURE 37.8A**). As the domed diaphragm contracts, it pulls down, expanding the thoracic cavity and pulling on the pleural membranes. The pleural membranes pull on the lungs, and the elastic lungs expand, drawing air in from outside. Exhalation, in contrast, is usually a passive

FIGURE 37.8 Into the Lungs and Out Again (A) Inhalation is an active process driven by contraction of the diaphragm. (B) Exhalation generally is a passive process as the diaphragm relaxes.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 37.2**
Airflow in Mammals

process requiring no muscular activity. The diaphragm simply relaxes, and the elastic recoil of the lung tissues pulls the diaphragm up and pushes air out through the airways (FIGURE 37.8B).

During strenuous exercise, additional muscles come into play. *External intercostal muscles* between the ribs expand the thoracic cavity by lifting the ribs up and outward, expanding the lungs more than usual and thus making use of the inspiratory reserve volume. Exhalation becomes an active process, with *internal intercostal muscles* pulling the ribs down and inward, and contraction of abdominal muscles pushing the abdominal contents up on the diaphragm. Together, the internal intercostal muscles and the abdominal muscles empty the lungs more than usual, making use of the expiratory reserve volume.

Do You Understand Concept 37.3?

- Name, in order, the anatomical structures that a molecule of O_2 passes through as it travels from the outside air to the site of gas exchange in the human lung. How many membranes must the O_2 molecule diffuse through in going from the alveolus to the inside of the red blood cell?
- Recall that Fick's law of diffusion describes all the variables that can affect the rate of diffusion of O_2 from air to blood. What aspects of the structure and anatomy of the human lung relate to (1) maximizing A , (2) maximizing $P_1 - P_2$, and (3) minimizing L ?
- A puncture wound to the chest wall can cause a collapsed lung. In terms of pressures involved in the breathing cycle, explain how this condition occurs, and once a lung collapses, why is it difficult to reinflate it.

We have seen how the respiratory muscles cause pressure changes in the thoracic cavity that cause the mammalian lung to inflate and deflate. Let's now see how the respiratory muscles are controlled.

concept 37.4 Respiration Is under Negative Feedback Control by the Nervous System

Breathing is an involuntary function of the central nervous system. The medulla oblongata in the brainstem controls the respiratory muscles and sets the respiratory rate. Groups of respiratory motor neurons in the medulla increase their firing rates just before an inhalation begins. As more and more of these neurons fire—and fire faster and faster—the diaphragm contracts. All of a sudden, the neurons stop firing, the diaphragm relaxes, and exhalation begins. Brain areas above the medulla can modify the breathing pattern to allow for eating, drinking, and vocalizing.

The depth and frequency of breathing are modulated to meet the body's demands for O_2 supply and CO_2 elimination.

What determines the respiratory rate? What cues can cause the medulla to increase or decrease the rate of breathing?

Respiratory rate is primarily regulated by CO_2

One might expect that respiratory rate is regulated by the O_2 content of the blood. In fishes, blood O_2 is indeed the primary feedback stimulus for gill ventilation. However, humans (and other mammals) turn out to be remarkably insensitive to falling levels of O_2 in arterial blood, and are instead extremely sensitive to increases in CO_2 . That is, arterial P_{O_2} can deviate considerably from normal without causing much of an increase in ventilation rate, but even a small rise in arterial P_{CO_2} causes a large increase in ventilation.

Is P_{CO_2} , then, the primary determinant of the increase in respiratory rate when we exercise? As the experiment in FIGURE 37.9 demonstrates, when dogs run on treadmills at a steady speed but with the slope gradually increased or decreased to change the workload, their respiratory rate does indeed track the P_{CO_2} of their blood quite closely. When an animal simply increases its speed, however, its respiratory rate increases immediately before any change in P_{CO_2} occurs (see Analyze the Data in Figure 37.9). You may have noticed the same phenomenon in yourself; when you start running, your respiratory rate jumps immediately. During exercise, information from receptors in muscles and joints changes the respiratory center's sensitivity to CO_2 , in anticipation of the rise in P_{CO_2} that will follow. This is an example of using *feedforward* information to maintain homeostasis.

LINK Review the discussion of feedforward information in Concept 29.2

CO_2 affects the medulla indirectly via pH changes

The major site of P_{CO_2} sensitivity is an area on the ventral surface of the medulla, not far from the groups of neurons that generate the breathing rhythm (FIGURE 37.10). These cells are not directly sensitive to CO_2 , however. Rather, they are stimulated by H^+ ions. The pH in the environment of these cells is a direct reflection of the P_{CO_2} of the blood. When the P_{CO_2} of the blood is higher than that of the extracellular fluid, CO_2 diffuses out of the blood. That CO_2 interacts with H_2O to form carbonic acid (H_2CO_3), which dissociates into H^+ ions and bicarbonate ions (HCO_3^-).

The H^+ ions stimulate the chemosensitive cells that increase respiratory gas exchange. Thus, blood P_{CO_2} indirectly controls breathing, via changes in pH.

O_2 is also monitored

Though respiratory rate is controlled primarily by blood P_{CO_2} (via pH), blood P_{O_2} is monitored as well. Minor fluctuations in P_{O_2} do not affect respiratory rate very much, but a large drop in P_{O_2} (such as occurs at high altitude) will stimulate an

INVESTIGATION

FIGURE 37.9 Sensitivity of the Respiratory Control System Changes with Exercise What is the metabolic feedback signal that controls ventilation rate during exercise? In experiments with dogs running on treadmills with different slopes, the ventilation rate

increases as the P_{CO_2} in the arterial blood increases. When the dogs run at different speeds instead, their ventilation rates are different but their arterial P_{CO_2} 's are the same. How can P_{CO_2} be the metabolic stimulus for breathing?

HYPOTHESIS

P_{CO_2} is the feedback stimulus controlling ventilation.

METHOD

1. Dogs are trained to run on a treadmill.
2. The dogs are equipped with instruments that measure respiratory rate and with arterial catheters that enable sampling of blood.
3. As a dog runs, either the slope of the treadmill or its speed is changed to increase the metabolic workload.
4. Ventilation rate (V ; L/min) is plotted as a function of arterial P_{CO_2} (mm Hg).

RESULTS

When the workload is altered by slowly changing the slope of the treadmill (no change in speed), the ventilation rate is a function of P_{CO_2} .

CONCLUSION

Arterial P_{CO_2} can be the metabolic feedback signal controlling ventilation in response to changes in workload.

ANALYZE THE DATA

Additional experiments were done in which the ventilation rate and arterial P_{CO_2} were measured when the treadmill speed was changed. The average values when the dog was running at 3 mph were $P_{CO_2} = 39.0$ and $V = 9$. The data for the first seven breaths after the treadmill speed was increased to 6 mph were:

Breath	P_{CO_2}	V	Breath	P_{CO_2}	V
1	38.0	13.0	5	37.2	12.0
2	37.0	14.0	6	36.8	13.0
3	36.5	11.2	7	37.2	13.0
4	37.2	11.2			

After the dog had run at 6 mph for several minutes, the values averaged $P_{CO_2} = 41.0$ and $V = 15.0$. Plot these data and use the information to answer the following questions:

- Do these data support the hypothesis that P_{CO_2} is the feedback signal controlling ventilation rate? Why or why not?
- How do you explain the average values after the dog had been running at the higher speed for a few minutes?
- Relate these results to those obtained in the experiment in which the slope of the treadmill was gradually raised and lowered. Explain the differences between the results in terms of the P_{CO_2} sensing mechanism.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

increase in respiratory rate. The P_{O_2} detectors reside in nodes of neural tissue on the large blood vessels leaving the heart, the aorta and the carotid arteries (see Figure 37.10). The nodes, called **carotid** and **aortic bodies**, are chemosensors sensitive

to O_2 . If their blood supply decreases, or if the blood P_{O_2} falls dramatically, the chemosensors are activated and send nerve impulses to the breathing control center.

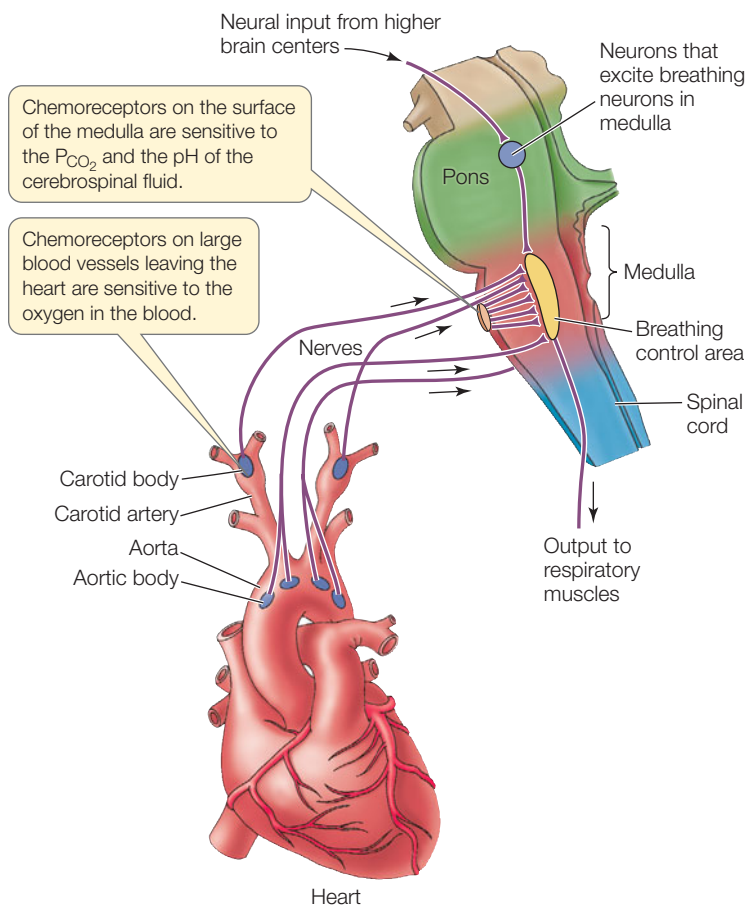

FIGURE 37.10 Feedback Information Controls Breathing The body uses feedback information from chemosensors in the heart and brain to match breathing rate to metabolic demand.

Do You Understand Concept 37.4?

- In 1875 three French physiologists went up in a hot air balloon to see what would happen to their respiration at high altitude. Without registering any unusual physiology or sense of danger in their notebooks, they all went unconscious and two died. Explain this event from what you know about regulation of respiration.
- An untreated diabetic who lacks insulin will metabolize fats for energy and produce an excess of acidic end products, lowering the blood pH. How would you expect this condition to affect the individual's breathing?
- People who have recently climbed to high altitude often show dramatic oscillations in respiratory rate. When they rest or sleep, their respiratory rates alternate between periods of rapid ventilation and periods when they stop breathing. Propose an explanation for this phenomenon, which is called Cheyne–Stokes respiration.

Now that we have discussed how respiratory gases move from the environment into the bloodstream, we can look at how these gases are transported to the rest of the body.

concept 37.5 Respiratory Gases Are Transported in the Blood

One of the main functions of the circulatory system is to transport respiratory gases to and from the lungs. O_2 , however, is a nonpolar molecule that does not dissolve well in aqueous solutions, such as the *blood plasma*, the liquid part of the blood. Human blood contains only about 0.3 ml of dissolved O_2 per 100 ml of plasma; this is inadequate to support even basal metabolism. Therefore most animals, vertebrate and invertebrate, have transport molecules in their blood that reversibly bind O_2 and thus augment the blood's transport capacity. These molecules pick up O_2 where P_{O_2} is high and release it where P_{O_2} is lower. In vertebrates this role is played by **hemoglobin**, a protein contained in red blood cells. Hemoglobin increases the capacity of blood to transport O_2 by about 60-fold, making high metabolic rates possible.

LINK The systems that circulate blood throughout the bodies of animals are described in Concepts 38.1 and 38.2

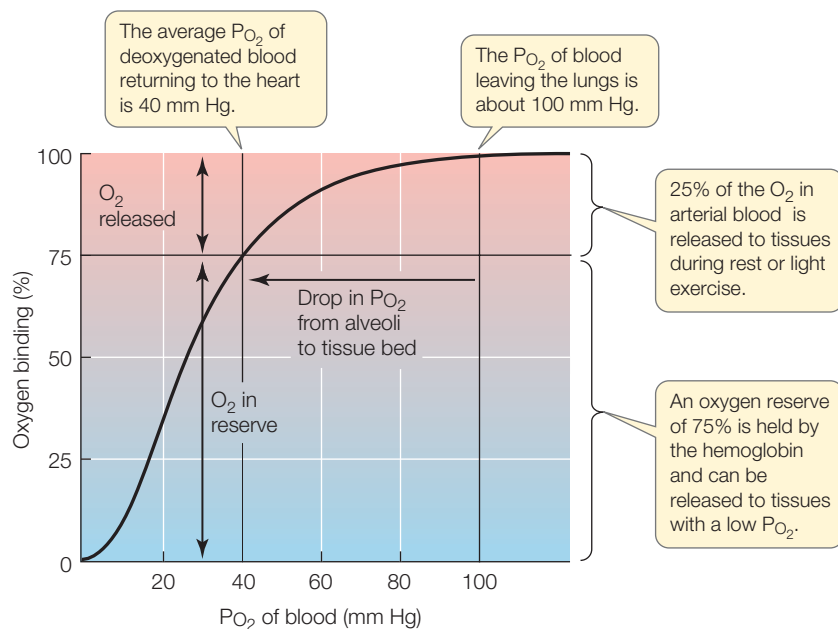

Hemoglobin combines reversibly with O_2

Hemoglobin consists of four polypeptide subunits called *globins* (see Concept 3.2, p. 44), each of which surrounds a *heme group*—an iron-containing ring structure that can reversibly bind a molecule of O_2 . Thus each hemoglobin molecule can bind up to four O_2 molecules.

Hemoglobin's ability to pick up or release O_2 depends on the P_{O_2} in its environment. When the P_{O_2} of the blood plasma is high, as it usually is in the lung capillaries, each hemoglobin molecule can carry its maximum load of four O_2 molecules. As the blood circulates through the rest of the body, it releases some of the O_2 it is carrying when it encounters lower P_{O_2} values (**FIGURE 37.11**).

The relation between P_{O_2} and the amount of O_2 bound to hemoglobin is not linear but S-shaped (sigmoidal). The O_2 binding/dissociation properties of hemoglobin that are reflected in this sigmoidal curve help get O_2 to the tissues that need it most. In the lungs, where the P_{O_2} is about 100 mm Hg, hemoglobin is 100 percent saturated with O_2 . The P_{O_2} in blood returning to the heart from the body is usually about 40 mm Hg. You can see in Figure 37.11 that at this P_{O_2} , the hemoglobin is still about 75 percent saturated. This means that as the blood circulates around the body, it releases only about one in four of the O_2 molecules it carries. This system seems inefficient, but it is really quite adaptive, because the hemoglobin keeps 75 percent of its O_2 in reserve to meet peak demands of highly active tissues.

If a tissue becomes starved of O_2 and its local P_{O_2} falls below 40 mm Hg, the hemoglobin flowing through that tissue is on the steep portion of the sigmoidal binding/dissociation curve. That means relatively small decreases in P_{O_2} below 40 mm Hg will result in the release of lots of O_2 to the tissue. Thus hemoglobin is very effective in making O_2 available to tissues precisely when and where it is needed most.

The O_2 transport function of hemoglobin can rapidly and tragically be disrupted by carbon monoxide (CO). CO binds to hemoglobin with a 240-fold higher affinity than O_2 and therefore prevents hemoglobin from binding and transporting O_2 . If CO accumulates in a closed space—often from a faulty heating system or engine exhaust—the results can be deadly. In the United States, more than 5,000 people die each year from CO poisoning.

Myoglobin holds an O_2 reserve

Muscle cells have their own O_2 -binding molecule, *myoglobin*. Myoglobin consists of just one polypeptide chain associated with an iron-containing ring structure that can bind one O_2 molecule (see Figure 15.22). Myoglobin has a higher affinity for O_2 than hemoglobin does, so it picks up and holds O_2 at PO_2

FIGURE 37.11 Binding of O_2 to Hemoglobin Depends on PO_2 Hemoglobin in blood leaving the lungs is 100 percent saturated (four O_2 molecules are bound to each hemoglobin molecule). Most hemoglobin molecules drop only one of their four O_2 molecules as they circulate through the body and are still 75 percent saturated when the blood returns to the lungs. The steep portion of this O_2 -binding curve comes into play when tissue PO_2 falls below the normal 40 mm Hg, at which point hemoglobin “unloads” its O_2 reserves.

values at which hemoglobin is releasing its bound O_2 (FIGURE 37.12).

Myoglobin facilitates the diffusion of O_2 in muscle cells and provides an O_2 reserve for times when metabolic demands are high. When tissue PO_2 values are low and hemoglobin can no longer supply more O_2 , myoglobin releases its bound O_2 . Diving mammals such as seals have high concentrations of myoglobin in their muscles, which is one reason they can stay underwater for so long. Even in nondiving animals, muscles called on for extended periods of work frequently have more myoglobin than muscles that are used for short, intermittent periods.

values at which hemoglobin is releasing its bound O_2 (FIGURE 37.12).

Various factors influence hemoglobin’s affinity for O_2

Many factors can influence hemoglobin’s affinity for O_2 , thereby influencing O_2 delivery to tissues. Here we examine three of those factors: the particular globin chains present in the hemoglobin, the blood pH, and the amount of 2,3-bisphosphoglyceric acid (BPG) in red blood cells.

HEMOGLOBIN COMPOSITION Recall that hemoglobin is composed of four globin chains. Mammals have several globin genes that code for different types of globin, which can be assembled in various combinations to form different versions of hemoglobin (see Figure 15.22). For example, the hemoglobin of adult humans has two α -globin chains and two β -globin chains. Before birth, the human fetus has a different form of hemoglobin, consisting of two α -globin and two γ -globin

FIGURE 37.12 Oxygen-binding Adaptations Myoglobin and the different hemoglobins have different O_2 -binding properties adapted to different circumstances. Human fetal hemoglobin has a higher affinity for O_2 than does maternal hemoglobin, facilitating O_2 transfer in the placenta. When high metabolism lowers the pH of the blood, hemoglobin releases more of its O_2 .

Oxygen-Binding Curves and
INTERACTIVE TUTORIAL 37.1
Hemoglobin: Loading and Unloading

chains. The functional difference between fetal and adult hemoglobin is that fetal hemoglobin has a higher affinity for O_2 . Therefore, the fetal hemoglobin–oxygen binding/dissociation curve is shifted to the left compared with that for adults (see Figure 37.12). You can see from these curves that if both types of hemoglobin are at the same P_{O_2} (as they are in the placenta), fetal hemoglobin has a greater affinity for O_2 than the maternal hemoglobin and will therefore pick up O_2 released from the maternal hemoglobin. The difference in O_2 affinities of fetal and maternal hemoglobin enables the efficient transfer of O_2 from the mother's blood to the fetus's blood.

HEMOGLOBIN AND pH As blood passes through metabolically active tissue such as exercising muscle, it picks up acidic metabolites such as lactic acid, fatty acids, and CO_2 . As a result, blood pH falls. The excess H^+ ions bind to hemoglobin and change its affinity for O_2 , shifting the binding/dissociation curve to the right. (This is an example of *allosteric regulation*, which is described in the context of enzyme regulation in Concept 3.4.) This shift, known as the **Bohr effect**, means the hemoglobin will release more O_2 in tissues where pH is low—another way that O_2 is supplied where and when it is most needed.

2,3-BISPHOSPHOGLYCERIC ACID BPG is a metabolite of glycolysis (see Concept 6.2). Mammalian red blood cells respond to low P_{O_2} by increasing their rate of glycolysis and producing more BPG. BPG, like excess H^+ , reversibly combines with deoxygenated hemoglobin and lowers its affinity for O_2 . The result is that at any P_{O_2} , hemoglobin releases more of its bound O_2 than it

otherwise would. In other words, BPG shifts the O_2 binding/dissociation curve to the right.

Going to high altitude or beginning to exercise after a sedentary lifestyle increases the production of BPG in the red blood cells, making it possible for hemoglobin to deliver more O_2 to the tissues. The reason fetal hemoglobin has a left-shifted O_2 binding/dissociation curve (a relatively high affinity for O_2) is that its γ -globin chains have a lower affinity for BPG than do the β -globin chains of adult hemoglobin.

CO_2 is transported primarily as bicarbonate ions in the blood

Delivering O_2 to tissues is only half the respiratory function of blood. Blood also takes CO_2 , a metabolic waste product, away from tissues (FIGURE 37.13). CO_2 is highly soluble and readily diffuses through cell membranes, moving from its site of production in the tissues into the blood. A small amount of CO_2 is then transported in the blood dissolved in the blood plasma, and a slightly greater amount is transported bound to hemoglobin. But most CO_2 produced by the tissues is transported to the lungs in the form of **bicarbonate ions**, HCO_3^- . As mentioned in Concept 37.4, when CO_2 dissolves in water, some of it reacts with the water to form carbonic acid (H_2CO_3), which dissociates into H^+ and HCO_3^- . This is a reversible reaction.

In the endothelial cells of the capillaries and in the red blood cells, the enzyme *carbonic anhydrase* speeds up the first step of this process, the conversion of CO_2 to H_2CO_3 . The newly formed H_2CO_3 dissociates, and the resulting bicarbonate ions enter the plasma in exchange for chloride ions (Cl^- ; see Figure 37.13).

In the lungs, these reactions are reversed. Remember that an enzyme such as carbonic anhydrase only speeds up a reversible reaction; it does not determine its direction. The direction is determined by concentrations of reactants and products.

FIGURE 37.13 Carbon Dioxide Is Transported as Bicarbonate Ions Carbonic anhydrase in capillary endothelial cells and in red blood cells facilitates conversion of CO_2 produced by tissues into bicarbonate ions carried by the plasma. In the lungs, the process is reversed as CO_2 is exhaled.

APPLY THE CONCEPT

Respiratory gases are transported in the blood

The transfer of O_2 from maternal to fetal blood is facilitated by the higher affinity of fetal hemoglobin for O_2 compared with that of maternal hemoglobin. South American llamas live at high altitude, and their hemoglobin has a higher affinity for O_2 than does the hemoglobin of other mammals that live at low altitude (e.g., humans). The O_2 affinities of the hemoglobins of fetal llamas and fetal humans are about the same. If we compare the affinities of the various hemoglobins for BPG, we find the following relationships: the affinity of human adult hemoglobin for BPG is about six times greater than that of human fetal hemoglobin, and the affinity of llama

adult hemoglobin for BPG is about three times greater than that of llama fetal hemoglobin.

1. Why is it significant that human fetal hemoglobin and llama adult hemoglobin have higher affinities for O_2 than human adult hemoglobin does?
2. The difference between fetal and adult hemoglobins' affinities for BPG is greater in humans than in llamas. Explain why.
3. Explain the differences in the way llamas and humans adapt to high altitude.

Ventilation keeps the CO_2 concentration in the alveoli low, so CO_2 diffuses from the blood plasma into the alveoli, lowering the CO_2 concentration in the blood, which favors the conversion of HCO_3^- into CO_2 .

Do You Understand Concept 37.5?

- Why do most animals have a transport protein in their blood that can bind to O_2 ?
- Draw the O_2 dissociation curve of fetal hemoglobin compared with that of adult hemoglobin. Explain why they differ chemically and the functional consequences of the difference.
- If you hyperventilate (pant deeply and rapidly), you can flush the residual volume in your lungs with fresh air, reducing the P_{CO_2} in your lungs below normal. How will this affect the bicarbonate reaction, and what will be the ultimate effect on blood pH and respiratory rate?

Throughout this chapter, we have seen that diffusion of respiratory gases in and out of the blood is affected by simple physical laws that have driven the evolution of gas exchange systems. We have also seen how the circulatory system works hand in

hand with the gas exchange system, perfusing the gas exchange organs with blood and then transporting the respiratory gases to and from the rest of the body. In the next chapter we will turn to the many other functions of the circulatory system.

How are bar-headed geese able to sustain the high metabolic cost of flight at altitudes higher than Mount Everest?

ANSWER Bar-headed geese are exquisitely adapted to function at high altitude by virtue of adaptations in every aspect of respiratory gas exchange we have discussed in this chapter. Most importantly, because they are birds they have a respiratory system that maintains a continuous and unidirectional flow of air across the respiratory exchange surfaces (Concept 37.2). In addition, bar-headed geese have greater ventilatory capacity (L/min) than do geese that live at low altitudes. When the geese are exposed to low O_2 , this ventilatory capacity increases even more. Their respiratory control (unlike that of humans) is not shut down by low CO_2 , but continues to be driven by low O_2 (Concept 37.4). Finally, they have a point mutation in their hemoglobin gene that gives their hemoglobin a higher affinity for O_2 —similar to the properties of llama hemoglobin (Concept 37.5; see Apply the Concept above). All of these adaptations work together to give bar-headed geese the ability to extract O_2 from the air at high altitudes in quantities that support the high cost of long-distance flight.

37

SUMMARY

concept 37.1 Fick's Law of Diffusion Governs Respiratory Gas Exchange

- Most cells require a constant supply of O_2 and continuous removal of CO_2 . These **respiratory gases** are exchanged between an animal and its environment by diffusion.
- **Fick's law of diffusion** shows how various physical factors influence the diffusion rate of gases. Adaptations to maximize respiratory gas exchange influence one or more variables of Fick's law.
- In water, gas exchange is limited by the low diffusion rate and low solubility of O_2 in water. O_2 becomes less soluble in water as water temperature increases.
- In air, the **partial pressure of oxygen** (P_{O_2}) decreases as altitude increases.

concept 37.2 Respiratory Systems Have Evolved to Maximize Partial Pressure Gradients

- Adaptations to maximize gas exchange include increasing the surface area for gas exchange and maximizing partial pressure gradients by ventilating the outer surface with the respiratory medium and perfusing the inner surface with blood.
- Insects distribute air throughout their bodies in a system of **tracheae**, tracheoles, and air capillaries. **Review Figure 37.2**
- The **internal gills** of fishes have large gas exchange surface areas that are ventilated continuously and unidirectionally with water. The **countercurrent flow** of blood helps increase the efficiency of gas exchange. **Review Figures 37.3 and 37.4**
- In all air-breathing vertebrates except birds, breathing is **tidal**, in which inhaled air is always mixed with some stale air. This is a less efficient form of gas exchange than that of fishes and birds.
- The gas exchange system of birds includes **air sacs** that supply fresh air to the lungs even during exhalation. Air flows unidirectionally and continuously through bird lungs. **Review Figure 37.5, ANIMATED TUTORIAL 37.1, and WORKING WITH DATA 37.1**

concept 37.3 The Mammalian Lung Is Ventilated by Pressure Changes

- In mammalian lungs, the gas exchange surface area provided by the millions of **alveoli** is enormous, and the diffusion path length is short. **Review Figure 37.6 and WEB ACTIVITY 37.1**

- Inhalation occurs when contractions of the **diaphragm** pull on the **pleural membranes** and reduce the pressure in the **thoracic cavity**. Relaxation of the diaphragm increases pressure in the thoracic cavity and results in exhalation. **Review Figure 37.7, ANIMATED TUTORIAL 37.2, and WORKING WITH DATA 37.2**
- During strenuous exercise, the intercostal muscles and abdominal muscles increase the volume of air inhaled and exhaled.

concept 37.4 Respiration Is under Negative Feedback Control by the Nervous System

- The breathing rhythm is generated by neurons in the medulla and modulated by higher brain centers.
- The most important feedback stimulus for breathing is the level of CO_2 in the blood, which is detected by the medulla indirectly via changes in the blood pH. **Review Figure 37.9**
- A large change in blood O_2 level can also affect respiration rate. O_2 is detected by chemosensors in the **carotid** and **aortic bodies** on the large vessels leaving the heart. **Review Figure 37.10**

concept 37.5 Respiratory Gases Are Transported in the Blood

- O_2 is reversibly bound to **hemoglobin** in red blood cells. Each hemoglobin molecule can carry a maximum of four O_2 molecules.
- Hemoglobin's affinity for O_2 depends on the P_{O_2} to which the hemoglobin is exposed. Therefore, hemoglobin picks up O_2 as it flows through respiratory exchange structures and gives up O_2 in metabolically active tissues. The affinity of hemoglobin for O_2 is altered by the structure of the hemoglobin molecules, by the presence of H^+ ions, and by the concentration of BPG in the red blood cells. **Review Figure 37.11 and INTERACTIVE TUTORIAL 37.1**
- Myoglobin serves as an O_2 reserve in muscle.
- Fetal hemoglobin has a higher affinity for O_2 than does maternal hemoglobin, allowing fetal blood to pick up O_2 from the maternal blood in the placenta. **Review Figure 37.12 and WEB ACTIVITY 37.2**
- CO_2 is transported in the blood principally as **bicarbonate ions** (HCO_3^-). **Review Figure 37.13**

See **WEB ACTIVITY 37.3** for a concept review of this chapter.

Circulatory Systems

38

Cardiovascular disease is responsible for about one-third of all deaths each year in the United States and Europe. The immediate cause of most of these deaths is heart attack or stroke, but those events are frequently the end result of arterial disease that begins years before symptoms are detected—hence the designation of cardiovascular disease as a “silent killer.”

Healthy arteries have a smooth internal lining of endothelial cells that can be damaged by chronic high blood pressure, smoking, a high-fat diet, or infection. A process of plaque formation occurs at these sites of damage. The damaged endothelial cells attract certain white blood cells to the site. These cells are joined by smooth muscle cells migrating from the deeper layers of the arterial wall. Lipids, especially cholesterol, are deposited in these cells, so that the developing plaque becomes fatty. Fibrous connective tissue made by the invading smooth muscle cells and deposits of calcium make the artery wall stiffer—hence “hardening of the arteries.” The growing plaque deposit narrows the artery and causes turbulence in the blood flow. Blood platelets stick to the plaque and initiate the formation of a blood clot (thrombus) that further occludes the artery or breaks loose and blocks a smaller downstream artery.

Coronary arteries supply blood to the heart muscle. These vessels are particularly susceptible to plaque formation, and as they narrow, blood flow to the heart muscle decreases, causing chest pain and shortness of breath during mild exertion. If a thrombus forms or lodges in one of these arteries, blood flow to a portion of the heart muscle is cut off, and the result is a heart attack. The weakened heart cannot pump enough blood to meet the demands of the body, and the victim

typically collapses. The events that follow are hardly “silent”: 911, sirens, flashing lights, paramedics, the emergency room, and the frantic treatments commonly seen on TV medical dramas.

Quick treatment is critical if the patient is to survive the initial consequences of a heart attack. The brain cannot be without blood flow for more than a few minutes, and the functions of other organs are compromised and the heart muscle itself will die if blood flow is not restored. First priorities are to get blood flowing by means of CPR, get the heart beating if it has stopped, and clear the blocked artery. These actions may help the patient survive, but they may not be enough to ensure recovery; for this, the responses of the patient over the next few days are critical.

Emergency medical workers need to work quickly in cases of heart attack to ensure the patient’s survival and recovery.

KEY CONCEPTS

- 38.1** Circulatory Systems Can Be Open or Closed
- 38.2** Circulatory Systems May Have Separate Pulmonary and Systemic Circuits
- 38.3** A Beating Heart Propels the Blood
- 38.4** Blood Consists of Cells Suspended in Plasma
- 38.5** Blood Circulates through Arteries, Capillaries, and Veins
- 38.6** Circulation Is Regulated by Autoregulation, Nerves, and Hormones

What are the critical factors that determine whether a person recovers from a heart attack?

concept 38.1 Circulatory Systems Can Be Open or Closed

The function of a **circulatory system** is to transport substances around the body—hormones, respiratory gases, blood cells, nutrients, waste products, and more. A circulatory system consists of a muscular pump (the heart), a fluid (blood), and a series of conduits (blood vessels) through which the fluid can be circulated.

Single-celled organisms and some very small multicellular organisms do not need a circulatory system because nutrients, respiratory gases, and wastes diffuse directly between the cells of their bodies and the environment. Some larger aquatic multicellular animals have highly branched central cavities called *gastrovascular systems* that essentially bring the external environment into close contact with every cell. All the cells of a sponge, for example, are in contact with, or very close to, the surrounding seawater. However, this system only works because sponges are not very active. Large, active animals need a true circulatory system.

Open circulatory systems move extracellular fluid

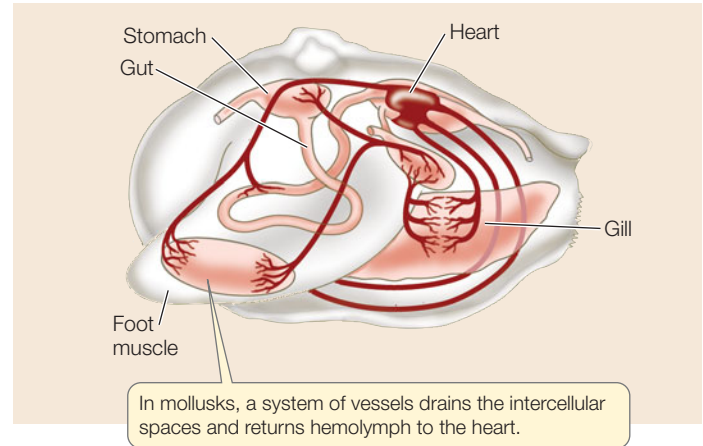

In **open circulatory systems**, the circulatory fluid (called *hemolymph*) leaves the vessels of the circulatory system, flows slowly between cells and through tissues, and then flows back into the heart or vessels of the circulatory system. Open circulatory systems are found in arthropods, mollusks (FIGURE 38.1A), and several other invertebrate groups.

Closed circulatory systems circulate blood through a system of blood vessels

In **closed circulatory systems**, blood vessels keep the circulating fluid (*blood*) separate from the fluid around the cells (*interstitial fluid*). The blood consists of a liquid *blood plasma* (containing dissolved solutes) and *blood cells*. Blood cells and large molecules stay within the circulatory system, but water and low-molecular-weight solutes leak out of the smallest vessels, the *capillaries*, which are highly permeable. Together, the blood plasma and the interstitial fluid make up the *extracellular fluid*.

Closed circulatory systems are found in annelids, vertebrates, and a few other groups. The earthworm (an annelid) provides a good example of a simple closed circulatory system. This animal has a large ventral blood vessel that carries blood from the worm's anterior end to its posterior end (FIGURE 38.1B). Small vessels branch off the ventral blood vessel and transport the blood to tiny capillaries, where respiratory gases, nutrients, and wastes diffuse between the blood and interstitial fluid. The blood then flows into larger vessels that lead into one large dorsal vessel, which carries the blood back to the anterior end of the body. Five pairs of muscular vessels connect the dorsal and ventral vessels. The dorsal vessel and the five connecting vessels also serve as simple hearts, contracting to keep the blood circulating. One-way valves keep the blood flowing in the right direction.

(A) Open circulatory system: mollusk

(B) Closed circulatory system: annelid worm

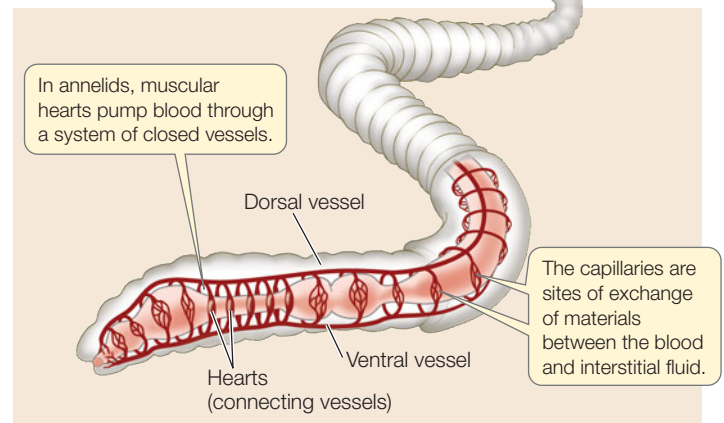

FIGURE 38.1 Circulatory Systems (A) Open circulatory systems are found in mollusks (illustrated here by a clam) and arthropods. Hemolymph is pumped by a tubular heart to different regions of the body, where it leaves the circulatory vessels and flows through intercellular spaces. (B) Annelids (illustrated by an earthworm) and vertebrates have a closed circulatory system, in which the blood is confined within a continuous system of vessels. The blood is pumped through those vessels by one or more muscular hearts.

Vertebrates have a closed circulatory system with a similar basic arrangement but with a more elaborate heart that has two or more chambers. In vertebrates, a multichambered **heart** pumps blood into large vessels called **arteries** that carry blood away from the heart. Arteries branch into smaller vessels called **arterioles**, which feed blood into **capillary beds**, networks of minute, thin-walled **capillaries** where materials are exchanged between the blood and the interstitial fluid. Small vessels called **venules** drain capillary beds. The venules join to form large **veins** that deliver blood back to the heart. Valves in the heart and in some of the veins prevent the backflow of blood.

Closed circulatory systems have several advantages over open systems:

- The circulatory fluid can flow more rapidly.
- The flow of blood to specific tissues can be controlled, by changing the diameter (hence resistance) of vessels.
- Specialized cells and molecules that transport oxygen, hormones, and nutrients can be kept in the vessels.

Generally, closed circulatory systems can support higher levels of metabolic activity than open systems because they have a higher capacity to circulate blood and can direct blood to the tissues that need it the most.

Do You Understand Concept 38.1?

- What characteristics of a sponge enable it to function without a circulatory system?
- What are the advantages of closed circulatory systems as compared with open circulatory systems?
- A grasshopper and a clam both have open circulatory systems. What enables the grasshopper to be more active and sustain a higher metabolic rate? (Hint: review the respiratory systems of insects in Concept 37.2, especially Figure 37.2.)

The closed circulatory system clearly has advantages for large, active animals. However, there is a further refinement that can make closed circulatory systems even more efficient: a separate circuit that sends blood just to the gas exchange organs.

concept 38.2 Circulatory Systems May Have Separate Pulmonary and Systemic Circuits

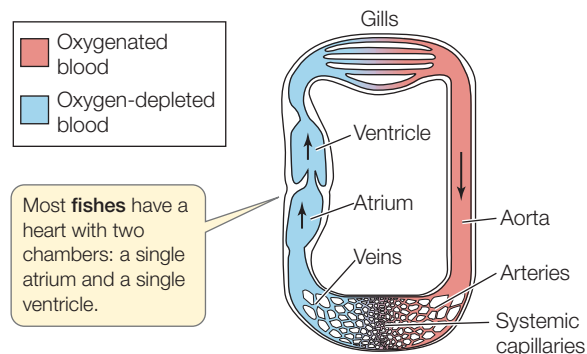

Closed circulatory systems in vertebrates move blood through the respiratory gas exchange organs and through the rest of the body. In fish there is a single circuit in which blood goes from the heart to the respiratory organ (gills) and then directly to the rest of the body and back to the heart. In birds, crocodilians, and mammals, there are separate circuits: the **pulmonary circuit** takes blood from the heart to the gas exchange organs (lungs) and back to the heart, and the **systemic circuit** takes blood from the heart to the rest of the body and back to the heart. In amphibians and all reptiles except birds and crocodilians, these two circuits are not completely separate. Here we will examine the anatomy and evolution of these different vertebrate circulatory systems.

yourBioPortal.com

Go to WEB ACTIVITY 38.1
Vertebrate Circulatory Systems

Most fishes have a two-chambered heart and a single circuit

Most fishes have a simple two-chambered heart. The first chamber of the heart is a thin-walled **atrium** that receives blood from the body and pumps it into a more muscular chamber, the **ventricle**. The ventricle pumps blood to the gills, which are arranged on supportive gill arches (see Figure 37.4). Blood flows into each gill arch in an *afferent arteriole* and leaves the gill in an *efferent arteriole*. The efferent arterioles join together into a single dorsal aorta that carries blood to capillaries in the rest of the body tissues.

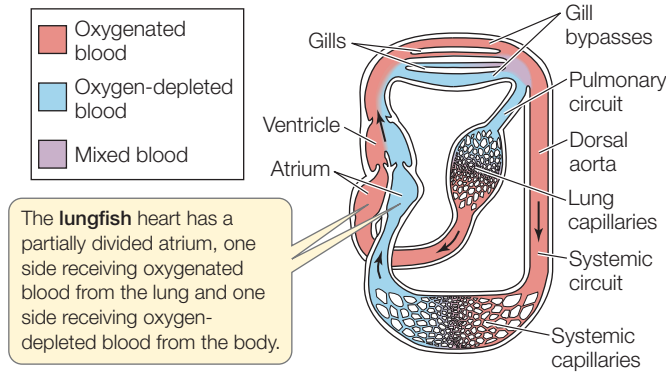

This simple design places a limit on an important feature of the circulatory system—the pressure that propels blood through the non-respiratory tissues and organs. Most of the pressure imparted to the blood by the contraction of the ventricle is lost as the blood travels through the narrow gill lamellae. Therefore, blood entering the aorta is under low pressure and moves relatively slowly as it travels to the rest of the body. This limits the maximum capacity of the fish circulatory system to supply tissues with oxygen and nutrients.

Lungfishes evolved a partially separate circuit that serves the lung

The evolutionary transition from breathing water to breathing air had important consequences for the vertebrate circulatory system. The African lungfishes (several species in the genus *Protopterus*) show how the circulatory system changed to serve a primitive lung.

African lungfish have gills and also a simple lung that forms as an outpocketing of the gut, near the gills. The blood vessels in the posterior pair of gill arteries have been modified to be a low-resistance path for blood to the lung. A new vessel carries oxygenated blood from the lung back to the heart. In addition, two anterior gill arches have lost their gills, and their blood vessels deliver blood from the heart directly to the dorsal aorta. The lungfish heart has a partially divided atrium, with the left side receiving oxygenated blood from the lungs, and the right side receiving oxygen-depleted blood from the other tissues. These two bloodstreams stay mostly separate as they flow through the ventricle and the large vessel leading to the gill arches. As a result, oxygenated blood goes mostly to the anterior gill arteries leading to the dorsal aorta, and oxygen-depleted blood goes mostly to those arteries that lead to the gills and to the lung.

The lung probably evolved as a means of supplementing the oxygen uptake from the gills. Lungfishes are periodically exposed to water with low oxygen content and to situations in which their aquatic environment dries up. When the water is fully oxygenated, lungfishes can depend on their gills; but in oxygen-depleted water, they can augment their oxygen intake by gulping air. The associated modifications of the lungfish vascular system set the stage for the evolution of separate pulmonary and systemic circulations in terrestrial vertebrates.

Amphibians and most reptiles have partially separated circuits

In adult amphibians and most reptiles, the pulmonary and systemic circuits are even more fully separated—each circuit has its own set of arteries, capillaries, and veins. The heart has two separate atria and thus is three-chambered. One atrium receives oxygenated blood from the lungs, and the other receives oxygen-depleted blood from the rest of the body. However, the oxygen-depleted blood and oxygenated blood mix to some degree as they pass into a single or only partially divided ventricle.

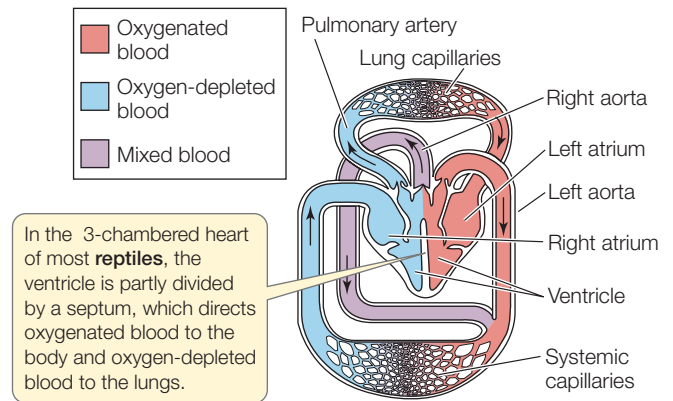

In adult amphibians, the ventricle has anatomical features that keep the oxygenated and oxygen-depleted blood somewhat separate. Compared with the circulatory system of fishes, this system can deliver blood at higher pressure into the systemic circuits, but the blood may not be totally oxygenated.

Turtles, lizards, and snakes have taken the amphibian design one step further by evolving a partially divided ventricle, so that oxygen-depleted and oxygenated blood are kept almost entirely separate. The partial connection between the

two sides of the ventricle is highly adaptive for the lifestyles of these animals. Some reptiles have burst activity but low resting metabolic rates, whereas others, such as sea turtles, do not breathe for long periods when they are underwater. If an animal doesn't need more oxygen (e.g., when it is resting) or isn't breathing, it is a waste of energy to pump blood through the lungs. These reptiles increase the efficiency of their circulatory system by being able to shunt blood from the pulmonary to the systemic circuit, and that ability depends on the anatomy of their heart and the arteries leaving it.

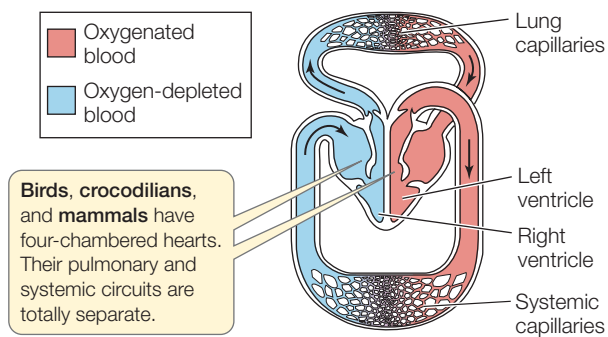

During development, all vertebrates have two systemic arteries leaving their heart—a left and a right aorta. In birds and mammals, the right aorta disappears during fetal life, leaving only the left aorta. In turtles, snakes, and lizards, the right aorta remains and is connected to the heart close to the location where the two sides of the ventricle are in communication. When the animal is breathing, the resistance in the pulmonary circuit is lower than the resistance in the systemic circuit, so blood from the right side of the ventricle mainly flows into the pulmonary artery that leaves the right side of the heart; blood from the left side of the ventricle mainly flows into the systemic circuit through the left and the right aortas. When the animal is not breathing, the resistance in the pulmonary circuit goes up. This higher resistance limits blood flow in the pulmonary circuit, and therefore blood from the right side of the ventricle flows primarily into the right aorta and into the systemic circuit.

Crocodylians, birds, and mammals have fully separated pulmonary and systemic circuits

Crocodylians, birds, and mammals have a four-chambered heart and completely separate pulmonary and systemic circuits. Oxygen-depleted blood from the body arrives in the right atrium of the heart and flows from there into the right ventricle. The right ventricle pumps the blood through **pulmonary arteries** to the lungs, where the blood picks up oxygen and sheds carbon dioxide. The oxygenated blood then returns to the heart in **pulmonary veins**, arriving in the left atrium of the heart from where it flows into the powerful left ventricle. The left ventricle pumps the oxygenated blood into a massive artery called the **aorta** that sends blood at high pressure to capillary beds in the rest of the body, where the blood delivers oxygen and picks up carbon

dioxide. Oxygen-depleted blood then returns in the **vena cavae**, large veins that empty into the right atrium of the heart.

The pulmonary arteries, lung capillaries, and pulmonary veins make up the pulmonary circuit. The aorta, the capillary beds in the rest of the body, and the associated veins make up the systemic circuit. The right side of the heart sends blood to the pulmonary circuit; the left side sends blood to the systemic circuit. But, since these two circuits are connected in series, each side of the heart is pumping the same volume of blood.

Fully separate circuits have several advantages:

- Oxygenated blood can be distributed to the tissues of the body at higher pressure and flow than is possible in fishes.
- Oxygenated and oxygen-depleted blood cannot mix. The systemic circuit always receives blood with the highest oxygen content, and the pulmonary circuit always receives blood with the lowest oxygen content, maximizing respiratory gas exchange.
- The pressures in the systemic and pulmonary circuits are different; low pressure in the pulmonary circuit protects the delicate lung tissues, and high pressure in the systemic circuit effectively delivers blood throughout the body.

Fully separate pulmonary and systemic circuits enable crocodilians, birds, and mammals to maintain a continuously high metabolic rate and to direct blood flow to where it is most needed.

Do You Understand Concept 38.2?

- Draw sketches of circulatory systems showing a single and a double circuit design. Label all of the parts.
- Why can a mammalian circulatory system have different pressures in the pulmonary and the systemic circuits, and why do you think this is important?
- Crocodiles have a fully separated four-chambered heart, but like reptiles they have two aortas and a low resting metabolic rate, and they spend time underwater. Thus they do not breathe continuously. Their right aorta leaves their right ventricle, but just outside the heart there is a connection between the left and the right aortas. Knowing that pressure is higher in the systemic circuit than in the pulmonary circuit and that the resistance in the pulmonary circuit goes up when an animal is not breathing, how do you think the crocodilian system functions to decrease blood flow to the lungs when these animals are not breathing?

All of these circulatory systems, whether single circuit or double circuit, require a steadily beating muscular pump—a heart—to propel the blood. In the next concept we will study the structure and function of the heart of a mammal—the human.

concept 38.3

A Beating Heart Propels the Blood

Your heart is a muscular pump that, at rest, beats an average of 60–70 times per minute. With each beat, it circulates about 70 milliliters of blood throughout the body. Without taking work or exercise into account, that is 300 liters per hour, 7,200 liters per day, 2.6 million liters per year—without a break. How does the heart accomplish this never-ending task?

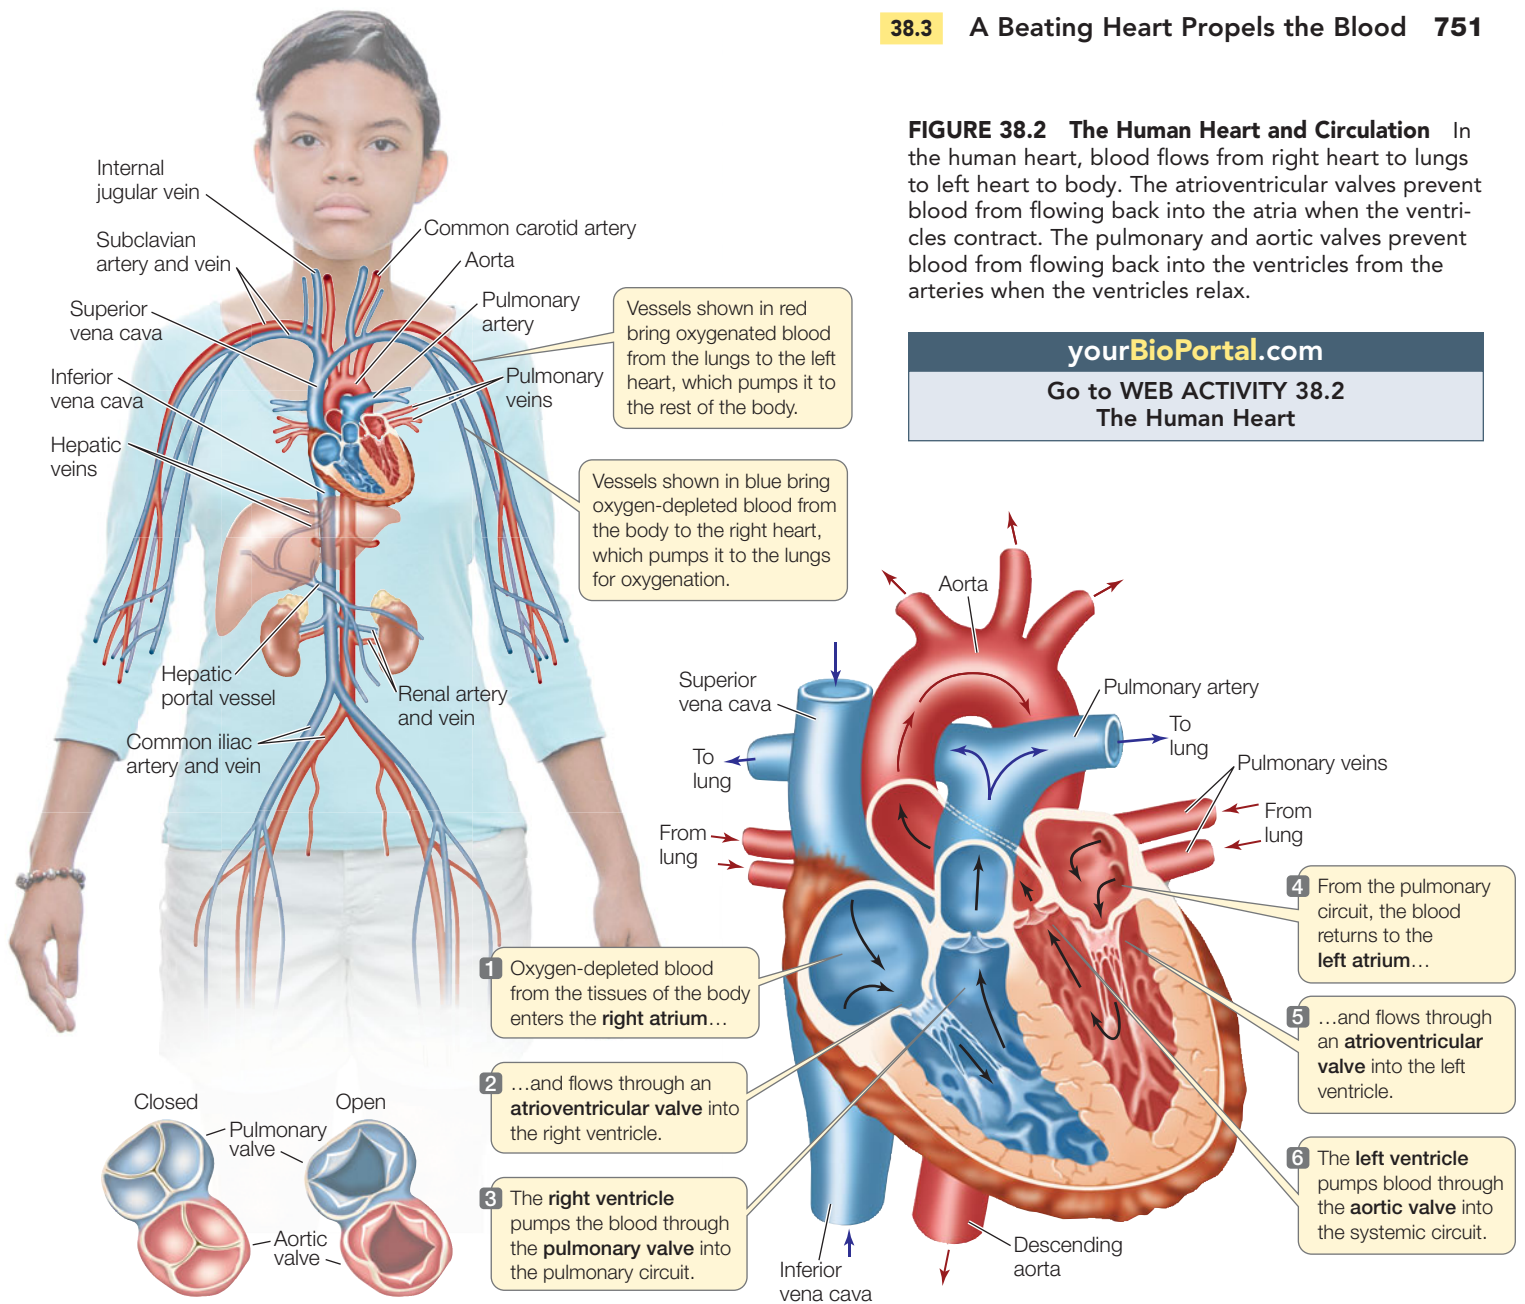

Blood flows from right heart to lungs to left heart to body

The structure of the four-chambered human heart is shown in **FIGURE 38.2**. The right atrium receives oxygen-depleted blood from the venae cavae, and also from veins coming from the heart muscle itself. From the right atrium, the blood flows through an *atrioventricular (AV) valve* into the right ventricle. Most of the filling of the ventricle results from passive flow while the heart is relaxed between beats. Just at the end of this interbeat interval, the atrium contracts and adds a little more blood to the ventricle. The right ventricle then contracts, causing the one-way flaps of the AV valve to close (preventing backflow into the atrium) and pumping blood into the pulmonary artery leading to the lungs. Once the ventricle relaxes, the *pulmonary valve* at the base of the pulmonary artery closes to prevent backflow into the heart.

Pulmonary veins return oxygenated blood from the lungs to the left atrium. From here blood flows into the left ventricle through another AV valve. As on the right side of the heart, most left ventricular filling occurs while the ventricle is relaxing, but at the end of this interbeat interval, atrial contraction adds a little more blood to the ventricle.

When the left ventricle contracts, it pumps the blood into the aorta to begin its circulation through the body. Since the systemic circuit has many more kilometers of blood vessels than does the pulmonary circuit, it presents a higher resistance to flow. To meet this challenge, the left ventricle has thicker walls than the right ventricle, contracts with more force, and generates higher pressure. When the left ventricle relaxes, the *aortic valve* at the base of the aorta closes to prevent backflow.

During exercise, a larger volume of blood returns to the heart between beats, and the ventricles must contract much more forcefully to move this increased volume. This adjustment in force of contraction occurs automatically because of a property of cardiac muscle cells known as the **Frank-Starling law**: if the cardiac muscle cells are stretched, as they are when the volume of returning blood increases, they contract more forcefully.

The cycle of contraction and relaxation of the heart is called the **cardiac cycle**. The cardiac cycle is divided into two phases: **systole** (pronounced *sís-toll-ee*), when the ventricles contract, and **diastole** (*die-ás-toll-ee*), when the ventricles relax (**FIGURE 38.3**). The atria contract a moment before the ventricles do, just at the end of diastole, to top off the volume of blood in the ventricles.

The sounds of the cardiac cycle, the “lub-dup” heard through a stethoscope, are created by the heart valves slamming shut. These valves open and close passively because of pressure differences. As the ventricles begin to contract, the pressure in them rises above the pressure in the atria, so the AV valves snap closed (“lub”). When the ventricles begin to relax, the high pressure in the aorta and pulmonary artery closes the aortic and pulmonary valves (“dup”).

Defective valves that do not close completely produce turbulent blood flow and the sounds known as *heart murmurs*. For

example, if an AV valve does not close completely, blood will flow back into the atrium with a “whoosh” following the “lub.”

The heartbeat originates in the cardiac muscle

Cardiac muscle has unique adaptations that enable it to function as a pump. First, cardiac muscle cells are in electrical contact with one another through gap junctions that enable *action potentials* to spread rapidly from cell to cell. Because a spreading action potential stimulates contraction, large groups of cardiac muscle cells contract in unison. This coordinated contraction is essential for pumping blood effectively.

LINK Action potentials are described in Concept 34.2; Concept 36.1 provides more details about the special characteristics of cardiac muscle

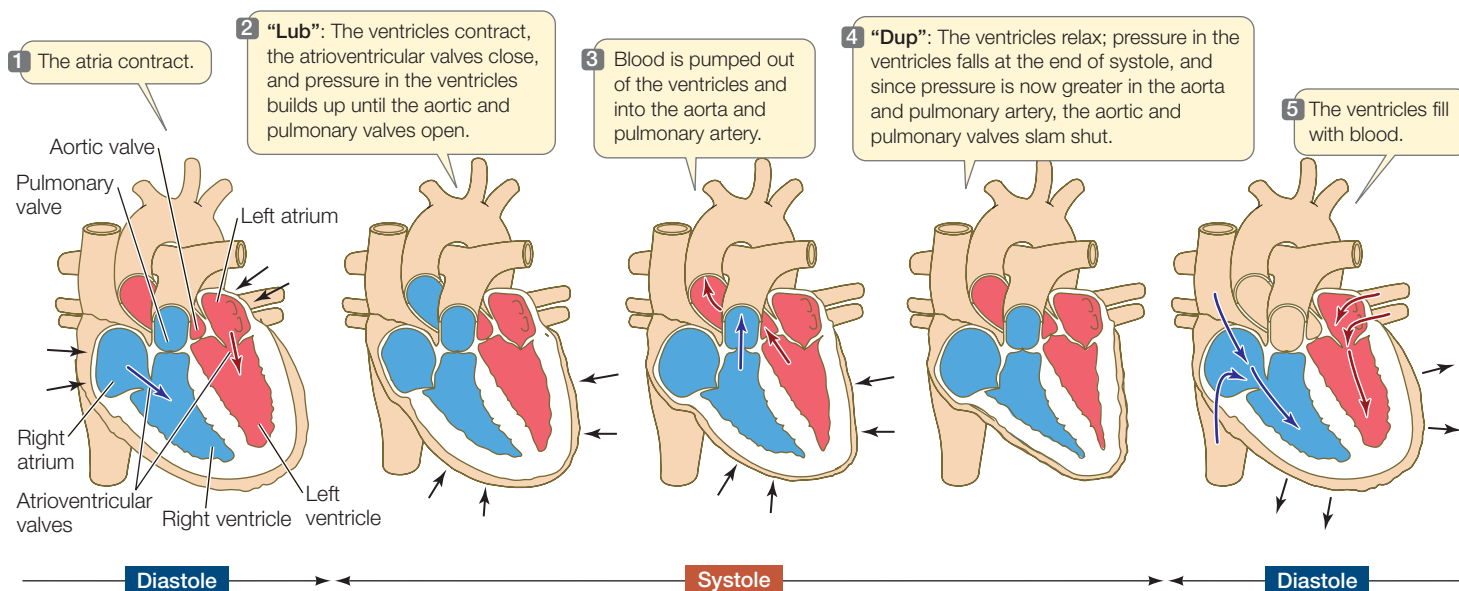

FIGURE 38.3 The Cardiac Cycle The rhythmic contraction (systole) and relaxation (diastole) of the ventricles is called the cardiac cycle.

Go to ANIMATED TUTORIAL 38.1
The Cardiac Cycle

Second, some cardiac muscle cells are **pacemaker cells** that can initiate action potentials without stimulation from the nervous system. When they fire action potentials, they stimulate neighboring cells to contract. The primary pacemaker of the heart is a group of modified cardiac muscle cells, the **sinoatrial node**, located at the junction of the superior vena cava and right atrium (see Figure 38.5). The electrical properties of pacemaker

cells are different from those of neurons and other muscle cells because of the types of ion channels in their membranes.

The action potential of the pacemaker cells is generated by voltage-gated Ca^{2+} channels. This is unlike the voltage-gated Na^+ channel mechanism in neurons and other muscle cells, and therefore the shape of the action potential of pacemaker cells is different (compare Figure 38.4 and Figure 34.7). Most important, however, is that the resting potential of these pacemaker cells is not stable, but slowly drifts upward. There are two reasons for this unstable resting potential. First, these cells are more permeable to Na^+ than are other cardiac muscle cells, as indicated by their higher resting potential; and second, their K^+ channels that open to repolarize the membrane following an action potential gradually close. As these channels close, the balance between Na^+ influx and K^+ efflux changes, and the membrane potential

APPLY THE CONCEPT

A beating heart propels the blood

During the cardiac cycle, each chamber of the heart goes through characteristic changes in pressure and volume. The graph shows measurements of the volume of the left ventricle and the pressure in the left ventricle during a single cardiac cycle. The sequence of these measurements goes from A to B to C to D to A.

1. Systole is between which two points?
2. Diastole is between which two points?
3. How much blood does the heart pump with each cycle?
4. Where on the curve would the first (“lub”) and second (“dup”) heart sounds occur?
5. Where on the curve would the aortic valve open?

INVESTIGATION

FIGURE 38.4 The Autonomic Nervous System Controls Heart Rate The membrane potentials of pacemaker cells spontaneously depolarize until action potential threshold is reached. Neurotransmitter signals from the two divisions of the autonomic nervous system speed up and slow down the rate at which the pacemaker membrane potential drifts upward, thereby controlling the rate at which pacemaker cells fire action potentials.

HYPOTHESIS

The ANS neurotransmitters norepinephrine (NE) and acetylcholine (ACh) influence the membrane potentials of pacemaker cells by altering the properties of the ion channels that determine membrane potential.

METHOD

1. Culture living sinoatrial node tissue in a dish. Insert an intracellular recording electrode into pacemaker cells.
2. Measure the membrane potential of pacemaker cells during a resting heartbeat (the control) and after applications of the ANS neurotransmitters NE (sympathetic) and ACh (parasympathetic).

RESULTS

CONCLUSION

The ANS neurotransmitters NE and ACh influence heart rate by altering the membrane resting potentials of pacemaker cells.

ANALYZE THE DATA

Additional experiments were performed using specific Ca^{2+} , Na^{+} , and K^{+} channel blockers to investigate the roles of these ion channels in generating action potentials (spikes) in pacemaker cells. The table shows the results.

Treatment	Spike height	Spike width	Interspike intervals
Control	+10 mV	100 msec	300 msec
Add Ca^{2+} channel blocker	Action potentials cease		
Add NE	+10 mV	100 msec	200 msec
Add ACh	+10 mV	100 msec	350 msec
Add Na^{+} channel blocker and NE	+10 mV	100 msec	250 msec
Add K^{+} channel blocker	+10 mV	100 msec	250 msec

- What ion channel is responsible for the spikes?
- How do the ANS neurotransmitters alter the characteristics of the pacemaker membrane potential?
- What ion channels are likely involved in the actions of the ANS neurotransmitters?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

drifts up until the threshold that opens the voltage-gated Ca^{2+} channels is reached.

Because of the pacemaker cells, the heart initiates its own contractions; that is, it does not need repetitive signals from nerves to beat. Instead, the pacemaker cells automatically depolarize, eventually reaching a threshold that triggers an action potential, repolarize, and repeat the entire process continuously. The pacemaker action potential rapidly spreads to other cardiac cells, triggering systole.

The autonomic nervous system does control the *rate* of the heartbeat, however, by speeding up or slowing down the pacemaker cells' rate of depolarization (FIGURE 38.4). Norepinephrine released onto pacemaker cells by sympathetic nerves increases the permeability of the Na^{+} channels and the Ca^{2+} channels, causing the pacemaker cells to depolarize more rapidly. As a result, the heart beats faster. Conversely, the parasympathetic neurotransmitter acetylcholine has the opposite effect, slowing the rate of depolarization and slowing down the heartbeat.

A conduction system coordinates the contraction of heart muscle

A normal heartbeat begins with an action potential in the sinoatrial node (FIGURE 38.5). This action potential spreads rapidly throughout the electrically coupled cells of the atria, causing them to contract. However, there are no gap junctions between the cells of the atria and those of the ventricles, so the action potential does not spread directly to the ventricles. Therefore, the ventricles do not contract in unison with the atria.

How does the action potential move from the atria to the ventricles? Situated at the junction of the atria and the ventricles is a nodule of modified cardiac muscle cells—the **atrioventricular node**—which is stimulated by the depolarization of the atria. With a slight delay, it generates action potentials that are conducted to the ventricles via the **bundle of His**, which consists of modified cardiac muscle fibers that do not contract. These fibers divide into right and left *bundle branches* that run to the very bottom of the ventricles (the apex of the heart) and then spread throughout the ventricular

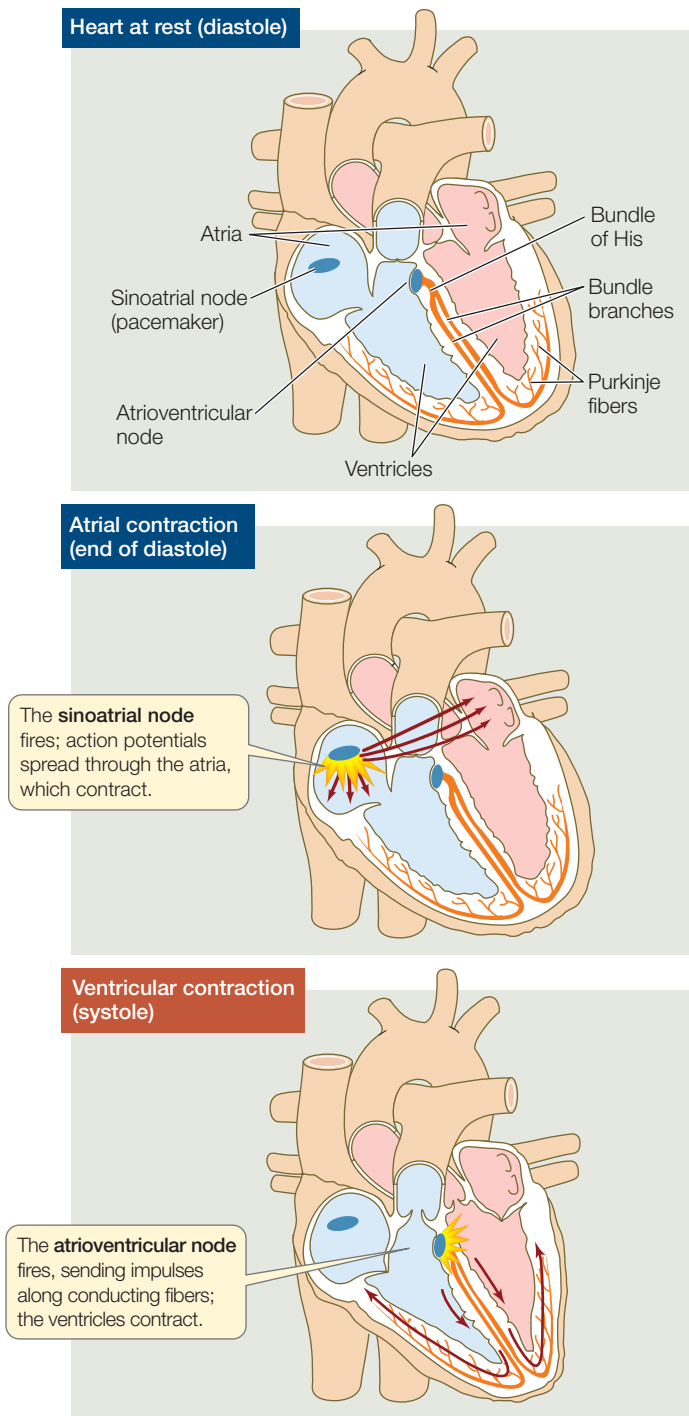

FIGURE 38.5 The Heartbeat Pacemaker cells in the sinoatrial node initiate the heartbeat by firing action potentials that spread through the electrically coupled atrial muscle. The atrial action potential eventually spreads to the atrioventricular node, which, with a delay, conducts it through the bundle of His and Purkinje fibers to the cells of the ventricles.

muscle mass as **Purkinje fibers**. These conducting fibers ensure that the cardiac action potential spreads rapidly throughout the ventricles. The short delay in the spread of the action potential

imposed by the atrioventricular node ensures that the atria contract before the ventricles do.

Electrical properties of ventricular muscles sustain heart contraction

The muscle fibers of the ventricles contract for about 300 milliseconds—much longer than the contractions of skeletal muscle fibers. As in neuronal and skeletal muscle fibers, the rising phase of the ventricular muscle cell action potential is due to the opening of voltage-gated Na^+ channels. Unlike neurons and skeletal muscle fibers, however, ventricular muscle cells remain depolarized for a long time. This extended plateau of the action potential is due to sustained opening of voltage-gated Ca^{2+} channels. As in other muscle, cardiac muscle contraction is stimulated by the release of Ca^{2+} from the sarcoplasmic reticulum and the binding of that Ca^{2+} to troponin (see Figure 36.6). As long as the Ca^{2+} channels remain open and Ca^{2+} remains in the sarcoplasm, the ventricular muscle cells continue to contract. The sustained contraction of ventricular muscle fibers facilitates the emptying of ventricles.

The ECG records the electrical activity of the heart

Electrical events in the cardiac muscle during the cardiac cycle can be recorded by electrodes placed on the surface of the body. Such a recording is an **electrocardiogram (ECG)**, an important tool for diagnosing heart problems (**FIGURE 38.6**).

The action potentials that sweep through the muscles of the atria and the ventricles when they contract are such massive, localized electrical events that they cause electric currents to flow throughout the body. Electrodes placed at different locations on the skin detect those electric currents at different times and register a voltage difference between them (see Figure 38.6B). The wave patterns of the ECG are designated P, Q, R, S, and T, each letter representing a particular event in the cardiac muscle, as shown in the figure.

Do You Understand Concept 38.3?

- A red blood cell is flowing through the superior vena cava. List all of the heart chambers, valves, vessels, and organs it will pass through before it leaves the heart in the aorta.
- How do pacemaker cells generate the cardiac cycle?
- Why do the atria contract before the ventricles? What would happen if they contracted at the same time?
- The drug digitalis impedes the Ca^{2+} transporter that moves Ca^{2+} into the sarcoplasmic reticulum. Explain why digitalis is effective in strengthening weakened hearts.

Let's turn now to the fluid that the heart is pumping: the blood. What are the major components of blood, and what are their major functions?

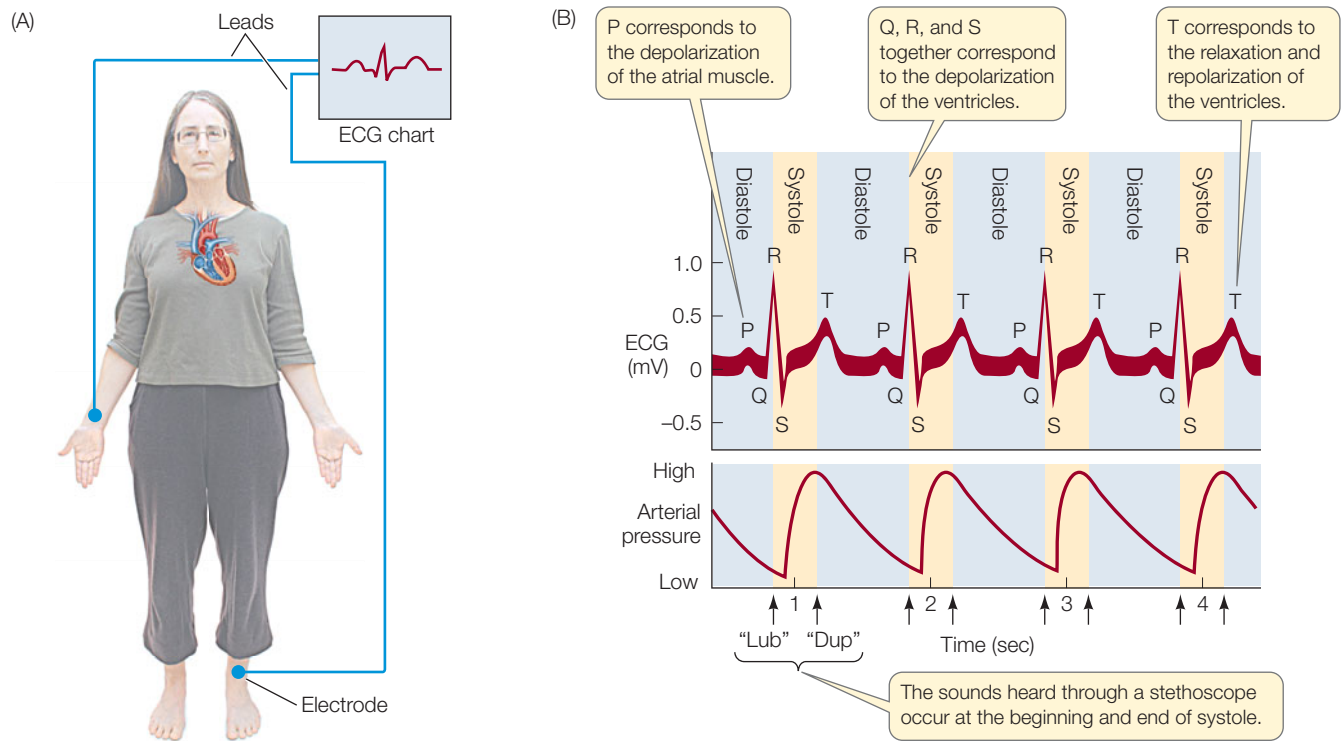

FIGURE 38.6 The Electrocardiogram An ECG records heart function. Electrodes attached to various parts of the body record electrical events that correspond to the sequence of contraction and relaxation of the atria and the ventricles.

concept 38.4 Blood Consists of Cells Suspended in Plasma

Blood consists of cells suspended in a liquid extracellular matrix called **plasma**. The plasma contains many solutes, such as glucose and other nutrients, ions, waste products, hormones, respiratory gases, clotting proteins, and many other components (FIGURE 38.7). Most of the cells suspended in the plasma are **erythrocytes** (red blood cells, or RBCs), which carry respiratory gases. Blood also contains a smaller number of **leukocytes** (white blood cells)—cells of the immune system—as well as **platelets** (pinched-off fragments of cells), which are involved in blood clotting. Here we discuss the red blood cells and platelets.

LINK The functions of leukocytes in the immune system are discussed in Chapter 31

Red blood cells transport respiratory gases

Mature RBCs are biconcave, flexible discs packed with hemoglobin. Their function is to transport respiratory gases. Their shape gives them a large surface area for gas exchange, and their flexibility enables them to squeeze through narrow capillaries (see Figure 38.10).

RBCs and all the other cellular components of blood are generated by stem cells in the bone marrow, particularly in the ribs, breastbone, pelvis, vertebrae, and the long bones of the limbs. RBC production is controlled by a hormone, **erythropoietin**, which is released by cells in the kidneys in response to insufficient oxygen—**hypoxia**. Increased circulating erythropoietin extends the lives of mature RBCs and stimulates production of new RBCs in the bone marrow, thereby increasing the blood's capacity for carrying oxygen.

FRONTIERS Hypoxia inducible factor (HIF) is a transcription factor that was first discovered as part of the mechanism whereby low oxygen levels stimulate kidney cells to produce erythropoietin. This mechanism is now known to be highly conserved. Transcription factors related to HIF are found in animals ranging from worms to humans and are involved in many developmental and physiological processes. HIF is constantly being produced and broken down, and the effect of hypoxia is to stabilize HIF, thereby increasing its activity. The many roles of HIF in health and disease are just beginning to be discovered.

Under normal conditions, your bone marrow produces about 2 million RBCs every second. Immature RBCs in the bone marrow produce a large amount of hemoglobin, storing it for later use. When an immature RBC nears maturity, the nucleus, endoplasmic reticulum, Golgi apparatus, and mitochondria of the cell begin to break down. In most mammals, the nucleus breaks down too, though in all other vertebrates the nucleus is retained. The new RBC—containing hemoglobin, a few enzymes, and not much else—then enters the circulation.

FIGURE 38.7 The Composition of Blood Blood consists of a complex aqueous solution (the plasma) and numerous cell types and cell fragments. The hematocrit (arrow) is a measure of the cellular portion as a percentage of total blood volume.

In humans, each RBC circulates for about 120 days. As it gets older, its membrane becomes less flexible, and eventually an old red blood cell will rupture as it bends to fit through narrow capillaries. The major site of destruction of old RBCs is the **spleen**, an organ just below the stomach. In the spleen, the blood passes through narrow spaces that cause the less flexible RBCs to rupture. The remnants are taken up and degraded by macrophages (leukocytes that ingest debris and foreign materials). The macrophages recycle the iron from the hemoglobin, sending the iron back into circulation so that new RBCs in the bone marrow can take up the iron to make new hemoglobin.

The RBC content of blood can be quickly assessed by spinning a blood sample in a centrifuge (see Figure 4.4). The cells are spun to the bottom of the tube, leaving the lighter, straw-colored plasma on top (see Figure 38.7). The *hematocrit* is the percentage of blood volume made up by cells, which are primarily RBCs. Normal hematocrit is about 42 percent for women and 46 percent for men, with some variation. A substantially lower number may indicate *anemia*—an insufficient number of RBCs. Anemia can cause body-wide oxygen deprivation, with symptoms such as fatigue, breathlessness, and fainting.

Platelets are essential for blood clotting

Besides producing erythrocytes and leukocytes, the bone marrow stem cells also produce cells called *megakaryocytes*.

Megakaryocytes are large cells that remain in the bone marrow and release platelets into the circulation. A platelet is just a tiny fragment of a cell; it has no organelles but is packed with enzymes and chemicals necessary for its function: sealing leaks in blood vessels and initiating **blood clotting** (FIGURE 38.8).

Clotting is triggered when damage to a blood vessel exposes collagen fibers. A platelet that encounters collagen becomes *activated*—it swells, becomes irregularly shaped and sticky, and releases chemicals that activate other platelets and initiate the clotting of blood. The sticky platelets also form a plug at the damaged site.

Blood clotting requires many *clotting factors*, most of which are proteins that circulate in the blood in an inactive form. Activated platelets trigger a complex cascade of biochemical reactions in which many of these clotting proteins are activated in succession. The end result of this cascade is to convert an inactive circulating enzyme, **prothrombin**, to its active form, **thrombin**. Thrombin cleaves molecules of **fibrinogen**, a plasma protein, forming persistent threads of **fibrin**. The fibrin quickly forms a meshwork—a clot—that binds platelets, seals the vessel, and provides a scaffold for the formation of scar tissue.

The absence of any one of the clotting factors can impair clotting, causing excessive bleeding. Because the liver produces most of the clotting factors, liver diseases such as *hepatitis* and *cirrhosis* can result in excessive bleeding. People with *hemophilia* have a genetic inability to produce one of the clotting factors, and if not treated with replacement clotting factor, they can experience uncontrolled bleeding from very minor injuries. A hemophiliac can bleed for weeks from a minor paper cut.

FIGURE 38.8 Blood Clotting (A) Damage to a blood vessel initiates a cascade of events that produce a fibrin meshwork. (B) As the meshwork forms, red blood cells are enmeshed in the fibrin threads, forming a clot, as shown in this color-enhanced electron micrograph.

Do You Understand Concept 38.4?

- List the major components of blood (liquid and cellular) and state their functions.
- An excess of clotting components can be as dangerous as a deficiency. How can excessive clotting be dangerous?
- Some competitive cyclists have admitted using erythropoietin as an illegal performance-enhancing drug. How can erythropoietin enhance performance?

The RBCs, white blood cells, and platelets, along with the many dissolved substances in the plasma, circulate continuously around the vertebrate body through a closed network of vessels. Let's turn our attention now to the vessels that carry the blood.

concept 38.5 Blood Circulates through Arteries, Capillaries, and Veins

Recall that blood leaves the heart in *arteries* and moves to *arterioles* that feed *capillary beds*, where nutrients and gases are exchanged. Blood leaving capillary beds collects in *venules* that empty into *veins* that conduct the blood back to the heart. These different types of blood vessels all have distinct characteristics that help control the distribution and flow of blood.

Arteries have elastic, muscular walls that help propel and direct the blood

Arteries must withstand much higher pressure than veins. Pressure in the arteries reaches a peak during systole when the ventricles contract, then drops during diastole when the ventricles relax. The walls of the large arteries have thick layers of extracellular collagen and elastin fibers, which enable them to withstand the high blood pressure of systole (**FIGURE 38.9A**). During systole, the pressure wave created by the contraction of the left ventricle surges through the arteries and can be felt as the pulsing of the arteries in the wrists, neck, and elsewhere.

The elastic tissues in artery walls also have another important function: because they are stretched during systole, they store some of the energy imparted to the blood by the heart. Elastic recoil during diastole returns this energy to the blood by squeezing it and pushing it forward. As a result, even though pressure in the arteries drops somewhat during diastole, it never drops all the way to zero. This means that blood continues moving forward, even during diastole when the heart is not contracting.

Arteries and arterioles also contain a layer of smooth muscle that can contract or relax, thereby constricting or dilating the vessel. This change in an artery's diameter in turn changes its resistance to blood flow, and that changes the volume of blood flowing through the artery. As we will see in the next concept, neural and hormonal mechanisms can control the flow of blood to certain tissues by acting on these smooth muscle cells.

APPLY THE CONCEPT

Blood circulates in arteries, capillaries, and veins

A physician measures your blood pressure with an inflatable pressure cuff and a pressure gauge, together called a *sphygmomanometer*, and a stethoscope. Typically the pressure cuff is placed around your upper arm, and the stethoscope is used to listen to the sounds of blood flowing through the artery at the crook of your elbow. When the cuff is inflated to a high enough pressure, only a background rumble is heard in the stethoscope. Now the physician slowly lowers the pressure in the cuff and makes the observations shown at the right.

- Why is there no sound at the high cuff pressure, and why does the tapping start as the pressure is lowered?
- Why does the tapping sound disappear as the cuff pressure is further lowered?
- What pressure reading is closest to the systolic pressure? To the diastolic pressure?

CUFF PRESSURE (mm Hg)	SOUND
160	None
140	None
130	None
120	Tapping
100	Tapping
80	Tapping
70	Tapping
60	None
50	None

FIGURE 38.9 Anatomy of Blood Vessels (A) The different anatomical characteristics of arteries and veins match their functions. (B) Blood from the arterial system feeds into capillary beds, where exchanges with the interstitial fluid occur. The venous system returns blood to the heart. (C) The area encompassed by each vessel type is graphed along with the pressure and velocity of the blood within it.

Capillaries have thin, permeable walls that facilitate exchange of materials with interstitial fluid

Blood slows down dramatically when it reaches the thin-walled capillaries that lie between arterioles and venules (**FIGURE 38.9B**). The slow flow of blood and the thin, permeable capillary walls facilitate exchanges of materials between the blood and the interstitial fluid surrounding nearby cells. Most cells lie within a few cell diameters of a capillary.

Why does blood slow down so dramatically in capillaries? Imagine a single garden hose spraying water out at high velocity. If we connected this hose to a large number of lawn sprinklers, the pressure and velocity in each sprinkler would be low. Similarly, a small number of arteries supplies a huge number of capillaries. Even though each capillary has a very small diameter, there are so many capillaries that their total cross-sectional area is much greater than that of the arteries, so the blood pressure and rate of flow decrease greatly when blood reaches the capillaries (**FIGURE 38.9C**).

Capillaries are extremely small vessels that require the RBCs to flow through in single file (**FIGURE 38.10**). Their walls consist of a single layer of thin endothelial cells that are permeable to oxygen, carbon dioxide,

yourBioPortal.com

Go to **WEB ACTIVITY 38.3**
Structure of a Blood Vessel

FIGURE 38.10 A Narrow Lane Capillaries have a very small diameter, and blood flows through them slowly.

glucose, lactate, and small ions such as Na^+ and Cl^- . However, capillaries vary in their permeability to larger molecules. In most tissues other than the brain, capillaries have tiny holes, or fenestrations (singular fenestra; “windows”). This allows some larger molecules to pass through, though the largest proteins are still retained in the capillaries. Capillaries are especially permeable in the digestive tract, where nutrients are absorbed, and in the kidneys, where wastes are filtered. In contrast, the capillaries of the brain do not have fenestrations, and therefore not much can pass through them other than lipid-soluble substances, such as alcohol and anesthetics. This low permeability of brain capillaries is known as the blood–brain barrier, and it helps protect the brain from toxins that are not lipid soluble (see Concept 34.1).

Most capillaries are so permeable that at their arterial (high-pressure) end, blood pressure squeezes water and some small solutes out of the capillaries and into the surrounding intercellular spaces. Why don’t water and small-molecular-weight solutes collect in the intercellular spaces? How is the blood volume maintained if fluid is continuously leaking out of the capillaries?

More than 100 years ago, the physiologist E. H. Starling suggested that water movement across capillary walls is a result of two opposing forces, which are now known as **Starling’s forces**:

- Blood pressure forces water and small solutes out of the capillaries.
- Osmotic pressure pulls water back into the capillaries.

Blood pressure is high at the arterial end of a capillary bed and steadily drops as blood moves toward the venous end (**FIGURE 38.11**). The osmotic pressure is due to the large protein

molecules that cannot leave the capillaries, and is assumed to be relatively constant along a capillary. As long as the blood pressure is above the osmotic pressure, fluid leaves the capillary. But at the venule end, blood pressure falls below the osmotic pressure, so fluid returns to the capillary.

Overall, there is still a *slight* net loss of fluid to the intercellular spaces. This loss, about 4 liters per day, percolates between cells and then enters lymphatic vessels, which we will discuss shortly.

Several observations support Starling’s model. In people with severe liver disease or protein starvation, a fall in blood protein concentration leads to an accumulation of fluid in the extracellular spaces, which results in tissue swelling, or *edema*. Edema is also characteristic of the inflammation response accompanying tissue damage or allergic responses (see Figure 31.3). *Histamine*, a mediator of inflammation, increases capillary permeability and relaxes the smooth muscles of the arterioles, raising blood pressure in the capillaries and leading to fluid leakage into tissues. The result is the typical swelling associated with inflammation.

FIGURE 38.11 Starling’s Forces Starling’s model explains how blood volume is maintained in the capillary beds. (A) When blood pressure is greater than osmotic pressure, fluid leaves the capillaries; when blood pressure falls below osmotic pressure, fluid returns to the capillaries. (B) The balance of these two forces changes over the capillary bed as blood pressure falls.

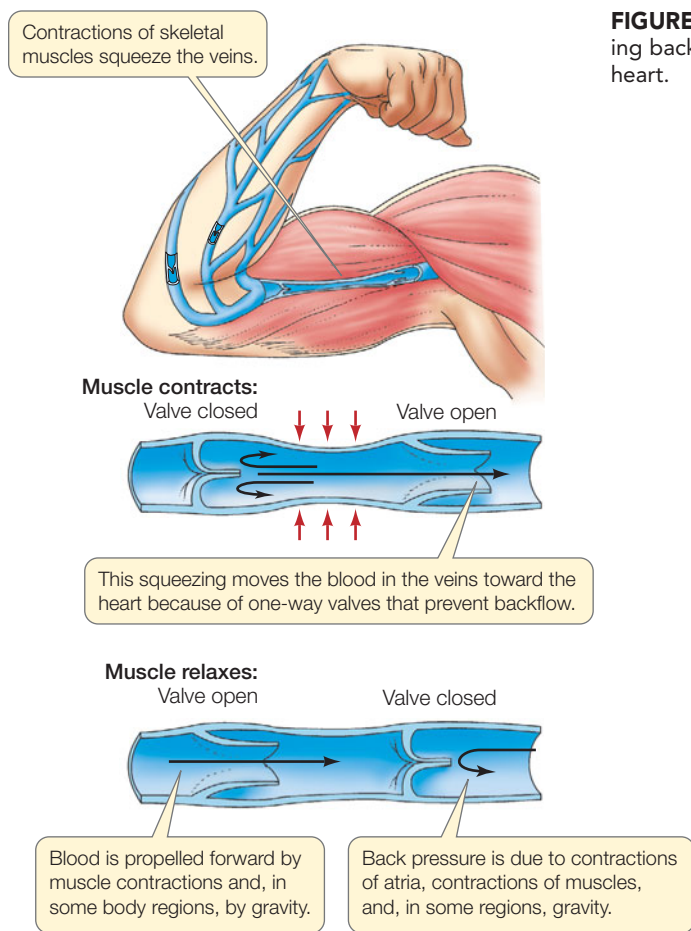

FIGURE 38.12 One-Way Flow Veins have valves that prevent blood from flowing backward, and contractions of skeletal muscle help move blood toward the heart.

prevent backflow of blood. Thus whenever a vein is squeezed by muscles, blood is propelled toward the heart (FIGURE 38.12).

If the muscles are inactive for a long period of time, gravity causes backpressure in capillary beds of the lower body. This shifts the balance between blood pressure and osmotic pressure, causing increased loss of fluid to the intercellular spaces. That is why your feet swell during a long airline flight.

Two other forces also assist with returning blood to the heart. The muscles involved in inhalation create negative pressure that pulls air into the lungs (see Figure 37.8), and this negative pressure also pulls blood toward the chest. Some of the largest veins contain smooth muscle that contracts at the onset of exercise, thereby increasing venous return to the heart.

Lymphatic vessels return interstitial fluid to the blood

Capillary beds experience a slight but steady loss of fluid to the surrounding interstitial fluid. A separate system of vessels—the **lymphatic system**—collects this excess fluid and returns it to the blood.

Each capillary bed contains at least one blind-ended *lymph capillary* that continuously takes up the excess fluid. Once in a lymphatic vessel, the interstitial fluid is called **lymph**. Fine lymphatic capillaries merge into progressively larger vessels and ultimately into two lymphatic vessels—the **thoracic ducts**—that empty into large veins at the base of the neck (FIGURE 38.13). Lymph, like blood, is propelled toward the heart by skeletal muscle contractions, breathing movements, and one-way valves.

Mammals and birds have **lymph nodes** along the major lymphatic vessels. Lymph nodes produce and house lymphocytes that continuously screen the lymph fluid for pathogens, removing microorganisms and other foreign material by phagocytosis.

FRONTIERS Starling's model does not explain certain puzzling phenomena. During strenuous exercise in humans, blood pressure can be very high, but edema does not occur. Birds have high blood pressure and low osmotic pressure, yet birds do not suffer from edema. Why not? Recent research suggests that bicarbonate ions (HCO_3^-), produced from carbon dioxide in the capillary endothelial cells and released into the blood, can increase the osmotic pressure and thereby serve as a force that pulls water back into the capillary. This hypothesis still requires further research.

Blood flow through veins is assisted by skeletal muscles

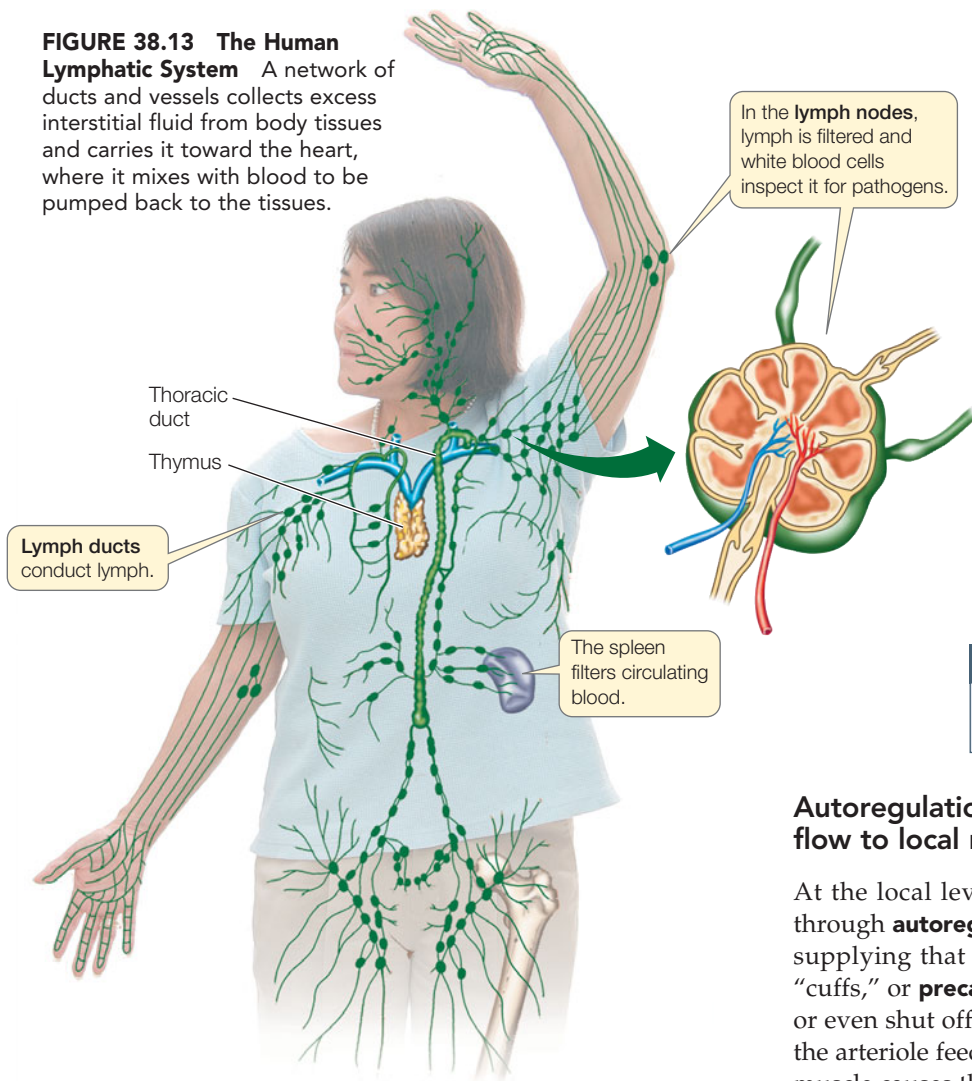

The walls of veins are more expandable than the walls of arteries, so blood tends to accumulate in veins. As much as 60 percent of your total blood volume may be in your veins when you are resting. Blood pressure in these veins is so low that it is often insufficient to propel blood back to the heart. How, then, does the blood get back to the heart?

Blood flow through veins that are above the heart is assisted by gravity. Below the level of the heart, however, venous return is against gravity. The most important force propelling blood from these regions is the squeezing of the veins by the contractions of surrounding skeletal muscles. One-way valves in the veins

Do You Understand Concept 38.5?

- In which vessels of the circulatory system does the blood move most rapidly? In which does it move most slowly? Why?
- Compare and contrast the structure of the walls of arteries, capillaries, and veins. How does the structure of the wall relate to each vessel's function?
- Certain parasitic worms can block lymph vessels. Suppose the lymph vessels draining a leg were completely blocked by a parasite infestation. What do you think would happen to the leg? Explain your answer.
- Occasionally soldiers or guards standing at attention and not moving will faint. Why do you think that occurs? How could they avoid that embarrassing situation?

FIGURE 38.13 The Human Lymphatic System A network of ducts and vessels collects excess interstitial fluid from body tissues and carries it toward the heart, where it mixes with blood to be pumped back to the tissues.

in the aorta. MAP is largely determined by two factors: the volume of blood that the heart pumps per minute, or *cardiac output* (CO), and the resistance to flow in the “downstream” blood vessels, or *total peripheral resistance* (TPR). Thus:

$$\text{MAP} = \text{CO} \times \text{TPR}$$

Cardiac output is the product of beats per minute, or *heart rate* (HR), and the volume of blood per beat, or *stroke volume* (SV). So:

$$\text{MAP} = \text{HR} \times \text{SV} \times \text{TPR}$$

Thus a deviation in blood pressure can be corrected by adjusting the heart rate, stroke volume, or total peripheral resistance. All three of these factors are controlled by multiple neural and hormonal mechanisms, at both the local and systemic levels.

 Go to **INTERACTIVE TUTORIAL 38.1**
Blood Pressure and Heart Rate Regulation

Every tissue in the body requires an adequate flow of blood. Blood flow depends on the maintenance of an appropriate blood pressure, which thus is carefully regulated, as we will see next.

concept 38.6 Circulation is Regulated by Autoregulation, Nerves, and Hormones

Blood flow through a vessel or a system of vessels depends on the pressure difference and the resistance. The relationship is analogous to Ohm’s law for electrical current in a circuit: current equals the voltage difference divided by the resistance. In the circulatory system, the heart creates the driving pressure and the characteristics and actions of the vessels determine the resistance. If the pressure imparted to the blood by the heart is too high, vessels may rupture. If the pressure is too low, tissues will not be adequately served. Therefore, arterial blood pressure is closely monitored and regulated.

Blood pressure is determined by heart rate, stroke volume, and peripheral resistance

If blood pressure deviates from normal, what can be done to correct the situation? The most important determinant of blood flow in the entire circulatory system is the *mean arterial pressure* (MAP)

Autoregulation matches local blood pressure and flow to local need

At the local level, each tissue controls its own blood flow through **autoregulatory mechanisms** that cause the arterioles supplying that tissue to constrict or dilate. Smooth muscle “cuffs,” or **precapillary sphincters**, on an arteriole can reduce or even shut off the supply of blood to the capillary bed that the arteriole feeds (**FIGURE 38.14**). Relaxation of this smooth muscle causes the arteriole to dilate, increasing blood flow to the capillary bed.

FIGURE 38.14 Local Control of Blood Flow Low O₂ concentrations or high levels of metabolic by-products cause the smooth muscle of the arteries and arterioles to relax, thus increasing the supply of blood to the capillary bed.

Autoregulation depends on the sensitivity of the smooth muscle to its local chemical environment. Low O_2 concentrations and high CO_2 concentrations cause the smooth muscle to relax, thus increasing the supply of blood, which brings in more O_2 and carries away CO_2 . Other by-products of metabolism, such as lactate, hydrogen ions, potassium, and adenosine (all of which increase in exercising muscle), also cause arterioles to dilate. Hence activities that increase the metabolic rate of a tissue also increase blood flow to that tissue.

The collective autoregulatory actions in the capillary beds in all tissues of the body determine TPR and therefore affect MAP. If many arterioles suddenly dilate, TPR goes down and MAP falls. If many arterioles constrict, TPR goes up and MAP goes up.

Sympathetic and parasympathetic nerves affect blood pressure

The diameter of arteries and arterioles is affected by the autonomic nervous system and by hormones. Arterioles especially are innervated by the sympathetic division of the autonomic nervous system. Sympathetic nerves release norepinephrine onto smooth muscle cells of arterioles, causing constriction of the arterioles. The result is reduction of blood flow through these arterioles and an elevation in MAP. The overall result is a diversion of blood flow from “nonessential” tissues (such as the gut) to skeletal muscle.

As we discussed earlier in this chapter, increased sympathetic activity also increases heart rate, and by increasing the strength of the cardiac muscle contraction, it also increases stroke volume. Thus sympathetic activation sharply raises blood pressure by all three mechanisms (HR, SV, and TPR), enabling rapid delivery of oxygen and fuel to those tissues that need it, principally the skeletal muscles.

Activation of the sympathetic nerves is coordinated by the medulla of the brainstem. The medulla receives information on blood pressure from **baroreceptors** (stretch receptors) in the major arteries and then issues appropriate commands via parasympathetic and sympathetic nerves (FIGURE 38.15). For example, suppose blood pressure becomes too high. Increased activity in baroreceptors of the large arteries signals this change to the medulla. This triggers two sets of commands from the medulla: (1) sympathetic nerves are inhibited, causing arterioles in most tissues to dilate; and (2) parasympathetic nerves slow the heart’s pacemaker (see Figure 38.5). Both of these responses help reduce blood pressure.

The medulla also monitors blood concentrations of certain key chemicals (such as oxygen and H^+) via *chemoreceptors* in the walls of the large arteries leading to the brain, and integrates this information with other inputs to adjust blood pressure.

LINK For more information about how the medulla monitors oxygen and pH, which also influence respiratory rate, see Concept 37.4

FIGURE 38.15 Regulating Cardiac Output The autonomic nervous system controls heart rate in response to information about blood pressure and blood composition originating in baroreceptors and chemosensors, as shown at the bottom of the figure. Information from these sensors goes to the cardiovascular control center in the medulla, where it is integrated with other information. The medullary center generates responses in the sympathetic and parasympathetic nervous systems that control cardiac output. Green lines indicate excitatory connections and red lines indicate inhibitory connections.

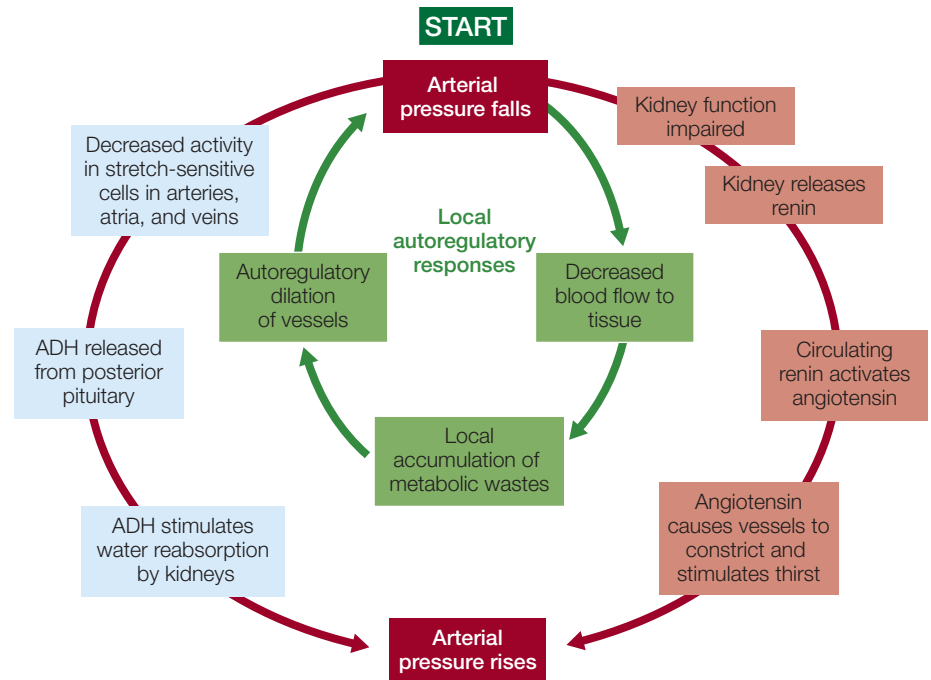

Many hormones affect blood pressure

By affecting the diameter of arteries and arterioles, hormones also play roles in regulating arterial pressure. Epinephrine, like norepinephrine, causes constriction of arterioles in some tissues, such as those of the digestive tract, and as a result diverts blood to other tissues, such as brain and skeletal muscle. Epinephrine is released from the adrenal gland in response to a fall in arterial pressure or by activation of the fight-or-flight response.

Another hormone, *angiotensin*, is produced when blood pressure to the kidneys falls (FIGURE 38.16). Angiotensin

FIGURE 38.16 Influences of Local and Systemic Mechanisms on Blood Pressure

A drop in arterial pressure reduces blood flow to tissues, resulting in local accumulation of metabolic wastes. This change in the extracellular environment stimulates autoregulatory dilation of arterioles that causes a further drop in arterial pressure (inner circle). Several systemic responses to a fall in arterial pressure serve to raise and maintain arterial pressure (outer circle).

constricts arterioles throughout the body, increasing MAP and blood flow to essential organs such as the heart, brain, and kidneys.

A third hormone, antidiuretic hormone (ADH, also called vasopressin), is secreted by the posterior pituitary when blood pressure drops. ADH causes the kidneys to reabsorb more water, thereby maintaining blood volume, which helps prevent blood pressure from dropping further (see Concept 40.5).

Overall, all of these hormonal and neural signals interact to maintain blood pressure near the ideal level necessary to maintain the flow of oxygen and nutrients to those tissues that need it.

Do You Understand Concept 38.6?

- What three factors determine the mean arterial pressure?
- If blood pressure gets too high, will angiotensin levels go up or down? What about ADH levels? Explain your answer.
- Suppose you suffer a bad cut and lose a lot of blood. The pressure in your aorta starts to drop precipitously. How will your body detect this change, and how it will attempt to restore homeostasis?

In this chapter we've learned how the circulatory system continuously circulates blood to all the cells of the body. The blood circulates so that it can transport substances such as respiratory gases (discussed in Chapter 37), nutrients, and waste products. In the next chapters we will turn to the nutrients and the waste products, and to the two physiological systems concerned with them: the digestive system (Chapter 39) and the excretory system (Chapter 40).

What are the critical factors that determine whether a person recovers from a heart attack?

ANSWER The critical factor for *surviving* a heart attack is rapid restoration of an adequate supply of blood to the brain, but the critical factor for *recovering* from a heart attack is sustaining a high enough cardiac output to all of the organs of the body. The immediate (within seconds) reaction of the body to a heart attack is massive sympathetic activity that increases cardiac output by increasing the rate and strength of contraction of the damaged heart (Concept 38.6). If cardiac output does not reach a critical level, which is about 5 liters of blood per minute for an adult human, many dangerous consequences begin to occur. Because the heart cannot pump the blood returning to it, blood slowly accumulates in the veins, causing a back pressure that increases leakage of fluids from the capillaries into the extracellular space (Concept 38.5). In the case of the lungs, this can compromise gas exchange, and therefore the blood being pumped by the heart may contain less oxygen, making the body even more hypoxic. Low cardiac output also has a negative effect on the kidneys, which as we will see in Chapter 40 depend on blood pressure for their function of filtering blood and eliminating fluid and wastes. The resulting fluid accumulation in the body puts an even greater load on the weakened heart. To recover from a heart attack, it is essential for the kidneys to resume functioning, and that requires the cardiac output to reach the life-sustaining level of about 5 liters per minute.

38

SUMMARY

concept 38.1 Circulatory Systems Can Be Open or Closed

- The metabolic needs of the cells of many small animals are met by direct exchange of materials with the external medium. Larger, active animals need a **circulatory system** that transports nutrients, respiratory gases, and metabolic wastes throughout the body.
- In **open circulatory systems**, found in mollusks and arthropods, extracellular fluid leaves vessels and percolates through tissues. **Review Figure 38.1A**
- In **closed circulatory systems**, found in annelids and vertebrates, the blood is contained in a system of vessels. Closed circulatory systems have several advantages, including faster transport and the ability to selectively direct blood to specific tissues, and the compartmentalization of functional elements such as red blood cells. **Review Figure 38.1B**
- The circulatory system of vertebrates consists of a **heart**, **arteries**, and **arterioles** that carry blood from the heart; **capillaries**, where materials are exchanged between blood and interstitial fluid; and **venules** and **veins** that carry blood back to the heart.

concept 38.2 Circulatory Systems May Have Separate Pulmonary and Systemic Circuits

- The vertebrate heart evolved from two chambers in fishes; to three in lungfishes, amphibians, and most reptiles; to four in crocodilians, birds, and mammals. This evolutionary progression has led to an increasing separation of blood that flows to the gas exchange organs and blood that flows to the rest of the body. **Review WEB ACTIVITY 38.1**
- The simplest (two-chambered heart) has an **atrium** that receives blood from the body and a **ventricle** that pumps blood out of the heart. An aorta distributes blood to arteries.
- In crocodilians, birds, and mammals, blood circulates through two completely separate circuits: the **pulmonary circuit**, which transports oxygen-depleted blood to the lungs, and the **systemic circuit**, which transports oxygenated blood to the rest of the body.

concept 38.3 A Beating Heart Propels the Blood

- The human heart has four chambers, with valves to prevent back-flow. Blood flows from the right atrium and ventricle to the lungs, then to the left atrium and ventricle, and then to the rest of the body. **Review Figure 38.2 and WEB ACTIVITY 38.2**
- The **cardiac cycle** has two phases: **systole**, when the ventricles contract, and **diastole**, when the ventricles relax. The heart sounds (“lub-dup”) are made by the closing of the heart valves. **Review Figure 38.3 and ANIMATED TUTORIAL 38.1**
- The heartbeat is generated by **pacemaker cells** in the **sinoatrial node** that spontaneously depolarize, triggering an action potential that spreads to the rest of the heart through the **atrioventricular node**, **bundle of His**, and **Purkinje fibers**. **Review Figure 38.5**

- The autonomic nervous system controls heart rate by changing the rate of depolarization of the pacemaker cells. Norepinephrine from sympathetic nerves increases heart rate, and acetylcholine from parasympathetic nerves decreases it. **Review Figure 38.4**

concept 38.4 Blood Consists of Cells Suspended in Plasma

- Blood consists of a liquid **plasma** and cellular components (**erythrocytes**, or red blood cells, **platelets**, and **leukocytes**, or white blood cells). All of the cellular components are produced in the bone marrow. **Review Figure 38.7**
- Erythrocytes transport oxygen. Their production in the bone marrow is stimulated by **erythropoietin**, which is produced in response to **hypoxia** (low oxygen levels) in the tissues.
- Platelets, along with circulating proteins, are involved in **blood clotting**, which results in a meshwork of **fibrin** threads that help seal vessels. **Review Figure 38.8**

concept 38.5 Blood Circulates through Arteries, Capillaries, and Veins

- Arteries and arterioles contain elastic fibers that enable them to withstand high pressure, and smooth muscle that can change their diameters. **Review Figure 38.9 and WEB ACTIVITY 38.3**
- Capillaries have thin, permeable walls that allow exchange of materials with the interstitial fluid. Capillaries in most tissues other than the brain have pores that allow many large molecules to pass through. **Review Figures 38.9 and 38.10**
- **Starling’s forces** suggest that blood volume is maintained in the capillary beds by an exchange of fluids driven by both blood pressure and osmotic pressure. **Review Figure 38.11**
- Veins have a high capacity for storing blood. Return of blood to the heart is aided by gravity, skeletal muscles, and breathing. **Review Figure 38.12**
- The **lymphatic system** returns interstitial fluid to the blood. **Review Figure 38.13**

concept 38.6 Circulation Is Regulated by Autoregulation, Nerves, and Hormones

- Deviations in blood pressure can be corrected by altering total peripheral resistance (TPR), heart rate (HR), or stroke volume (SV). **Review INTERACTIVE TUTORIAL 38.1**
- Autoregulation causes arterioles to dilate in response to low oxygen, high carbon dioxide, and certain metabolic waste products. This increases blood flow to the area. **Review Figure 38.14**
- Blood pressure and heart rate are also regulated by the autonomic nervous system, which responds to information about both blood pressure and blood composition that is integrated by regulatory centers in the medulla. **Review Figure 38.15**
- Many hormones affect blood pressure, including epinephrine, angiotensin, and ADH. **Review Figure 38.16**

Nutrition, Digestion, and Absorption

39

There is an obesity epidemic in the United States. About 75 percent of the adult U.S. population is overweight, and more than one-third of those individuals are obese. This problem is relatively recent in origin; the obesity percentage increased from 19 percent to 27 percent in only 10 years.

How do we define obesity, what causes it, and what are the consequences? An objective measure of body composition is the Body Mass Index. Your BMI is your mass in kilograms divided by your height in meters squared. A BMI of 18.5 to 24.9 is considered normal, 25 to 29.9 overweight, and 30 or above, obese. A simple statement of what causes obesity is the consumption of more calories than the body burns. But the problem is much more complicated. Multiple factors determine how many calories the body burns; the caloric density of foods varies enormously; and appetite is not a simple calorie meter. To find answers to questions about the causes and consequences of obesity, it is valuable to have homogeneous populations in which the problems can be studied.

For about 2,000 years the Pima people were hunters and gatherers who supplemented their diet with subsistence agriculture. Their home is the arid environment that is now the southwestern United States and northern Mexico. Archeological studies have revealed vast, sophisticated networks of irrigation canals that enabled the Pima to raise plants in that arid environment. These peoples frequently encountered drought and subsequent starvation.

Today most individuals of the ethnic Pima population in the southwestern U.S. are clinically obese. As a population, they are one of the heaviest in the world. With

obesity come health problems such as adult onset diabetes, and obesity is associated with high blood pressure and heart disease. In the 1960s, epidemiologists first noticed a disturbing incidence of type II diabetes mellitus among the Pima in Arizona. Recently, the incidence of diabetes among adult Pima was claimed to be 50 percent, and 95 percent of those individuals were obese. Furthermore, diabetes is occurring in younger Pima than ever before.

Another population of Pima lives in northern Mexico. Genetically, the Pima in Mexico and Arizona are nearly identical. Yet somehow the Mexican Pima have avoided the diabetes that plagues their northern kin; they have a diabetes incidence of only 6 percent. Even this, however, is higher than that of non-Pima Mexicans, who almost never have diabetes. The two populations of Pima people have provided researchers with an opportunity to investigate the causes and consequences of obesity.

The American Pima are an example of a human population that has a high incidence of obesity.

Why are some ethnic groups of humans much more prone to obesity and diabetes than other groups?

KEY CONCEPTS

- 39.1** Food Provides Energy and Nutrients

concept
39.1

Food Provides Energy and Nutrients

Animals are **heterotrophs**—they derive their nutrition from eating other organisms. In contrast, **autotrophs** (most plants, some bacteria, some archaea, and some protists) can use solar energy or inorganic chemical energy to serve all of their energy needs. Directly and indirectly, heterotrophs take advantage of—indeed, depend on—the organic synthesis carried out by autotrophs (**FIGURE 39.1**). But what, exactly, do heterotrophs need from their food? First, heterotrophs need energy. Second, they also need certain *nutrients* from their food—specific molecules and ions required for optimal health.

Food provides energy

One of the primary reasons that heterotrophs must eat is to obtain energy. *Energy is the capacity to do work*, and it comes in different forms: electrical energy, chemical energy, and thermal energy (see Concept 2.5). The energy in food is in the form of chemical energy, stored in chemical bonds of carbon compounds.

The energy content of any food item can be measured by the amount of heat energy the food produces if it is completely burned. Specifically, a *calorie* (note the small *c*) is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. Since this is a tiny amount of energy, physiologists commonly use the **kilocalorie (kcal)** as a unit of measure (1 kcal = 1,000 calories). Nutritionists refer to the kilocalorie as the **Calorie (Cal)**, always capitalized to distinguish it from the single calorie. For example, a pat of butter has about 35,000 calories =

35 kilocalories = 35 Calories. Physiologists also use a unit called the *joule*, which is the unit of energy measurement in the metric system. One joule equals 0.239 calories.

How many calories, or joules, an animal needs per day depends on its *metabolic rate*, a measure of the overall rate of chemical reactions throughout its entire body. *Basal metabolic rate (BMR)* is the minimum energy necessary to sustain life when an animal is resting quietly and is not expending any extra energy on growth, thermoregulation, or digestion. The basal metabolic rate of a human is about 1,400 Cal/day for an adult female and 1,700 Cal/day for an adult male. Any physical activity adds to this basal energy requirement. For example, a woman doing a day of hard physical labor may need 3,000 Cal/day. Professional athletes may need even more; cyclists in the Tour de France can eat an astonishing 9,000 Cal/day during the toughest part of the race.

Generally, fats yield 9.5 Cal/gram, carbohydrates 4.2 Cal/gram, and proteins about 4.1 Cal/gram. Thus fats store far more energy per gram than do carbohydrates or proteins.

Excess energy is stored as glycogen and fat

Catabolism of food molecules results in energy transfers needed for life. The cells of the body use energy continuously, but most animals do not eat continuously. Therefore, animals must store fuel molecules that can be released as needed between meals. A small portion of fuel, about a day's worth of energy requirements, is stored in the form of the carbohydrate *glycogen* in liver and muscle cells. But animals store the majority of their fuel—usually several weeks' worth—in the form of fat. (Proteins are not usually used for energy storage, although body protein can be broken down for energy as a last resort.)

(A)

(B)

FIGURE 39.1 Heterotrophs Get Energy from Autotrophs

(A) Some heterotrophs—herbivores—get their energy directly from autotrophs. (B) Other heterotrophs—carnivores—obtain energy indirectly from autotrophs, since the energy stored in their prey was originally obtained from autotrophs.

APPLY THE CONCEPT

Food provides energy and nutrients

MET, the *metabolic equivalent of task*, is an index of the intensity of physical activity. Exercise physiologists define the resting metabolic rate as 1 MET and increasingly energetic activities as multiples of 1 MET. Thus walking has a value of about 5 METs (i.e., it uses five times as much energy as resting quietly), jogging about 8 METs, and cross-country skiing about 10 METs. Assuming that your basal metabolic rate is 1,600 Cal/day, fill in the table with the time it would take you to burn off the calories from the listed foods while resting, jogging, or cross-country skiing.

FOOD	CALORIES	TIME REQUIRED TO BURN OFF CALORIES		
		RESTING	JOGGING	CROSS-COUNTRY SKIING
Fruit yogurt (6 oz)	130			
Turkey sandwich on whole wheat bread	215			
Sports energy bar	250			
Small cheeseburger	530			
Chicago-style cheese pizza	1,300			

Not only does fat have more energy per gram than glycogen, but it can be stored with little associated water, making it more compact. If migrating birds had to store all their energy as glycogen instead of fat, they would be too heavy to fly.

Food provides essential molecular building blocks

In addition to obtaining energy from their food, animals also need to ingest specific nutrients for the biosynthesis and function of essential molecular structures. If a nutrient cannot be synthesized in the body but is absolutely required, it is an *essential nutrient*. Nutrients required in large amounts are called **macronutrients**; those required in only tiny amounts (generally less than 100 mg/day) are called **micronutrients**.

Macronutrients generally are the building blocks of molecules found in large amounts throughout the body, such as proteins, nucleic acids, sugars, fats, and heme groups. Animals typically cannot make all parts of many of these molecules from scratch, so their food must contain specific compounds whose carbon skeletons are used as building blocks.

Amino acids, for example, are the building blocks of proteins. Most animals can synthesize some of the amino acids they need, but not all of them. Thus each species must eat certain **essential amino acids**. Essential amino acids vary by species. Adult humans need eight essential amino acids in their diets: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. (Babies require four additional amino acids: histidine, tyrosine, cysteine, and arginine.)

Milk, eggs, meat, and soybeans contain all eight essential amino acids, but most plants do not. A *complementary* diet of plant foods, however, supplies all eight essential amino acids (**FIGURE 39.2**). In general, grains (such as rice, wheat, and corn) complement legumes (such as beans and peas). Long before the chemical basis for this complementarity was understood, societies with little access to meat developed complementary diets. Many Central and South American peoples traditionally eat beans with corn, and the native peoples of North America complemented their beans with squash.

We also need certain **essential fatty acids**. Humans can synthesize most lipids from other compounds, but we must have a dietary source of certain fatty acids, especially linoleic acid. Linoleic acid is an unsaturated fatty acid needed to synthesize membrane phospholipids, signaling molecules such as prostaglandins, and some other molecules. A deficiency of linoleic acid causes symptoms that include dermatitis, infertility, and impaired lactation. Linoleic acid is common in vegetable oils, so deficiencies are rare.

FIGURE 39.2 A Strategy for Vegetarians By combining cereal grains with legumes, an adult vegetarian can obtain all eight essential amino acids.

Food provides essential minerals

A chemical element required in the diet is known as an **essential mineral**. Familiar examples are calcium, iron, and potassium (**TABLE 39.1**). Most minerals are needed only in minute quantities and hence are considered micronutrients, but a few qualify as macronutrients.

Calcium, for example, is the fifth most abundant element in the body; a 70-kg person contains about 1.2 kg of calcium.

TABLE 39.1 Mineral Elements Required by Animals

ELEMENT	SOURCE IN HUMAN DIET	MAJOR FUNCTIONS
MACRONUTRIENTS		
Calcium (Ca)	Dairy foods, eggs, green leafy vegetables, whole grains, legumes, nuts, meat	Found in bones and teeth; blood clotting; nerve and muscle action; enzyme activation
Chlorine (Cl)	Table salt (NaCl), meat, eggs, vegetables, dairy foods	Water balance; digestion (as HCl); principal negative ion in extracellular fluid
Magnesium (Mg)	Green vegetables, meat, whole grains, nuts, milk	Required by many enzymes; found in bones and teeth
Phosphorus (P)	Dairy, eggs, meat, whole grains, legumes, nuts	Found in nucleic acids, ATP, and phospholipids; bone formation; buffers; metabolism of sugars
Potassium (K)	Meat, whole grains, fruits, vegetables	Nerve and muscle action; protein synthesis; principal positive ion in cells
Sodium (Na)	Table salt, dairy foods, meat, eggs	Nerve and muscle action; water balance; principal positive ion in extracellular fluid
Sulfur (S)	Meat, eggs, dairy foods, nuts, legumes	Found in proteins and coenzymes; detoxification of harmful substances
MICRONUTRIENTS		
Chromium (Cr)	Meat, dairy, whole grains, legumes, yeast	Glucose metabolism
Cobalt (Co)	Meat, tap water	Found in vitamin B ₁₂ ; formation of red blood cells
Copper (Cu)	Liver, meat, fish, shellfish, legumes, whole grains, nuts	Found in active site of many redox enzymes and electron carriers; production of hemoglobin; bone formation
Fluorine (F)	Most water supplies	Found in teeth; helps prevent decay
Iodine (I)	Fish, shellfish, iodized salt	Found in thyroid hormones
Iron (Fe)	Liver, meat, green vegetables, eggs, whole grains, legumes, nuts	Found in active sites of many redox enzymes and electron carriers, hemoglobin, and myoglobin
Manganese (Mn)	Organ meats, whole grains, legumes, nuts, tea, coffee	Activates many enzymes
Molybdenum (Mo)	Organ meats, dairy, whole grains, green vegetables, legumes	Found in some enzymes
Selenium (Se)	Meat, seafood, whole grains, eggs, milk, garlic	Fat metabolism
Zinc (Zn)	Liver, fish, shellfish, and many other foods	Found in some enzymes and some transcription factors; insulin physiology

Calcium is a component of calcium phosphate (the principal structural material in bones and teeth) and is also necessary for nerve function and muscular contraction (see Concepts 34.2 and 36.1). Calcium is lost from the body in urine, sweat, and feces, so it must be replaced regularly. Humans require 800–1,000 mg of calcium per day in their diet, and hence calcium is a macronutrient. Insufficient calcium can cause *osteoporosis*, a progressive thinning and weakening of the bones.

Iron is an example of a micronutrient. It is the oxygen-binding atom in hemoglobin and myoglobin and is also a component of enzymes in the respiratory chain. Nevertheless, the total amount of iron in a 70-kg person is only about 4 g. Men require only about 8 mg per day of iron, since iron is recycled efficiently in the body and is not lost in the urine. However, women lose some iron every month during menstruation, so adult women require about 18 mg per day. This is still a tiny amount, yet many adult women do not get sufficient iron in their diets. Insufficient dietary iron causes *iron-deficiency anemia*, too few red blood cells in the blood, with symptoms including fatigue, lightheadedness, and fainting. Iron-deficiency

anemia is the most common mineral nutrient deficiency in the world.

Mineral Elements Required by Animals

Food provides essential vitamins

Vitamins are carbon compounds that are micronutrients. Most vitamins are coenzymes or parts of coenzymes (see Table 3.3). Different species may need different vitamins. Most mammals, for example, can make their own ascorbic acid (*vitamin C*), but primates (including humans) cannot synthesize it and must obtain it in the diet. If we do not get vitamin C in our food, we develop a disease known as *scurvy*, a progressive breakdown of connective tissue characterized by bleeding gums, loss of teeth, extensive bruising, and slow wound healing. The disease was a frequently fatal problem for sailors on long voyages until a Scottish physician, James Lind, discovered that scurvy could be

prevented if the sailors ate citrus fruit, a good source of vitamin C. The British Admiralty made limes standard provisions for its ships (and British sailors have been called “limeys” ever since). When the active ingredient in limes was isolated, it was named *ascorbic* (“without scurvy”) *acid*.

Humans require 13 vitamins (TABLE 39.2). They are divided into two groups: water-soluble and fat-soluble. Excess water-soluble vitamins are simply eliminated in the urine. (This is the fate of much of the excess vitamin C that people take.) Fat-soluble vitamins, however, can accumulate in body fat and may build up to toxic levels in the liver if taken in excess.

The fat-soluble vitamin D, which is actually a hormone that stimulates calcium absorption (see Figure 30.11), is a special case because the body can synthesize it if the skin is exposed to sunlight. Thus vitamin D must be obtained in the diet only if there is inadequate sun exposure. The need for vitamin D may be the reason that human races differ in skin color. Races that live in low latitudes are exposed frequently to strong UV light and have no trouble manufacturing plenty of vitamin D, but they run the risk of UV damage. The dark skin common in these latitudes is protection against the damage of UV radiation. Races from higher latitudes have less risk of UV damage but a much greater risk of vitamin D insufficiency, and this is likely the reason they evolved pale skin. The Inuit of the Arctic are an exception, but these dark-skinned people obtain ample vitamin D from the abundant whale blubber and fish oils in their diet.

Go to WEB ACTIVITY 39.2
Vitamins in the Human Diet

Nutrient deficiencies result in diseases

The lack of any essential nutrient in the diet produces a state of deficiency called **malnutrition**, and chronic malnutrition leads to a characteristic **deficiency disease** (see Table 39.2). We have already mentioned scurvy, caused by vitamin C deficiency. Another deficiency disease, *beriberi*, was directly involved in the discovery of vitamins.

Beriberi is a nervous system disorder characterized by extreme fatigue. It became prevalent in Asia in the nineteenth century when people began to eat white rice (discarding the brown hulls). Interestingly, chickens and pigeons developed beriberi-like symptoms when fed only white rice. In 1912, Casimir Funk cured pigeons of beriberi by feeding them rice hulls. Funk proposed that beriberi and some other diseases are caused by dietary deficiencies of what he called “vitamines” (or “vital amines”—he mistakenly thought all vitamins had amino groups). In 1926, thiamin (vitamin B₁)—the substance present in rice hulls—was the first vitamin to be isolated.

Lack of minerals can also cause deficiency diseases. Insufficient iron causes anemia; insufficient iodine causes goiter and hypothyroidism (see Concept 30.4). Goiter is rare today because of the addition of iodide to salt. However, it is still a

TABLE 39.2 Vitamins in the Human Diet

VITAMIN	SOURCE	FUNCTION	DEFICIENCY SYMPTOMS
WATER-SOLUBLE			
B ₁ (thiamin)	Liver, legumes, whole grains	Coenzyme in cellular respiration	Beriberi, loss of appetite, fatigue
B ₂ (riboflavin)	Dairy, meat, eggs, green leafy vegetables	Coenzyme in FAD	Lesions in corners of mouth, eye irritation, skin disorders
Niacin	Meat, fowl, liver, yeast	Coenzyme in NAD and NADP	Pellagra, skin disorders, diarrhea, mental disorders
B ₆ (pyridoxine)	Liver, whole grains, dairy foods	Coenzyme in amino acid metabolism	Anemia, slow growth, skin problems, convulsions
Pantothenic acid	Liver, eggs, yeast	Found in acetyl CoA	Adrenal problems, reproductive problems
Biotin	Liver, yeast, bacteria in gut	Found in coenzymes	Skin problems, loss of hair
B ₁₂ (cobalamin)	Liver, meat, dairy foods, eggs	Formation of nucleic acids, proteins, and red blood cells	Pernicious anemia
Folic acid	Vegetables, eggs, liver, whole grains	Coenzyme in formation of heme and nucleotides	Anemia
C (ascorbic acid)	Citrus fruits, tomatoes, potatoes	Formation of connective tissues; antioxidant	Scurvy, slow healing, poor bone growth
FAT-SOLUBLE			
A (retinol)	Fruits, vegetables, liver, dairy	Found in visual pigments	Night blindness
D (cholecalciferol)	Fortified milk, fish oils, sunshine	Absorption of calcium and phosphate	Rickets
E (tocopherol)	Meat, dairy foods, whole grains	Muscle maintenance, antioxidant	Anemia
K (menadione)	Intestinal bacteria, liver	Blood clotting	Blood-clotting problems

major health problem in some areas of the world. Probably the single least expensive action to improve global health would be to provide iodized salt for everyone.

Do You Understand Concept 39.1?

- Describe three deficiency diseases and the nutrients that can cure them.
- Suppose a friend of yours is so concerned about obesity in children that she puts her baby on an entirely fat-free diet. Is this wise?
- As you have probably noticed, two people of identical weight can spend identical amounts of time per day exercising, and yet often one person can eat more food than the other without gaining weight. Propose at least two explanations for this phenomenon.

Heterotrophs need food that contains sufficient energy and certain essential nutrients. However, food usually consists of complex macromolecules that cannot be used as is; the food must be broken down into smaller components for absorption.

concept 39.2 Digestive Systems Break Down Macromolecules

The function of the digestive system, or the *gut*, is to break down large pieces of food into small molecules that can be absorbed—providing the animal with the energy and the essential nutrients it needs. Proteins, carbohydrates, and fats are all broken down into their constituent monomers by hydrolytic enzymes produced by the digestive system. All of these enzymes cleave the chemical bonds of macromolecules through *hydrolysis*, a reaction that splits a bond by adding a water molecule, leaving one product with an additional H^+ and the other with an additional OH^- (see Figure 2.8). Digestive enzymes are classified according to the substances they hydrolyze: *proteases* hydrolyze the bonds between adjacent amino acids in proteins; *carbohydrases* hydrolyze the bonds between adjacent sugar units of carbohydrates; *peptidases* hydrolyze peptides; *lipases*, fats; and *nucleases*, nucleic acids.

LINK For more on the reactions that interconvert macromolecules and their constituent monomers, see Concepts 2.2–2.4, 3.1, and 3.2

Some heterotrophs such as sea stars and spiders secrete hydrolytic enzymes onto or into food sources in the external environment and then take in the resulting monomers. However, most animals *ingest* (take in) the food into a digestive tract, consisting of a body cavity that is continuous with the outside environment.

Simple digestive systems are cavities with one opening

The simplest digestive systems are **gastrovascular cavities**, which connect to the outside world through a single opening. A jellyfish, for example, captures its prey with stinging organs called *nematocysts* and uses its tentacles to pull the prey into a gastrovascular cavity. Enzymes in the gastrovascular cavity digest the prey, and cells lining the cavity take in small food particles by endocytosis. Since there is no *anus*, any undigested pieces are released through the same opening through which the prey entered. Most cnidarians and flatworms have a gastrovascular cavity.

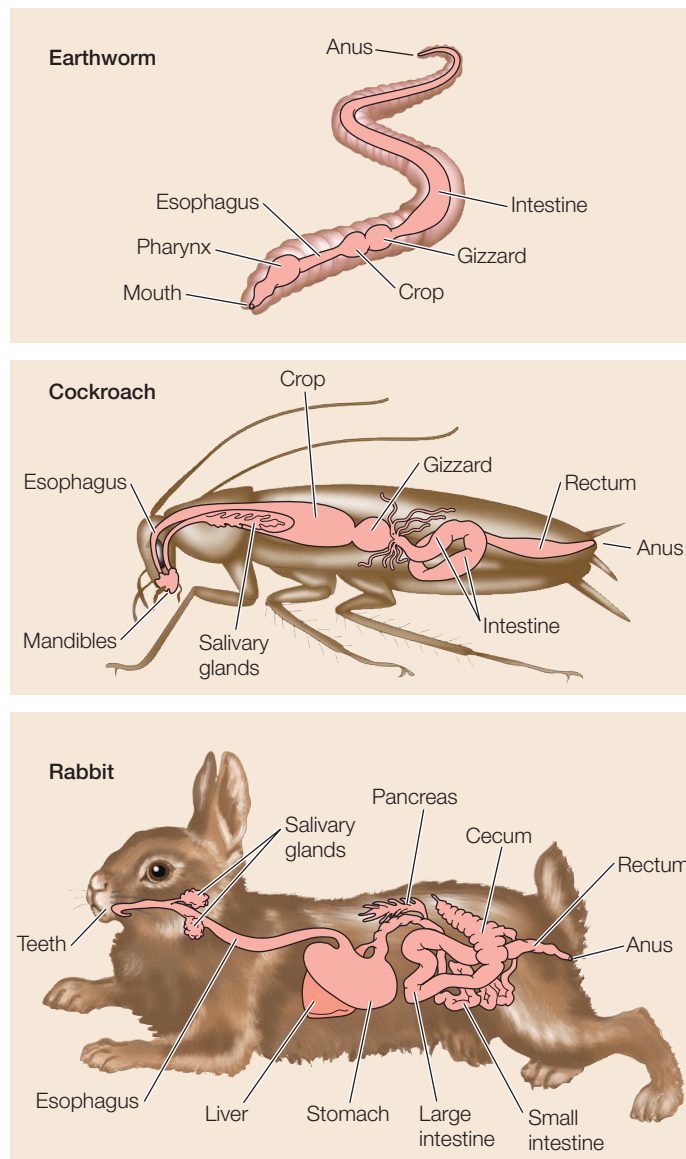

FIGURE 39.3 Compartments for Digestion and Absorption Most invertebrates and all vertebrates have a tubular gut that begins with a mouth, which takes in food, and ends in an anus, which eliminates wastes. Between these two structures are specialized regions for digestion and nutrient absorption; the structures in these regions are adapted to different diets and vary from species to species.

Tubular guts have an opening at each end

Other animals have a tubular gut with two ends. A **mouth** takes in food, molecules are digested (broken down into monomers) and then absorbed throughout the length of the gut, and undigested wastes are eliminated through an anus. Different regions in the gut are specialized for particular functions (**FIGURE 39.3**). In most animals the gut can be roughly divided into three sections: foregut, midgut, and hindgut.

FOREGUT The foregut is where food is physically broken up into small pieces, preparing it for enzymatic digestion. The foregut begins with a mouth cavity. In many animals, sharks for instance, the mouth is simply where food is grasped and swallowed, with little processing. In others, the mouth contains tools for fragmenting or liquefying the food, such as the *radula* in snails, *mandibles* in many arthropods, and specialized *teeth* in vertebrates.

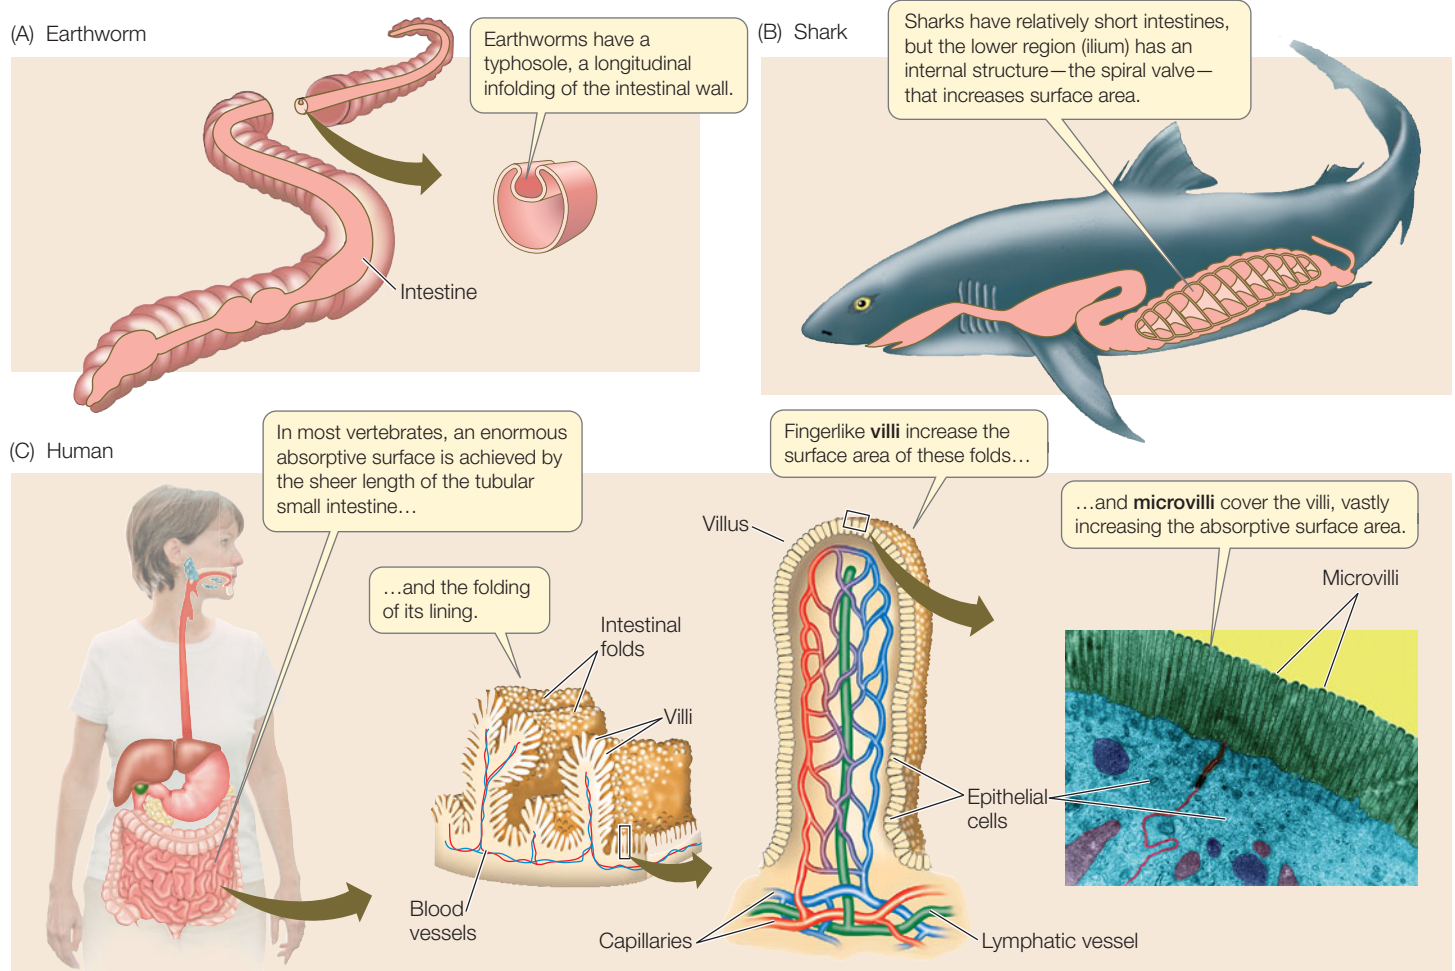

From the mouth, food moves through a tube, the **esophagus**, to a storage sac, usually called a **stomach**. The stomach physically (and sometimes enzymatically) breaks down the food, producing a slurry of small particles that is then delivered to the midgut, ready for digestion. Many animals, among them reptiles (including birds), earthworms, and various insects, have two stomachlike organs in a row: the first is a simple

storage sac called a **crop** that just holds food, and the second is a muscular organ called a **gizzard** that grinds up the food (see Figure 39.3).

MIDGUT After leaving the stomach (or gizzard), food travels through the midgut. A long, thin midgut is often called a **small intestine** (“small” referring to its diameter, not its length). The midgut is the primary site of digestion and absorption. Here hydrolytic enzymes are secreted by intestinal cells and associated glands, and macromolecules are broken down into monomers that are absorbed into the blood. In many vertebrates the midgut is highly convoluted or has fingerlike projections called **villi** (singular *villus*) to increase the surface area of contact between the gut wall and the food (**FIGURE 39.4**). The villi in turn have microscopic projections called **microvilli**, which provide even more surface area for absorbing nutrients.

HINDGUT The final segment of the gut, called the hindgut or **large intestine**, recovers water and ions and stores undigested wastes, or **feces**, until they can be expelled. The end of the

FIGURE 39.4 Intestinal Surface Area and Nutrient Absorption Maximizing the surface area of the gut increases an animal’s ability to absorb nutrients.

digestive tract is usually called the **anus**. If urinary wastes and digestive wastes are expelled through the same opening, as is the case in most amphibians and in birds and other reptiles, the opening is called a **cloaca** (Latin, “sewer”).

SYMBIOTIC BACTERIA The digestive tracts of most animals contain symbiotic bacteria. The human gut contains roughly 10^{14} bacteria—10 times more than the number of human cells in the body, and representing at least 500 different species. In many species, gut bacteria assist in the digestive process. For example, leeches of the genus *Hirudo* feed on vertebrate blood, and they depend on their gut bacteria to produce the enzymes needed to digest the blood proteins. The resulting amino acids are subsequently used by both the leech and the bacteria, so the arrangement is mutually beneficial. Similarly, many plant-eating animals, from cows to termites, house large colonies of symbiotic gut bacteria that can break down the plant polysaccharide *cellulose* in their food, producing sugars that are used both by the bacteria and by the host. We will see some examples of this in Concept 39.3.

Heterotrophs may specialize in different types of food

Heterotrophs can be classified by how they acquire their food. **Saprobies** (or *decomposers*) are organisms—mostly protists and fungi—that absorb nutrients from dead organic matter. **Detritivores**, such as earthworms and crabs, feed on dead organic material. Animals that feed on living organisms are **predators**: **herbivores** prey on plants, **carnivores** prey on animals, and **omnivores** prey on both. **Filter feeders**, such as clams and blue whales, prey on small aquatic organisms by filtering them from water. **Fluid feeders** include mosquitoes, aphids, leeches, vampire bats, and hummingbirds.

Each of these dietary specializations has its distinctive suite of morphological, physiological, and behavioral adaptations. Compare, for example, carnivorous and herbivorous mammals. Most mammals have four types of **teeth**: *incisors* at the front of the jaws for cutting; *canines* just behind the incisors for stabbing; and *premolars* and *molars* (distinguished by the number of roots) in the back for grinding. In many carnivores such as lions and wolves, the canines are greatly enlarged for seizing prey, and the premolars and molars are short, powerful shears that can cut through meat and crack bone (FIGURE 39.5). But in herbivores such as horses and cows, the canines may be completely absent, whereas the premolars and molars have enlarged into a long array of flat-topped grinding teeth that grow continuously out of the jaw as they are worn down.

Diet affects the rest of the digestive system too. Carnivores tend to have very short digestive tracts, because meat is easy to digest. Plant material is harder to digest and also has a lower energy content, so herbivores have longer digestive tracts (relative to body size), often with large compartments for the cellulose-digesting bacteria mentioned above.

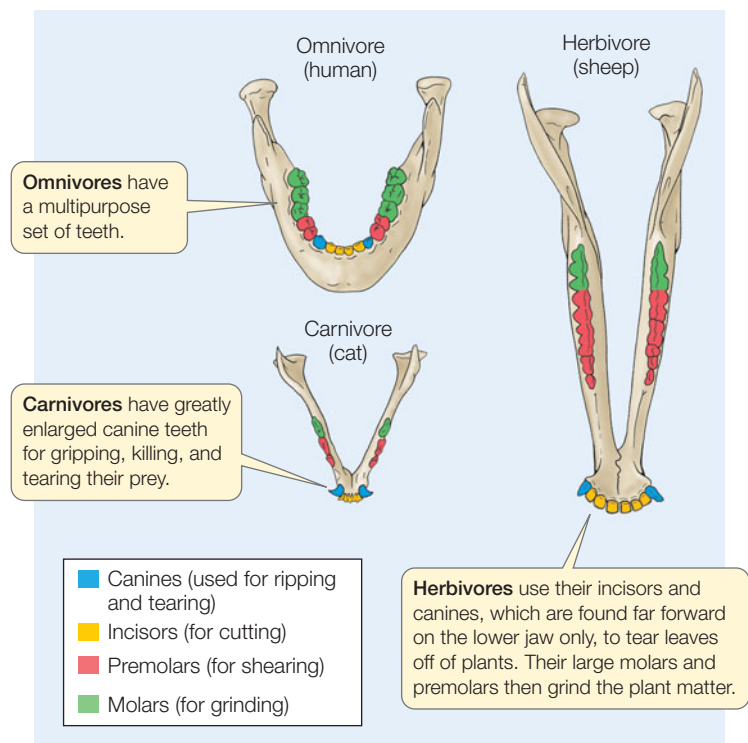

FIGURE 39.5 Mammalian Teeth The teeth of different mammalian species are specialized for different diets. This illustration depicts the teeth of the lower jaw, viewed from above.

What about humans? We have canine teeth (like carnivores), but they are small (see Figure 39.5). Our molars and premolars are shaped for grinding (like those of herbivores) but are not enlarged and do not grow continuously. We do not have cellulose-digesting bacteria, and our gut length is intermediate between that of herbivores and carnivores. Overall, these traits indicate that we are omnivores.

Do You Understand Concept 39.2?

- What are the respective terms for the enzymes that break down proteins, fats, carbohydrates, and nucleic acids?
- How would the digestive system of a fluid feeder differ from that of a detritivore? For instance, which animal would have the longer gut? How would the mouthparts differ?
- Very few birds are herbivores. Why? (Hint: The few birds that are herbivorous, such as geese, are so heavy that they sometimes have trouble taking flight.)

We have seen that the structural and functional details of the digestive system vary from species to species. Let’s take a closer look at the processes of digestion in the vertebrate gut.

concept 39.3 The Vertebrate Digestive System Is a Tubular Gut with Accessory Glands

The vertebrate digestive system is a tubular gut running from mouth to anus, with several accessory glands, including the liver and pancreas (FIGURE 39.6). The digestive system functions like an assembly line, or rather a *dis*-assembly line that takes food apart. Different processes occur sequentially in different sections. We will first consider the basic structure common to all regions of the tubular gut, and then we will examine the functions of each region. Our focus will be the human system.

The vertebrate gut consists of concentric tissue layers

The tissues of the vertebrate gut are arranged in concentric layers (FIGURE 39.7). Surrounding the gut cavity, or **lumen**, is the innermost layer of the gut, the **mucosa**. The mucosa consists

FIGURE 39.6 The Vertebrate Digestive System Different compartments in the long tubular gut specialize in digesting food, absorbing nutrients, and storing and expelling wastes. Accessory organs provide secretions containing enzymes and other molecules.

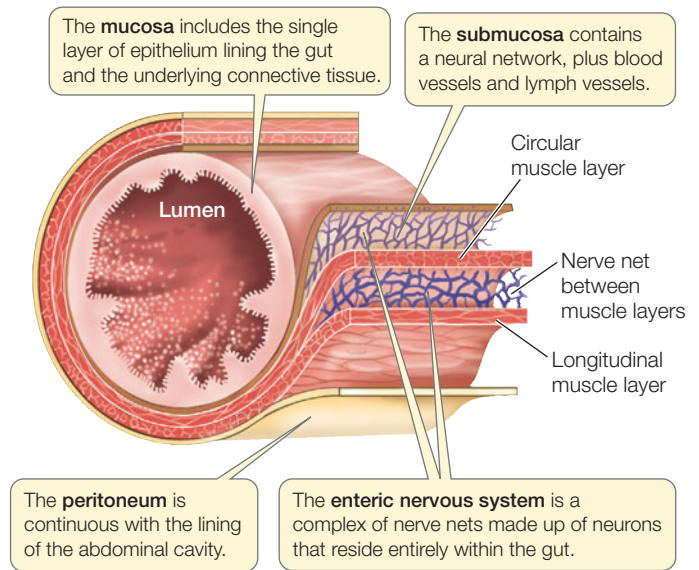

FIGURE 39.7 Tissue Layers of the Vertebrate Gut The organization of tissue layers is the same in all compartments of the gut, but specialized adaptations of specific tissues characterize different regions.

of delicate epithelial cells that secrete mucus, enzymes, and hormones. Outside the mucosa is the **submucosa** tissue layer, containing blood and lymph vessels that carry absorbed nutrients to the rest of the body. The submucosa also contains a network of sensory and motor nerves that mostly control the secretory functions of the gut.

Surrounding the submucosa is a *circular muscle layer* that constricts the gut, then another nerve net, and over that a *longitudinal muscle layer* that shortens the gut. These smooth muscle layers contract automatically in response to being stretched, such as when food passes through the lumen. The nerve net coordinates these contractions so that the contents of the gut are pushed along by a rippling muscular action called **peristalsis**. The passage of the contents through the gut is further controlled by sphincter muscles at the entrance to the stomach, the small intestine, the large intestine, and at the anus.

The nerve nets in the submucosa and between the smooth muscle layers are together called the **enteric nervous system**. They are unusual because most of their nerves do not synapse with the central nervous system (CNS). Instead they synapse with other neurons in their network. Although the CNS can influence the activity of the enteric nervous system and can receive information from it, the gut truly has a “mind” of its own.

Finally, the outermost layer of the gut is a membrane called the visceral **peritoneum** that surrounds the gut and other abdominal organs. The parietal peritoneum lines the wall of the abdominal cavity and is continuous with the visceral peritoneum. The peritoneum secretes a fluid that lubricates the organs so they can easily slide against each other.

Digestion begins in the mouth

The digestive tract begins with the mouth. Most vertebrates, such as fishes, amphibians, and birds and other reptiles, simply

The Human Digestive System

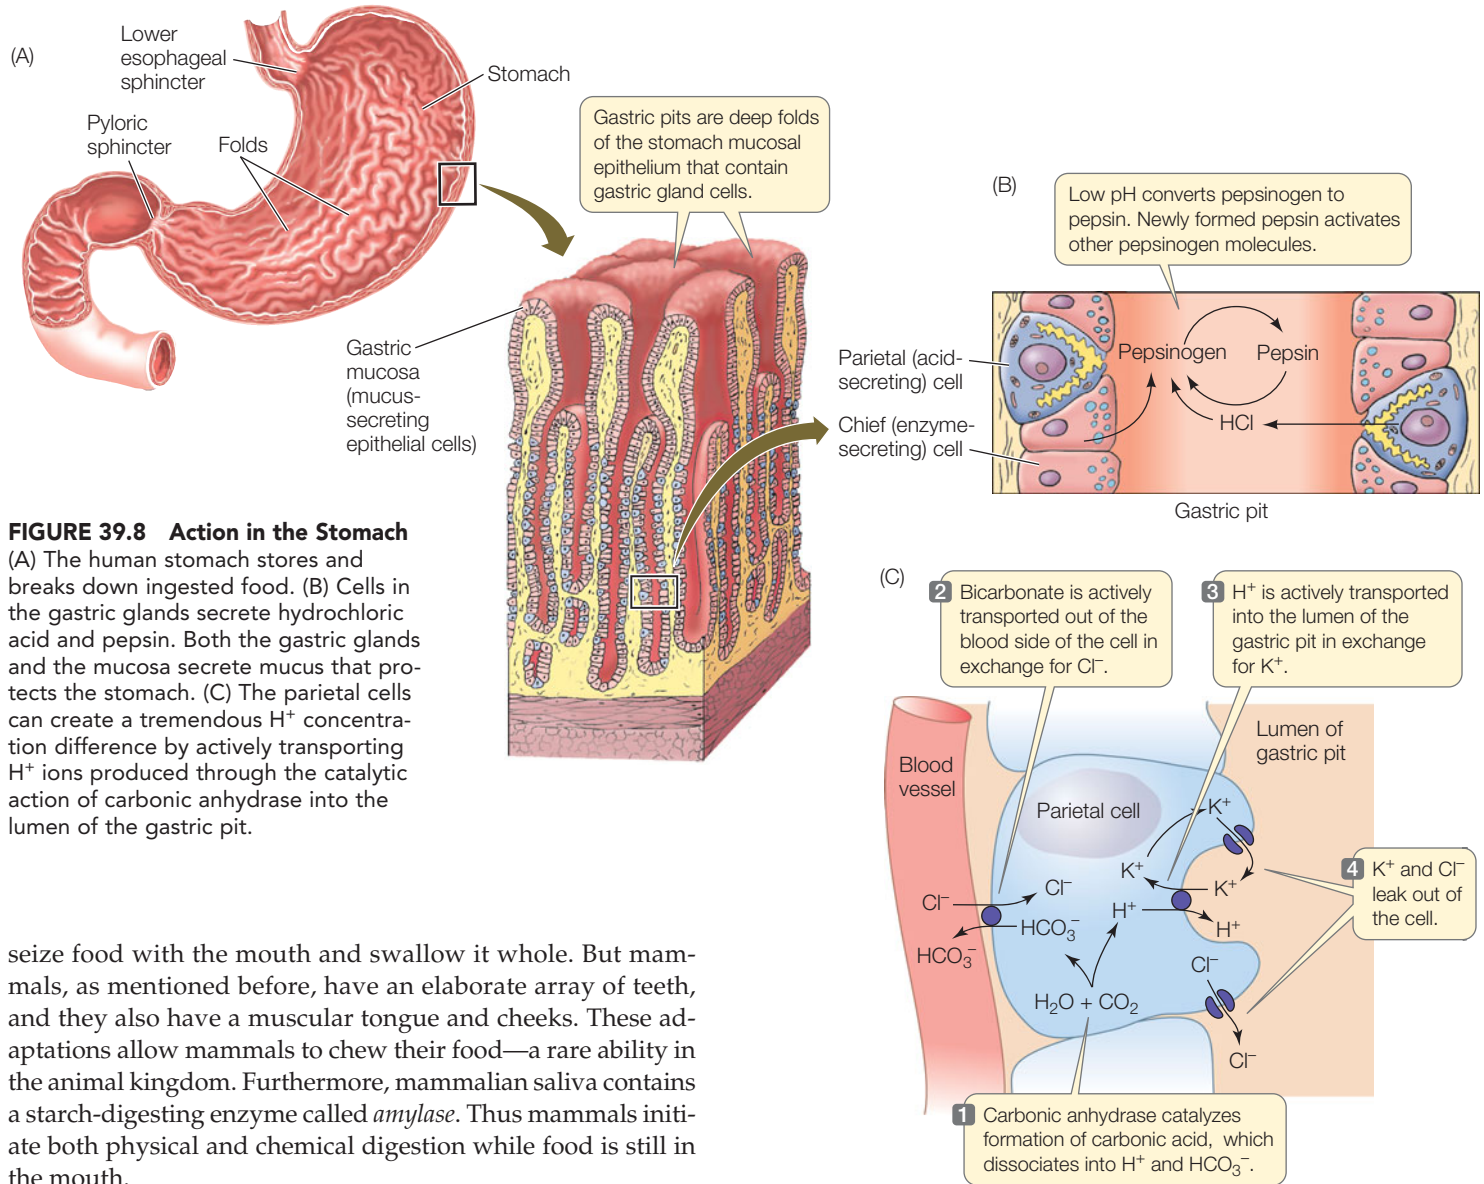

FIGURE 39.8 Action in the Stomach

(A) The human stomach stores and breaks down ingested food. (B) Cells in the gastric glands secrete hydrochloric acid and pepsin. Both the gastric glands and the mucosa secrete mucus that protects the stomach. (C) The parietal cells can create a tremendous H^+ concentration difference by actively transporting H^+ ions produced through the catalytic action of carbonic anhydrase into the lumen of the gastric pit.

seize food with the mouth and swallow it whole. But mammals, as mentioned before, have an elaborate array of teeth, and they also have a muscular tongue and cheeks. These adaptations allow mammals to chew their food—a rare ability in the animal kingdom. Furthermore, mammalian saliva contains a starch-digesting enzyme called *amylase*. Thus mammals initiate both physical and chemical digestion while food is still in the mouth.

A mouthful of food is called a *bolus*, and when that bolus is *swallowed*, it is propelled through the pharynx (where the mouth and nasal passages join), over the opening of the trachea (windpipe), and into the esophagus. To prevent food from entering the trachea, a flap of tissue called the *epiglottis* moves down to cover the entrance to the larynx (voice box). Swallowing involves many muscles contracting in a precise sequence. That sequence is an autonomic reflex that is stimulated by contact of the bolus with the tissue at the back of the mouth. If you take a cotton swab and carefully touch the back of your mouth, you will see that you cannot do it without triggering a swallowing reflex.

The bolus moves toward the stomach via peristalsis, aided by gravity. The enteric nervous system helps coordinate peristalsis by creating an *anticipatory wave of relaxation*. As one region of the gut contracts, the smooth muscles of the region just beyond that point relax to accommodate the bolus. A sphincter at the end of the esophagus is normally closed to prevent the contents of the stomach from going back into the esophagus. The anticipatory wave of relaxation allows the sphincter to open so the bolus can pass into the stomach.

The stomach breaks up food and begins protein digestion

The vertebrate stomach has several functions. It holds large batches of food, physically breaks up the food, and begins protein digestion. It also kills many of the microorganisms that inevitably enter with food.

Deep infoldings in the walls of the stomach called **gastric pits** are lined with three types of secretory cells (FIGURE 39.8A). *Chief cells* secrete **pepsinogen**, the inactive form of the protease **pepsin**. Pepsin is secreted in an inactive form so that it will not digest the very cells that secrete it. Another cell type, *parietal cells*, secrete hydrochloric acid (HCl), which kills most ingested microorganisms, helps break down food, and also converts the pepsinogen to active pepsin. Once some pepsin is activated, it activates other pepsin molecules—a process called autocatalysis (FIGURE 39.8B). This nasty mix of substances could damage the stomach wall, but a third cell type secretes mucus that provides a protective coating for the stomach.

If the mucus lining of the stomach is damaged, an *ulcer* can develop—a place where the acid and pepsin begin to eat through the stomach wall. Pioneering research by Robin Warren showed that most stomach ulcers are caused by a bacterium, *Helicobacter pylori*, that has adapted to the acidic environment of the stomach. *H. pylori* infection causes inflammation of the stomach lining, which in turn causes thinning of the mucus layer, allowing stomach juices to eat into the stomach lining. Dr. Warren memorably tested his theory by drinking a glass of *H. pylori* giving himself a pre-ulcerous inflammation and then curing himself with antibiotics. In 2005 Dr. Warren and his colleague Barry Marshall received a Nobel Prize for their work on bacterial causes of ulcers, and the practical result is that many ulcers are now treated successfully with antibiotics.

The parietal cells lining the gastric pits produce about 2 liters of a concentrated HCl solution per day, enough to bring the stomach contents below a pH of 1—the same as that of battery acid and 10 times more acidic than lemon juice. This means that parietal cells can create a H^+ concentration difference of 3 million-fold across their plasma membranes. Such a feat of ion transport is not seen anywhere else in the body. How do they do it?

Parietal cells contain the enzyme *carbonic anhydrase*, which catalyzes the formation of H_2CO_3 from CO_2 and water. H_2CO_3 immediately dissociates into H^+ and bicarbonate ion (HCO_3^-). On the blood side of the parietal cells, an *antiporter* protein (a type of secondary active transport protein; see Concept 5.3) exports HCO_3^- into the blood, exchanging it for Cl^- . On the gastric side, a different antiporter pumps H^+ into the stomach cavity, exchanging it for K^+ (FIGURE 39.8C). However, this K^+ can leak out again down its concentration gradient. Thus the inward transport of K^+ acts like an endless conveyor belt moving H^+ out of the parietal cells and into the stomach lumen.

LINK Carbonic anhydrase is also important for CO_2 transport in blood; see Figure 37.13

Muscle contractions mix the stomach's contents and push them into the small intestine

The contractions of the smooth muscles in the wall of most of the stomach do not contract and relax in a clear peristaltic fashion as in the esophagus. Instead, they create mixing motions that turn over the contents of the stomach and create a slurry of partly digested food, acid, and enzymes called **chyme**. In the lower regions of the stomach, the peristaltic contractions resume and push the chyme up against the pyloric sphincter leading to the small intestine (see Figure 39.8A). Anticipatory waves of relaxation cause the pyloric sphincter to open and allow small squirts of chyme to enter the small intestine. This measured introduction of food into the small intestine enables it to continue the digestive processes efficiently. If the contents pass through too quickly, digestion and absorption will not be complete; if the contents pass through too slowly, the metabolic needs of the animal will not be met.

Ruminants have a specialized four-chamber stomach

In **ruminants** (cud chewers), the stomach is highly specialized to house cellulose-digesting bacteria (FIGURE 39.9). The ruminant stomach has four chambers. The first two, the **rumen** and the **reticulum**, are packed with bacteria. The ruminant periodically regurgitates the contents of the rumen (the *cud*) into the mouth for rechewing. Enormous numbers of microorganisms leave the rumen along with the partially digested food. This mass is concentrated by water absorption in the **omasum** before it enters the true stomach, the **abomasum**, which functions much like our own stomach—secreting acid and enzymes, and killing the bacteria. This system provides a cow not only with glucose from cellulose breakdown, but also with more than 100 grams of protein per day from digestion of its own bacterial culture.

The small intestine continues digestion and does most absorption

In the small intestine, the digestion of carbohydrates and proteins continues, the digestion of fats begins, and nutrients of all types are absorbed. The small intestine is actually a very

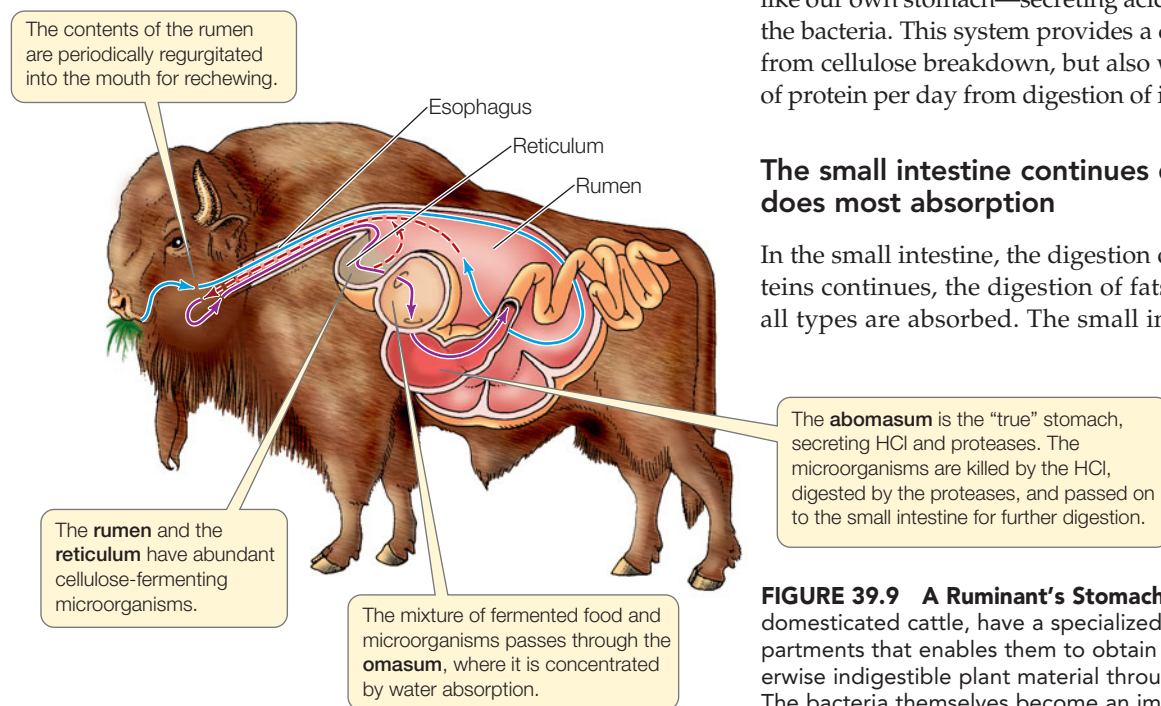

FIGURE 39.9 A Ruminant's Stomach Bison, like their relatives domesticated cattle, have a specialized stomach with four compartments that enables them to obtain energy from coarse, otherwise indigestible plant material through bacterial fermentation. The bacteria themselves become an important source of nutrition.

long organ, about 6 meters in an adult human. The mucosal epithelium in the small intestine has an enormous surface area for absorption because of its many villi and microvilli.

The small intestine of humans has three sections. A short initial section called the **duodenum** carries out most digestion. This requires many specialized enzymes and other secretions, some from the duodenum itself and some from the liver and pancreas. Most of the nutrients are then absorbed in the later sections of the small intestine, the **jejunum** and **ileum** (see Figure 39.6).

DUODENUM In the duodenum, mucosal epithelial cells produce peptidases that cleave small peptides into absorbable amino acids. These epithelial cells also produce the enzymes maltase, lactase, and sucrase that cleave the common disaccharides into absorbable monosaccharides—glucose, galactose, and fructose. The epithelial cells also produce some **lipases**—enzymes that digest fats.

FRONTIERS Most mammals, including most humans, stop producing the enzyme *lactase* after weaning. Without lactase, adult mammals have difficulty digesting the disaccharide *lactose*, which is abundant in milk. Undigested lactose is metabolized by bacteria in the large intestine, causing gas, diarrhea, and abdominal cramps. Why, then, can some people drink milk as adults? Recent research indicates that about 10,000 years ago, several human ethnic groups in northern Europe and Africa gained the ability to produce lactase throughout adulthood. This evolutionary event coincided with the domestication of cattle in each of those ethnic groups, a striking example of culture driving evolution.

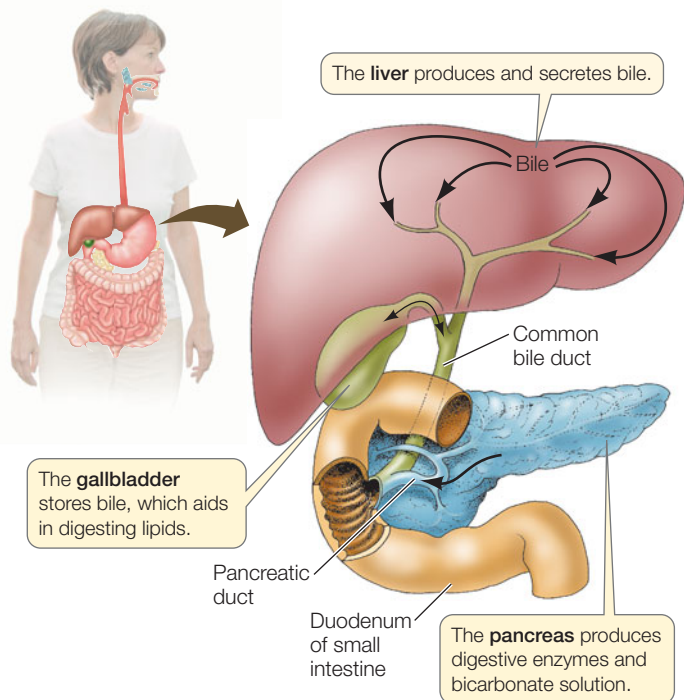

FIGURE 39.10 The Liver, Gallbladder, and Pancreas The liver and pancreas produce enzymes and other secretions that aid digestion and are released into the duodenum through the common bile duct.

LIVER The liver produces and secretes a green liquid known as **bile** that is stored temporarily in the **gallbladder** before being sent to the duodenum through the *common bile duct* (**FIGURE 39.10**). Bile's main function is to *emulsify* fats—break up large fat droplets so they will mix more readily in water. Bile includes molecules called **bile salts** that have one lipophilic end (soluble in fat) and one hydrophilic end (soluble in water). The lipophilic ends merge with the fat droplets, leaving their hydrophilic ends sticking out. As a result, bile salts prevent the fat droplets (micelles) from sticking together (**FIGURE 39.11A**). This greatly increases the surface area of the fats that can be exposed to lipases. Soon, the fats are digested into their component fatty acids, after which they move into the plasma membranes of the intestinal cells.

FIGURE 39.11 Digestion and Absorption of Fats (A) Dietary fats are broken up by bile into small micelles that present a large surface area to lipases. (B) The products of fat digestion are absorbed by intestinal mucosal cells, where they are resynthesized into triglycerides and exported to lymphatic vessels.

The Digestion and Absorption of Fats

PANCREAS The **pancreas** is a large gland that lies just behind and below the stomach (see Figures 39.6 and 39.10). It is both an endocrine gland (secreting hormones into the blood) and an exocrine gland (secreting digestive juices to the gut lumen). The endocrine cells of the pancreas produce the glucose-regulating hormones *insulin* and *glucagon*, which we will discuss in the next concept. The exocrine cells of the pancreas produce a host of digestive enzymes, including lipases, amylases, proteases, and nucleases (**TABLE 39.3**). They also secrete bicarbonate ions (HCO_3^-) that neutralize the highly acidic pH of the chyme that enters the duodenum from the stomach. The pancreatic enzymes cannot function in an acidic solution.

Pancreatic enzymes are produced and secreted into the pancreatic duct in inactive forms called zymogens. An enzyme called *enterokinase*, secreted by the duodenal epithelium, initiates the activation of these zymogens once they leave the common bile duct that conducts the secretions of the gallbladder and the pancreas into the duodenum. One of the zymogens, trypsinogen, is converted to its active form *trypsin* by enterokinase. Trypsin can then activate other trypsinogen molecules—autocatalysis, another example of positive feedback—as well as the other zymogens.

JEJUNUM AND ILEUM The breakdown of complex food molecules into their constituent units by pancreatic enzymes

continues in the jejunum. In addition, dipeptidases and disaccharidases produced by the cells lining the jejunum complete the breakdown of proteins and carbohydrates into the basic monomeric units of amino acids and six-carbon sugars. This final step is accomplished on the surfaces of the cells, and therefore these final breakdown products can be absorbed immediately and not contribute to a drastic rise in the osmotic potential of the gut contents. Throughout the length of the jejunum and ileum, the small molecules that are the final products of digestion—amino acids, sugars, nucleic acids, ions, and so forth—are absorbed into the bloodstream across the microvilli-covered surfaces of the intestinal epithelial cells.

Nutrients and ions are absorbed by diverse methods, including diffusion, facilitated diffusion, osmosis, active transport, and secondary active transport. Fructose, for example, is transported by facilitated diffusion, moving down its concentration gradient from the gut lumen into the cell. This mechanism works because once fructose enters an intestinal cell, it is converted to glucose. Thus the concentration of fructose in the cell is always low and the concentration gradient is maintained.

In contrast, glucose and many amino acids are transported against a concentration gradient by secondary active transporters that exploit the concentration gradient of Na^+ between the outside and the inside of the epithelial cells that is maintained by the Na^+/K^+ pump common to all animal cells (see Figure 5.7). As Na^+ is pulled down its concentration gradient into the cell, the “hitchhiking” molecules (e.g., glucose) are carried along with it.

LINK Active transport mechanisms and the Na^+/K^+ pump are described in Concept 5.3

Many inorganic ions such as sodium, calcium, and iron are also absorbed by active transport. For example, Na^+ pumps move Na^+ from the interior of the epithelial cells to the blood. This maintains a low concentration of Na^+ in the epithelial cells. About 30 grams of Na^+ are transported this way every day, and Cl^- follows. The transport of Na^+ and other ions is also important for water absorption because it creates an osmotic concentration gradient across the epithelial lining of the gut. At least 7 to 8 liters of water per day are absorbed because of this osmotic gradient, and it is mostly through the tiny spaces between the individual epithelial cells.

FRONTIERS Because water moves out of the gut through spaces between the epithelial cells and not through the cells themselves, it can carry with it nutrients that are in solution. Since calculations of the maximum capacity of the transport mechanisms of the epithelial cells fall short of the actual amounts of nutrients absorbed, it has been proposed that absorption of dissolved nutrients by hydraulic flow (solvent drag) through the intercellular spaces is a major mechanism of absorption. More research is needed to test this hypothesis.

TABLE 39.3 Major Digestive Enzymes of Humans

SOURCE/ENZYME	ACTION
SALIVARY GLANDS	
Salivary amylase	Starch → Maltose
STOMACH	
Pepsin	Proteins → Peptides; autocatalysis
PANCREAS	
Pancreatic amylase	Starch → Maltose
Lipase	Fats → Fatty acids and glycerol
Nuclease	Nucleic acids → Nucleotides
Trypsin	Proteins → Peptides; zymogen activation
Chymotrypsin	Proteins → Peptides
Carboxypeptidase	Peptides → Shorter peptide and amino acids
SMALL INTESTINE	
Aminopeptidase	Peptides → Shorter peptides and amino acids
Dipeptidase	Dipeptides → Amino acids
Enterokinase	Trypsinogen → Trypsin
Nuclease	Nucleic acids → Nucleotides
Maltase	Maltose → Glucose
Lactase	Lactose → Galactose and glucose
Sucrase	Sucrose → Fructose and glucose

Fats, as we have seen, pose a problem for the digestive process because of their poor solubility in water. The same problem applies to their transport in the blood stream. The intestinal epithelial cells solve this problem by packaging fats into water-soluble particles called **chylomicrons**. The products of fat digestion (fatty acids and monoglycerides) move readily through the plasma membranes of the intestinal epithelium. These cells then resynthesize triglycerides from these fatty acids and monoglycerides, package them with cholesterol and phospholipids, and coat them with protein to form the water-soluble chylomicrons (**FIGURE 39.11B**). Rather than enter the blood directly, chylomicrons pass into blind-ended lymph vessels that are in each villus. They then flow through the lymphatic system, finally entering the bloodstream through the thoracic ducts at the base of the neck (see Figure 38.13).

Absorbed nutrients go to the liver

In most organs, blood leaving a capillary bed flows directly back to the heart. The digestive system is an exception. Blood leaving the capillary beds of the digestive tract flows in the *hepatic portal vein* to the liver. There it circulates through small spaces between groups of liver cells. Thus the liver is able to process, store, and screen the newly absorbed materials before they are sent on to the rest of the body. The liver cells replenish their store of glycogen from glucose, sucrose, and fructose; build proteins from amino acids; and break down various toxins and drugs that are ingested.

The large intestine absorbs water and ions

The small intestine gradually empties into the *large intestine*, or **colon**. Most of the available nutrients have been absorbed by now, leaving a lot of water, inorganic ions, and any indigestible components. The colon absorbs the water and ions and packs the remaining material into semisolid *feces*. Feces are stored in the final portion of the colon, the **rectum**, until elimination.

The colon's reabsorption of water is important. In humans, the small intestine adds about 8 liters of water per day into the gut lumen during the digestive process. If this water is not reabsorbed, the resulting *diarrhea* will rapidly cause serious dehydration. Cholera toxin, for example, stimulates excessive ion and fluid secretion from the small intestine and can cause such extreme diarrhea that death may occur in hours.

The colon often houses symbiotic bacteria. In humans, colon bacteria produce most of our vitamin K, essential for blood clotting. In most vertebrates, there is a dead-end sac at the junction of the small and large intestines, called the *cecum* (plural *ceca*), that houses cellulose-digesting bacteria in many herbivores. Horses, rabbits, geese, and iguanas are among those herbivores that have enormous ceca packed with bacteria. Some of these animals can absorb in the colon carbohydrates and other nutrients produced by bacterial action, and others re-ingest feces that contain these nutrients (coprophagy). In humans, however, the cecum has become a vestigial, almost functionless stub called the *appendix*.

LINK For more on the diverse bacteria in the human gut and their possible effects on human health, see Concept 42.1

Do You Understand Concept 39.3?

- Where in the digestive tract does digestion of proteins, carbohydrates, and fats begin, and how are those processes initiated?
- If a person's stomach is surgically removed, what will be the consequences?
- Sometimes a gallbladder has to be removed. How does this affect digestion?
- A blow to the abdomen can damage the common bile duct and block the flow of pancreatic zymogens. If in this condition, a molecule of trypsinogen is spontaneously converted to trypsin, what could be the consequences?

We have seen how the vertebrate digestive system digests a single meal. But what happens in between meals, and what triggers the drive to begin eating the next meal? Food intake and nutrient flow are both carefully regulated.

concept 39.4 Food Intake and Metabolism Are Regulated

Most animals do not eat continuously. Instead, they cycle between an **absorptive state** (food in the gut) and a **postabsorptive state** (no food in the gut). Nutrients must be stored while they are abundant (during the absorptive state) and then released gradually from those stores in between meals (during the postabsorptive state). Furthermore, hunger must be regulated, to ensure that animals search for food when they need to eat and stop eating when the gut is full. These processes are critical for homeostasis and are regulated by multiple neuronal and hormonal systems.

Neuronal reflexes control many digestive functions

As already mentioned, the digestive tract contains its own *enteric nervous system*. The enteric nervous system communicates some information to and from the CNS, but its most important role is to coordinate the digestive tract. In particular, the enteric nervous system is able to coordinate, largely on its own, the movement of food through the gut.

A few digestive reflexes do involve the CNS. Swallowing is one example; salivation at the sight or smell of food is another, and defecation is a third.

Hormones regulate many digestive functions

Over two dozen hormones regulate the activities of the digestive tract and its accessory organs (**FIGURE 39.12**). Several of

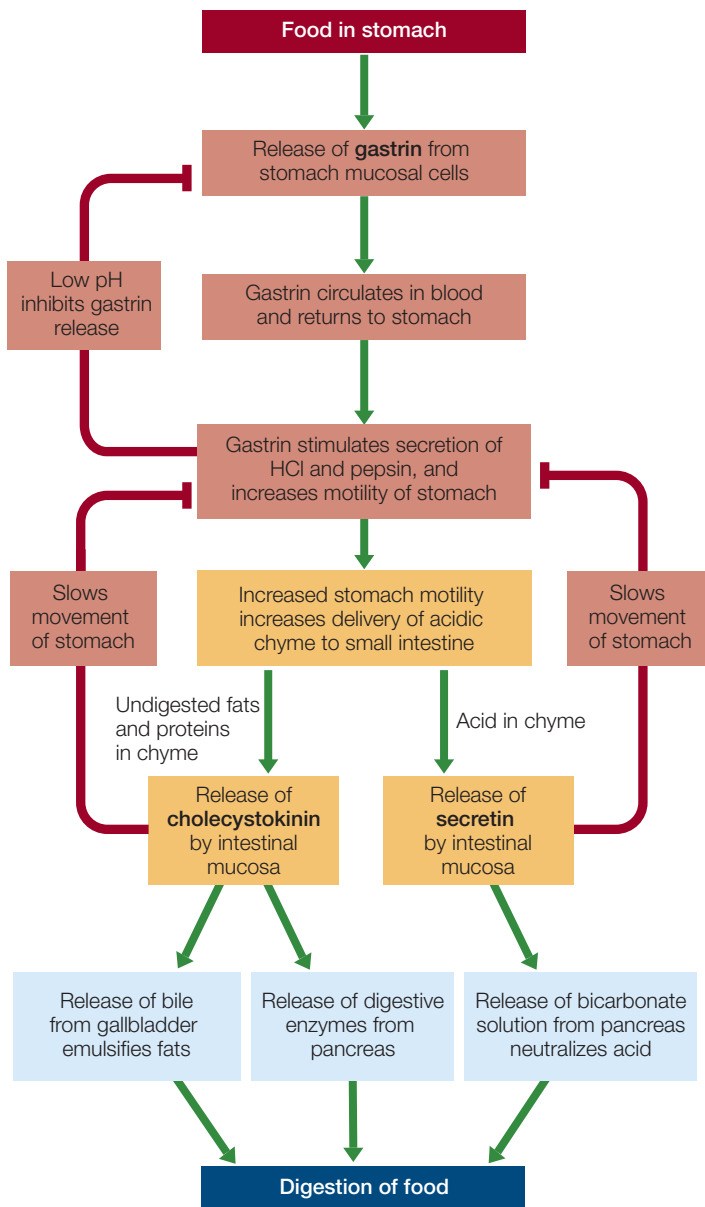

FIGURE 39.12 Hormones Control Digestion The hormones gastrin, cholecystikinin, and secretin are involved in feedback loops that control the sequential processing of food in the digestive tract. Red lines indicate inhibitory actions; green lines indicate stimulatory actions.

these hormones are released when food arrives in the stomach and duodenum. The presence of food in the stomach causes cells in the wall of the stomach to secrete the hormone **gastrin**. Gastrin circulates in the blood and returns to the stomach, causing an increase in motility and the secretion of digestive juices. Gastrin release begins to be inhibited when the pH of the stomach contents falls below 3—an example of negative feedback (see Concept 29.2).

Acidic chyme arriving in the duodenum stimulates cells in the duodenal epithelium to release **secretin** (the first hormone ever discovered, hence its name). Secretin stimulates the pancreas to produce and secrete bicarbonate ions that neutralize the acidic chyme. Similarly, the presence of fats and proteins in the chyme stimulates duodenal cells to release **cholecystikinin (CCK)**. CCK then stimulates the delivery of bile into the

common bile duct by increasing peristalsis of the gallbladder and the duct. CCK also stimulates the pancreas to release digestive enzymes. Both secretin and CCK are negative feedback signals to the stomach to slow the delivery of chyme into the duodenum (see Figure 39.12).

Insulin and glucagon regulate blood glucose

Two of the most important hormones from the digestive system, *insulin* and *glucagon*, regulate glucose metabolism. Glucose is a fuel that can be used by all cells of the body, and it gets into cells by diffusion. Thus it is necessary to have an adequate blood glucose concentration to provide a concentration gradient across cell membranes. When blood glucose levels fall, most cells can switch to alternative fuels, mostly fats, but the nervous system tissues cannot—they require glucose. **Insulin** is the major hormone that maintains blood glucose levels.

Insulin regulates fuel metabolism by controlling the presence of the transporters in the cell membrane that facilitate the diffusion of glucose into cells. When an animal is in the absorptive state (food in gut), the rise in blood glucose as carbohydrates are digested stimulates the β cells of the *islets of Langerhans* in the pancreas to secrete insulin (**FIGURE 39.13**).

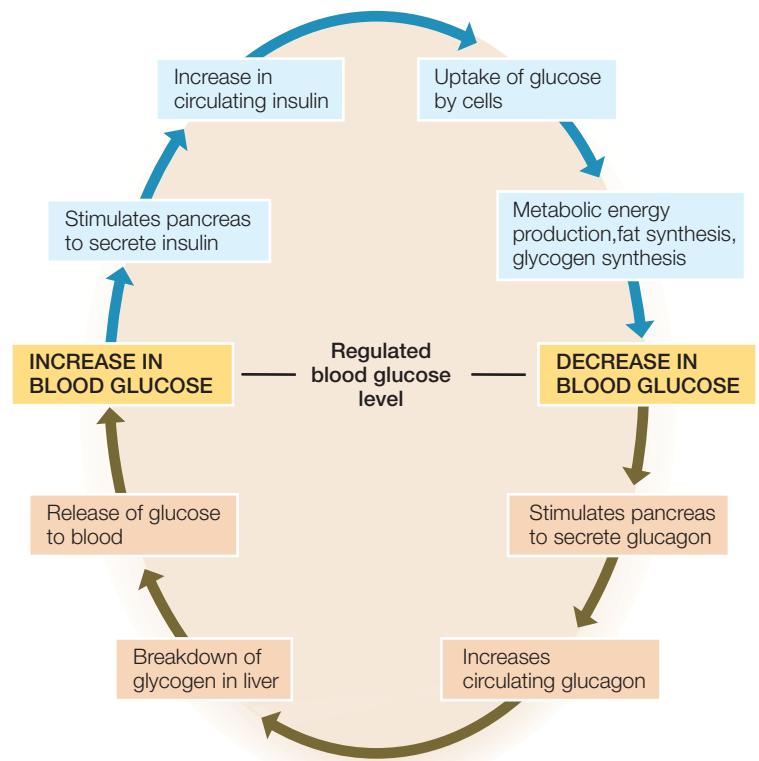

FIGURE 39.13 Regulating Glucose Levels in the Blood Insulin (blue) and glucagon (brown) interactions maintain the homeostasis of circulating glucose. It is important for blood glucose to remain stable because it is the essential source fuel for the nervous system.

yourBioPortal.com

Go to **ANIMATED TUTORIAL 39.2**
Insulin and Glucose Regulation

Circulating insulin causes the insertion of glucose transporters into cell membranes so that more glucose can diffuse into the cells, and the cells use the glucose for energy and for the synthesis of energy storage molecules—glycogen and fat.

In the postabsorptive state, blood glucose levels decline and insulin secretion stops. The lack of insulin decreases the uptake of glucose into cells, forcing them to use alternative energy supplies. The lack of insulin also changes enzymatic activity in key tissues, enabling the body to maintain blood glucose levels and to shift fuel usage to fats. In the liver, the enzymes of glycogen synthesis become less active, and the enzymes that break down glycogen and provide glucose to the blood are activated. In fat cells, lipases are activated. The cells of the nervous system do not require insulin to take up glucose, so they continue to take up glucose during the postabsorptive phase. Thus the lack of insulin protects glucose supplies for the nervous system.

The metabolism of fuel molecules during the postabsorptive state is mostly controlled by the lack of insulin, but if blood glucose falls too low, another pancreatic hormone, **glucagon**, is released. Glucagon's effect is opposite that of insulin: it stimulates liver cells to break down glycogen and to carry out gluconeogenesis—the synthesis of glucose from some amino acids and from lactate. Thus, under the influence of glucagon, the liver produces glucose and releases it into the blood.

Lack of insulin, or lack of the ability to respond to insulin, causes a dangerous metabolic condition known as **diabetes mellitus**. Type I diabetes is caused by lack of insulin; type II diabetes is caused by poor responsiveness to insulin. Both types of diabetes result in the same basic problem: most cells cannot take up enough glucose to meet their metabolic needs, and so much glucose accumulates in the blood that it starts to spill over into the urine, causing excessive urination, dehydration, and thirst. Meanwhile, body cells suffer from a lack of metabolic fuel; there may be plenty of glucose circulating in the blood, but without insulin it does not diffuse into cells. Body glycogen and fat stores become depleted, and eventually muscle cells begin to break down protein for fuel. The cells of a person with diabetes are literally starving in the midst of plenty.

Type I diabetes is also called juvenile diabetes because its onset is frequently early in life, when an autoimmune reaction destroys the insulin-producing cells in the pancreas. Type II diabetes is referred to as adult-onset diabetes because it is mostly caused by lifestyle patterns such as lack of exercise, smoking, and obesity. There is also a strong genetic predisposition for type II diabetes. Type I diabetes is mostly treated through use of supplemental insulin to control blood sugar levels, whereas type II diabetes is mostly treated through changes in lifestyle.

The liver directs the traffic of the molecules that fuel metabolism

The liver coordinates many of the changes necessary to switch between absorptive and postabsorptive states. During the absorptive state the liver (under the influence of insulin) stores fuel in the form of glycogen and fats. The liver also synthesizes blood plasma proteins from circulating amino acids. Later,

when fuel molecule levels in the blood decline, the liver taps its reserves and delivers nutrients into the blood.

The liver is also a major controller of fat metabolism through its production of **lipoproteins**. Lipoproteins are particles of fat and cholesterol with a covering of protein that allow them to be suspended in water. The chylomicrons made by the intestine are a type of lipoprotein. As chylomicrons travel through the bloodstream, their triglyceride and cholesterol cargo is delivered to the liver or to fat cells. The liver repackages the dietary lipids into various other types of lipoproteins that shuttle the lipids to and from the tissues of the body. The “good cholesterol” and “bad cholesterol” that you have probably heard of are actually types of lipoproteins, categorized by density:

- **High-density lipoproteins (HDLs)** remove cholesterol from tissues and carry it to the liver, where it is used to synthesize bile. These are the “good” lipoproteins, and their levels are higher in people who exercise.
- **Low-density lipoproteins (LDLs)** transport cholesterol around the body for use in biosynthesis and for storage. These are the “bad” lipoproteins associated with a high risk for cardiovascular disease.
- **Very low-density lipoproteins (VLDLs)** contain mostly triglyceride fats, which they transport to fat cells. These are especially “bad”; they are associated with excessive fat deposition as well as a high risk for cardiovascular disease.

Many hormones affect food intake

Obesity is a major health issue in the United States. A simple rule—take in fewer calories than your body burns while eating a balanced diet—should solve the problem, but it doesn't. Why not? Lifestyle plays a major role in obesity, but genetic and regulatory factors “weigh in” as well. Ultimately, the amount of food an animal eats is governed by its sensations of hunger and satiety. These sensations are influenced by the hypothalamus (see Concept 30.3). But how does the hypothalamus know whether the body has adequate (or even excessive) stores of fuel? It appears that the hunger and satiety centers in the hypothalamus are powerfully affected by several digestive hormones, among them insulin, CCK, and **leptin**.

Leptin was discovered in a strain of mice that tend to eat enormous amounts of food (**FIGURE 39.14**). Given free access to food, these mice always become obese. The mice have a mutation in the gene for leptin, now known to be a peptide hormone produced by adipose cells. The more fat an adipose cell contains, the more leptin it produces. Thus the overall level of leptin in the bloodstream is the body's “fat report”—the higher the leptin, the more fat the body has. The hypothalamic centers that control hunger and satiety contain leptin receptors. Thus leptin is probably providing feedback information to the hypothalamus about the status of the body's fat reserves.

Parabiotic Mice: Regulation of Food Intake

INVESTIGATION

FIGURE 39.14 A Single-Gene Mutation Leads to Obesity in Mice In mice the *Ob* gene codes for the protein leptin, a satiety factor that signals the brain when enough food has been consumed. The recessive *ob* allele is a loss-of-function allele, so *ob/ob* mice do not produce leptin; they do not experience satiety and become obese. The *Db* gene encodes the leptin receptor, so mice homozygous for the recessive loss-of-function allele *db*, even if they produce leptin, cannot use it and so become obese.

HYPOTHESIS

Mice who cannot produce the satiety signal protein leptin will not become obese if they are able to obtain leptin from an outside source.

METHOD

1. Create two strains of genetically obese laboratory mice, one of which lacks functional leptin (genotype *ob/ob*) and one which lacks the receptor for leptin (genotype *db/db*).
2. Create parabiotic pairs by surgically joining the circulatory systems of a non-obese (wild-type) mouse with a partner from one of the obese strains.
3. Allow mice to feed at will.

Parabiotic pair

Wild-type mouse (*Ob*^{+/+} and *Db*^{+/+}) Genetically obese mouse (either *ob/ob* or *db/db*)

RESULTS

Parabiotic *ob/ob* mice obtain leptin from the wild-type partner and lose fat. Parabiotic *db/db* mice remain obese because they lack the leptin receptor and thus the leptin they obtain from their partner has no effect.

CONCLUSION

The protein leptin is a satiety signal that acts to prevent overeating and resultant obesity.

ANALYZE THE DATA

In a further experiment, leptin was purified and injected into *ob/ob* and *Ob/Ob* (wild-type) mice daily. The data in the table were collected before the injections began (baseline) and 10 days later.

Parameter	Baseline		Day 10	
	<i>ob/ob</i>	<i>Ob/Ob</i>	<i>ob/ob</i>	<i>Ob/Ob</i>
Food intake (g/day)	12.0	5.5	5.0	6.0
Body mass (g)	64	35	50	38
Metabolic rate (ml O ₂ /kg/hr)	900	1150	1100	1150
Body temperature (°C)	34.8	37.0	37.0	37.0

- Do the data support the hypothesis that leptin is a satiety signal? Why or why not?
- Discuss what factors might explain the loss of body mass in the *ob/ob* mice.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

When leptin was injected into the obese mice, they ate much less and lost body fat. This led to great excitement that leptin injections might be able to “cure” obesity in humans. In a few obese people, leptin injections did cause dramatic weight loss, but unfortunately, leptin injections had no effect on most obese people. Most obese people actually turn out to have *higher* levels of leptin than normal; it appears they are unable to respond normally to leptin (this is analogous to type II diabetes; the hormone is being produced, but the body cannot respond).

Many other hormones and feedback signals are now known to be involved in regulating food intake in mammals. A hormone called *peptide YY* from the gut reduces appetite. The hormone *ghrelin*, produced by the stomach when it is empty, strongly stimulates appetite. Over a dozen other hormones and neurotransmitters are also known that affect the hunger and satiety centers of the hypothalamus. The search for an “obesity cure” continues. If one thing is clear, it is that the control of food intake involves more than just willpower; powerful physiological feedback systems are also at work.

FRONTIERS

Recent research has identified the enzyme AMP-activated protein kinase (AMPK) as a possible signal of nutrient insufficiency that may drive hunger. When most cells are nutrient deprived, they produce AMPK, which stimulates the catabolism of substrates to replenish ATP. In the hypothalamus, increased levels of AMPK stimulate food intake, and lowered levels of AMPK inhibit food intake. In addition, AMPK activity in the hypothalamus is inhibited by leptin and insulin and is stimulated by ghrelin. Thus AMPK may sit at a point where several signaling pathways involved in controlling food intake converge into a single pathway. If true, this would make AMPK an attractive target for therapies to treat obesity and other types of eating disorders.

Do You Understand Concept 39.4?

- Briefly describe the anatomical origins, the factors that stimulate release, and the effects of the hormones gastrin, secretin, cholecystokinin, insulin, and leptin.
- Which condition do you think would more rapidly cause death: complete pancreatic failure or complete liver failure? Why?
- This concept described a strain of obese mice that could not produce leptin. A different strain of obese mice also has a defect in the leptin system, yet these mice did not respond to leptin injections—they continued eating and remained obese. Can you figure out why?

Why are some ethnic groups of humans much more prone to obesity and diabetes than other groups?

ANSWER At least two interacting factors are involved in the Pimas' struggle with diabetes and obesity: genetics

and lifestyle. Geneticists hypothesize that recurring episodes of starvation produced strong selective pressure for “thrifty genes”—alleles that result in greater-than-average efficiency in storing fat. Thrifty genes would give individuals a strong selective advantage when food is scarce. The Pima, for example, turn out to have a very low resting metabolic rate (Concept 39.1). They also release a large amount of insulin in response to glucose (recall that insulin promotes the synthesis of fat) (Concept 39.4). A typical Pima responds to a standard amount of glucose with a rise in insulin levels that is three times higher than in Americans of European ancestry.

The other major factor in the Pima obesity epidemic is an abrupt change in their traditional lifestyle. Pima living in the United States today eat a typical “American” diet of high-fat, high-calorie fast foods, and they also engage in less physical activity than their ancestors did. In contrast, the Mexican Pima still live a traditional lifestyle and eat traditional foods. Whereas the Arizona Pima engage in an average of only 2 hours of physical work per week, the Mexican Pima average 23 hours per week.

A high-calorie diet and sedentary lifestyle affect not just the Pima but undoubtedly contribute to the alarming increase in obesity that has occurred throughout the U.S. population in recent decades.

39

SUMMARY

concept 39.1

Food Provides Energy And Nutrients

- Animals are **heterotrophs** that derive their energy and molecular building blocks, directly or indirectly, from **autotrophs**. **Review Figure 39.1**
- Carbohydrates, fats, and proteins in food supply animals with metabolic energy. A measure of the energy content of food is the **Calorie (Cal)**. Excess energy is stored as glycogen and fat.
- Food also provides **macronutrients**, which are needed in large quantities, and **micronutrients**, which are needed in small amounts.
- Food provides essential carbon skeletons that animals cannot synthesize themselves.
- Adult humans require eight **essential amino acids** and at least one **essential fatty acid**. **Review Figure 39.2**
- **Essential minerals** are chemical elements that are required in the diet. **Review Table 39.1 and WEB ACTIVITY 39.1**
- **Vitamins** are small organic molecules needed as micronutrients, usually functioning as enzymes or coenzymes. **Review Table 39.2 and WEB ACTIVITY 39.2**
- **Malnutrition** results when any essential nutrient is lacking from the diet. Chronic malnutrition causes **deficiency diseases**.

concept 39.2

Digestive Systems Break Down Macromolecules

- Digestion involves the breakdown of complex food molecules into monomers that can be absorbed and used by cells. Hydrolytic enzymes break down proteins, carbohydrates, fats, and nucleic acids into their monomeric units.
- In most animals, digestion takes place in a tubular gut that has two openings. The tubular gut can be divided into a foregut that physically breaks up food, a midgut that digests and absorbs the food, and a hindgut that packages wastes. **Review Figure 39.3**
- In most vertebrates, absorptive areas of the gut are characterized by a large surface area produced by extensive folding and numerous **villi** and **microvilli**. **Review Figure 39.4**
- Animals can be characterized by how they acquire their food: **saprobies** and **detritivores** eat dead organic matter, **filter feeders** strain the aquatic environment for small food items, **herbivores** eat plants, and **carnivores** eat animals.

concept 39.3

The Vertebrate Digestive System Is a Tubular Gut with Accessory Glands

- The vertebrate gut can be divided into several compartment with different functions. **Review Figure 39.6 and WEB ACTIVITY 39.3**

- The gut consists of an inner **mucosa** that secretes mucus, enzymes, and hormones and absorbs nutrients; a **submucosa** containing blood and lymph vessels; two layers of smooth muscle; and a semi-independent nerve network called the **enteric nervous system**. **Review Figure 39.7**
- **Peristalsis** moves food throughout the length of the gut. Sphincters block the gut at certain locations, but they relax as a wave of peristalsis approaches.
- Digestion begins in the **mouth**. Mammals chew their food, and their saliva contains the starch-digesting enzyme amylase.
- The **stomach** breaks up food, begins the process of protein digestion, controls the flow of chyme to the small intestine, and kills many microorganisms. Stomach cells secrete HCl, **pepsinogen** (the inactive form of **pepsin**), and mucus that protects the stomach wall. **Review Figure 39.8**
- In the **duodenum**, pancreatic enzymes carry out most of the digestion of food. Bile from the liver and **gallbladder** emulsifies fats for digestion. Bicarbonate ions from the **pancreas** neutralize the pH of the **chyme**. **Review Figure 39.10**
- The **jejunum** and **ileum** absorb most of the products of digestion, including amino acids, monosaccharides, and inorganic ions. Specific transporter proteins are sometimes involved.
- Fats broken down by **lipases** are resynthesized into triglycerides within intestinal cells, combined with cholesterol and phospholipids, and coated with protein to form **chylomicrons**, which move into lymph vessels. **Review Figure 39.11 and ANIMATED TUTORIAL 39.1**
- Water and ions are absorbed in the large intestine as waste matter and consolidated into **feces**, which are periodically eliminated.
- Microorganisms in some compartments of the gut digest materials that their host cannot. **Review Figure 39.9**

concept 39.4 Food Intake and Metabolism Are Regulated

- Animals cycle between an **absorptive state** (food in the gut) and a **postabsorptive state** (no food in the gut).
- Neuronal reflexes coordinate much of the activity of the digestive tract.
- The actions of the stomach and small intestine are largely controlled by the hormones **gastrin**, **secretin**, and **cholecystokinin (CCK)**. **Review Figure 39.12**
- **Insulin** from the pancreas largely controls glucose metabolism. In the postabsorptive state, lack of insulin blocks the uptake and use of glucose by most cells of the body except neurons. If blood glucose levels fall, **glucagon** secretion increases, stimulating the liver to break down glycogen and release glucose to the blood. **Review Figure 39.13 and ANIMATED TUTORIAL 39.2**
- The liver plays a central role in directing the traffic of fuel molecules. In the absorptive state, the liver takes up and stores fats, carbohydrates, and proteins. In the postabsorptive state, the liver can produce glucose, either via breakdown of glycogen or via gluconeogenesis from proteins or other molecules.
- Fat and cholesterol are shipped out of the liver as **low-density lipoproteins (LDLs)**. **High-density lipoproteins (HDLs)** act as acceptors of cholesterol and are believed to bring fat and cholesterol back to the liver.
- Food intake is governed by sensations of hunger and satiety, which are determined by brain mechanisms responding to feedback signals such as insulin, **leptin**, and ghrelin. **Review INTERACTIVE TUTORIAL 39.1**

Salt and Water Balance and Nitrogen Excretion

40

Blood, sweat, and tears taste salty; their ionic concentrations are similar to those of the interstitial fluids of the body. The volume and solute composition of the interstitial fluids must remain within certain limits and be kept relatively free of wastes. Maintaining homeostasis of the interstitial fluids is the job of the excretory system, and it can be challenging. The challenges depend on an animal's environment and lifestyle. Some desert animals rarely encounter free water. Like all animals, they derive water from the metabolism of food, but how can they survive with only a meager water budget?

Animals such as fish, invertebrates, and even some terrestrial animals that live in fresh water, such as beavers, have the opposite problem; water continuously enters their bodies by osmosis or with the food they consume, so they must excrete water while conserving important ions that are scarce in their food. Some marine animals such as albatrosses have a still different problem: they take in enormous amounts of ions with their food and have to excrete them without losing much water. Some animals face dramatic changes in their salt-water-waste balance within a single day. Consider vampires—the bats, not the horror-film kind.

Vampire bats are small tropical mammals that feed on the blood of large mammals such as cattle. The bat lands on a sleeping victim and uses its sharp incisor teeth to nick a blood vessel close to the skin surface. The bat laps up the blood that wells out. Blood contains nutritious protein, but it is mostly water.

Feeding may be cut short by the victim waking up, so the bat needs to quickly consume as much as it can. To maximize

its protein intake and keep its weight low enough to fly, it rapidly eliminates the water from its meal. Within minutes of starting to feed, the bat is producing copious dilute urine. The warm trickle down the neck of the victim is not blood!

Between meals, the bat must conserve water. Metabolizing protein produces nitrogenous wastes that have to be excreted even though water may be scarce. Within a short time, the excretory system of the bat switches from producing abundant, dilute urine to producing a tiny amount of concentrated urine. Rapidly, the bat cycles from an excretory physiology typical of a mammal such as a beaver to that of a desert rodent.

The feeding behavior of this Common Vampire Bat (*Desmodus rotundus*) poses extreme challenges for the animal's excretory system.

KEY CONCEPTS

- 40.1** Excretory Systems Maintain Homeostasis of the Extracellular Fluid
- 40.2** Excretory Systems Eliminate Nitrogenous Wastes
- 40.3** Excretory Systems Produce Urine by Filtration, Reabsorption, and Secretion
- 40.4** The Mammalian Kidney Produces Concentrated Urine
- 40.5** The Kidney Is Regulated to Maintain Blood Pressure, Blood Volume, and Blood Composition

How do excretory systems of animals maintain homeostasis of the interstitial fluid in the face of extreme challenges?

concept 40.1 Excretory Systems Maintain Homeostasis of the Extracellular Fluid

The concentration of solutes in extracellular fluid determines the water balance of the cells and thus influences the health and functions of all the organs of the body. In most marine vertebrates and in all freshwater and terrestrial animals, the composition of the extracellular fluid differs considerably from the external environment. These animals must depend on **excretory systems** to maintain the volume, concentration, and composition of their extracellular fluid.

Excretory systems have four basic functions:

- Regulating the volume of fluid in the body
- Regulating the overall solute concentration—the *osmolarity*—of the extracellular fluid within a narrow range
- Maintaining individual solutes such as Ca^{2+} , H^+ , Na^+ , and glucose at appropriate concentrations
- Eliminating the toxic *nitrogenous wastes* produced by protein and nucleic acid catabolism

The excreted water, solutes, and nitrogenous wastes form the liquid waste product called **urine**.

Excretory systems maintain osmotic equilibrium

The **osmolarity** of a solution is the number of osmoles of solute particles per liter of solvent. For example, seawater has an osmolarity of about 1 mole of solute particles, or 1 *osmole*, per liter of water (1 osm/L). In vertebrates, the extracellular fluid has a much lower osmolarity of about 0.3 moles of solute particles per liter of water, or 300 *milliosmoles* per liter (300 mosm/L).

Why is it so important to regulate the osmolarity of the extracellular fluid? Any difference in osmolarity between the extracellular fluid and the intracellular fluid could cause dangerous changes in cell volume. If the osmolarity of the extracellular fluid is less than that of the cytoplasm, water moves into the cells via *osmosis*, causing them to swell and possibly burst (see Figure 5.3). If the osmolarity of the extracellular fluid is greater than that of the cytoplasm, the cells lose water, shrink, and can ultimately die.

Note that osmolarity can be different from the *molarity* of a solution because some molecules dissociate in solution into more than one particle. Thus a 1 molar solution of glucose is also a 1 osmolar (1 osmole per liter) solution, but a 1 molar solution of sodium chloride (NaCl) is a 2 osmolar solution, because each NaCl molecule dissociates into two ions, Na^+ and Cl^- .

Animals can be osmoconformers or osmoregulators

Animals that live in terrestrial, freshwater, or marine environments face different osmolarity problems. On land, both salts and water are usually scarce and must be conserved, so terrestrial animals are **osmoregulators**; they actively regulate the osmolarity of their extracellular fluid.

In fresh water, water is plentiful but salts are scarce, so freshwater animals have to conserve salts and excrete the water

that continuously invades their bodies through osmosis. So freshwater animals also are osmoregulators.

Seawater, however, has abundant salts. Most marine invertebrates simply allow their extracellular fluid to equilibrate with seawater and are therefore called **osmoconformers**. But most marine vertebrates (except sharks and rays) are osmoregulators that maintain extracellular fluid osmolarities much lower than seawater.

Even animals that can osmoconform over a wide range of osmolarities must osmoregulate in extreme environments. *Artemia* brine shrimp, for example are found in huge numbers in the saltiest environments known, such as Utah's Great Salt Lake (**FIGURE 40.1**). They can survive in fluid with an osmolarity of an astonishing 2,500 mosm/L. In these extremely salty environments, *Artemia* actively transport Na^+ (with Cl^- following) from their extracellular fluid across their gill membranes to the environment. *Artemia* can also survive in dilute seawater (though not in pure fresh water) by reversing the direction of transport of ions across their gill membranes. Because of their excellent control of sodium transport across the gills, *Artemia* can live in environments of almost any osmolarity.

Animals can be ionic conformers or ionic regulators

Even if the extracellular fluid is at a proper osmolarity, the concentrations of certain ions may still need to be adjusted. Most animals are thus *ionic regulators*, regulating the ionic composition of their extracellular fluid. Even many osmoconformers are ionic regulators—although they may not regulate overall

FIGURE 40.1 Osmoconformity Has Limits *Artemia* brine shrimp are osmoconformers over a wide range of salinities. In extremely low- or high-salt environments, however, the shrimp osmoregulate by actively transporting ions across their gill membranes—in either direction, depending on the situation.

osmolarity, they usually do regulate the concentrations of certain ions. Some osmoconformers, however, are *ionic conformers*, allowing the ionic composition, as well as the osmolarity, of their extracellular fluid to match that of the environment.

Some commonly regulated ions are Na^+ , Cl^- , K^+ , Ca^{2+} , H^+ , HCO_3^- (bicarbonate), and several others. Many of these ions are critical for cellular transport, cellular signaling, or protein function. For example, H^+ concentration (i.e., pH) is usually closely regulated because pH changes can drastically influence the structure and function of proteins.

LINK For information on the effects of pH on protein structure, see Concept 3.4

One way to minimize pH changes in a solution is to add a *buffer*—a substance that can either absorb or release hydrogen ions. In mammals, the major buffer in the blood is bicarbonate ions (HCO_3^- ; see Figure 37.13). HCO_3^- is indirectly formed from CO_2 , as follows:

From this equation, you can see that if excess hydrogen ions are added to this reaction mixture, the reaction will move to the left as bicarbonate absorbs the excess H^+ ions. If hydrogen ions are removed from the reaction mixture, however, the reaction will move to the right and supply more H^+ . The HCO_3^- buffer system is important for controlling pH, because the reaction can be pushed to the right or the left physiologically: vertebrate lungs can eliminate CO_2 from the blood, and vertebrate kidneys can reabsorb HCO_3^- from the urine and excrete H^+ into the urine.

LINK Blood pH is an important input in the control of respiratory rate and thus the elimination of CO_2 ; see Concept 37.4

In mammals, for example, kidney tubule cells reabsorb bicarbonate ions by transporting H^+ into the urine in exchange for Na^+ . The H^+ combines with HCO_3^- in the urine, producing H_2CO_3 , which disassociates into H_2O and CO_2 . The CO_2 diffuses into the tubule cell, where the enzyme carbonic anhydrase catalyzes the combination of CO_2 with water to produce HCO_3^- , which is transported into the interstitial fluid and thence to the blood, and a H^+ ion that is transported into the urine; thus leading to the excretion of acid.

Do You Understand Concept 40.1?

- Would you expect a freshwater snail to be an osmoconformer or an osmoregulator? Explain.
- Salmon hatch in fresh water and migrate to the ocean where they spend several years before returning to the spawning grounds where they hatched. Describe the osmotic challenges salmon have to solve during their lifetimes.
- When a person first climbs to high altitude, he or she will hyperventilate (breathe rapidly) because of the low oxygen content of the air. This causes blood pH to rise, often causing headache and nausea. These symptoms resolve in a week or two, because of an adjustment made by the kidney. First, explain why hyperventilation causes blood pH to rise (you may find it helpful to review Concepts 37.4 and 37.5); then develop a hypothesis about what the kidney is doing to correct the pH problem.

In addition to maintaining salt and water balance and regulating ion concentrations, excretory systems must also eliminate the waste products of metabolism. The major problem is nitrogen.

APPLY THE CONCEPT

Excretory systems maintain homeostasis of the extracellular fluid

One way the mammalian kidney excretes hydrogen ions and buffers the blood with HCO_3^- is to secrete ammonia (NH_3) into the tubular fluid. It was thought that this occurred by simple diffusion until a protein called Rhcg, a member of the Rh blood antigen family, was discovered to play a role. Mice in which the gene for this protein was knocked out had difficulty dealing with NH_4Cl (a mild acid) in their drinking water. NH_4Cl was administered for 6 days to wild-type and knockout mice, and the effects on blood pH, NH_4^+ in the urine, and HCO_3^- in the blood plasma were recorded (see table).

1. What is the effect of ingestion of NH_4Cl on wild-type mice, and how do the knockout mice differ?

DAY	BLOOD pH		NH_4^+ IN URINE ($\mu\text{MOL/DAY}$)		HCO_3^- IN BLOOD PLASMA (mM)	
	WILD TYPE	KNOCKOUT	WILD TYPE	KNOCKOUT	WILD TYPE	KNOCKOUT
0	7.28	7.31	20	15	18.0	17.9
2	7.12	7.14	265	145	12.3	12.1
6	7.25	7.13	225	145	16.5	11.0

2. What is the evidence that the response to ingestion of NH_4Cl is the excretion of NH_3 from the renal tubules? Are the knockout mice impaired in this regard?
3. What is the relationship between the excretion of NH_4^+ and blood buffering mechanisms (see Figure 37.13)?

concept 40.2 Excretory Systems Eliminate Nitrogenous Wastes

The end products of the catabolism of carbohydrates and fats are water and carbon dioxide, which are not difficult to eliminate. Proteins and nucleic acids, however, contain nitrogen, so their catabolism produces not only water and carbon dioxide, but also **nitrogenous wastes**, which can be toxic and must be excreted from the body.

Animals excrete nitrogen in a number of forms

The most common nitrogenous waste is **ammonia** (NH_3). Because it is highly toxic, ammonia must be either excreted continuously to prevent its accumulation, or detoxified by conversion into **urea** or **uric acid** (FIGURE 40.2).

AMMONIA Ammonia is highly soluble in water and diffuses rapidly, so its excretion is relatively simple for many water-breathing animals; they continuously lose ammonia from their blood to the environment by diffusion across their gill membranes. Animals that excrete ammonia, such as aquatic invertebrates and bony fishes, are **ammonotelic**.

UREA **Ureotelic** animals, such as mammals, most amphibians, and cartilaginous fishes (sharks and rays), excrete urea as their principal nitrogenous waste product. Urea is quite soluble in water, but its excretion still requires a large loss of water that many animals can ill afford. As we will see later in this chapter, excretory systems that conserve water have evolved in mammals. A different strategy has evolved in sharks and

rays, which can tolerate unusually high concentrations of urea in their body tissues.

URIC ACID **Uricotelic** animals, which include insects, some amphibians, and reptiles (including birds), excrete uric acid. Uric acid is not very soluble in water, so it forms a colloidal suspension in the urine and is excreted as a semisolid, such as the whitish paste in bird droppings. A uricotelic animal loses very little water in excreting its nitrogenous wastes because precipitated uric acid does not exert an osmotic force in the urine, allowing water to be reabsorbed.

Most species produce more than one nitrogenous waste

Most species produce primarily one nitrogenous waste but also produce small amounts of the others. For example, humans are ureotelic, but we also excrete some uric acid, largely from the metabolism of nucleic acids and caffeine. If uric acid levels in the extracellular fluids rise too high, uric acid crystals can precipitate in joints, causing the age-old malady called gout. As we saw earlier, mammals can also excrete ammonia, which is one of our mechanisms for regulating pH of the extracellular fluid (see Apply the Concept on the opposite page).

Species that live in different habitats at different developmental stages may use more than one mechanism of nitrogen excretion. The tadpoles of frogs and toads, for example, excrete ammonia across their gill membranes, but adult frogs and toads generally excrete urea.

Do You Understand Concept 40.2?

- Name the three major nitrogenous wastes. Which one is the most toxic?
- Some desert-dwelling amphibians excrete uric acid as adults, instead of urea as other adult amphibians do. What selective advantage would this adaptation have had for the early ancestors of these desert species?
- Urea excretion generally rises after a period of heavy physical exercise. Why?

Whichever nitrogenous waste an animal excretes, and whatever osmotic challenge it might be facing in its environment, all excretory systems use the same basic processes to produce urine: filtration, reabsorption, and secretion.

FIGURE 40.2 Waste Products of Metabolism The metabolism of proteins and nucleic acids produces nitrogenous wastes. Many aquatic animals, including most fishes, excrete nitrogenous wastes as ammonia, which is highly diffusible and soluble in an aqueous environment. Most terrestrial animals and some aquatic animals excrete either urea or uric acid.

concept 40.3 Excretory Systems Produce Urine by Filtration, Reabsorption, and Secretion

Most animal excretory systems produce urine by first *filtering* the extracellular fluid into some sort of cavity or tubule. In animals with a closed circulatory system, blood pressure drives the filtration of blood through the capillary walls and into the excretory tubule. The resulting fluid, called a *filtrate*, is initially similar in composition to the blood plasma, except that it contains no cells and few large molecules. As the filtrate flows through the tubules, its composition and concentration are modified by *reabsorption* of any valuable solutes that need to be retained (such as glucose) and by *secretion* of certain solutes that the body tries to excrete (such as some drugs, e.g., penicillin). This modified filtrate becomes the urine that leaves the body.

The processing of the filtrate into urine involves movement of water into and out of the tubules. However, recall that there is no mechanism for active transport of water. Instead, water must be moved either by a pressure difference (as in filtration) or by a difference in osmolarity (via osmosis). Water always flows down a pressure gradient or up a solute concentration gradient.

In this concept we will explore how filtration (driven by hydrostatic pressure) and osmosis are used in three different excretory systems: the *metanephridia* of annelids, the *Malpighian tubules* of insects, and the *kidneys* of vertebrates.

The metanephridia of annelids process coelomic fluid

Annelids, such as the earthworm, are segmented worms. In each segment they have a fluid-filled body cavity called a *coelom* (see Figure 23.3). Annelids have a closed circulatory system through which blood is pumped under pressure. The pressure causes the blood to be filtered across the thin, permeable capillary walls into the coelom. Some waste products, such as ammonia, diffuse directly from the tissues into the coelom. Where does this coelomic fluid go?

Each segment of the earthworm contains a pair of **metanephridia** (singular *metanephridium*; Greek *meta*, “akin to,” and *nephros*, “kidney”).

FIGURE 40.3 Metanephridia in Earthworms

The metanephridia of annelids are arranged segmentally. Coelomic fluid enters the nephrostome and flows through tubules leading to the nephridiopore. A close association of the tubules and blood capillaries facilitates the active exchange of substances between the blood and the tubular fluid.

Each metanephridium begins as a ciliated, funnel-like opening called a *nephrostome* in one segment, continues as a tubule in the next segment, and ends in a pore called a *nephridiopore* that opens to the outside of the animal (FIGURE 40.3). Coelomic fluid is swept into the metanephridia through the ciliated nephrostomes. As the fluid passes through the tubules, the tubule cells actively reabsorb certain molecules and actively secrete others. Eventually a dilute urine containing nitrogenous wastes and other solutes leaves the nephridiopores.

The Malpighian tubules of insects depend on active transport

The insect excretory system consists of **Malpighian tubules**. An individual insect has from 2 to more than 100 of these blind-ended tubules that open into the gut between the midgut and hindgut (FIGURE 40.4). Insects have an open circulatory system and therefore cannot use a pressure difference to filter extracellular fluids into the Malpighian tubules. Instead, the cells of the tubules actively transport uric acid, potassium ions, and sodium ions from the extracellular fluid into the tubules. The high concentration of solutes in the tubules causes water to follow osmotically, which flushes the tubule contents toward the gut. However, the water must then be recovered. Epithelial cells of the hindgut and rectum actively transport sodium and potassium ions from the gut back into the extracellular fluid, creating an osmotic gradient that pulls water out of the rectal contents. The final waste product is a semisolid mixture of uric acid mixed with other wastes. The Malpighian tubule system is highly effective at excreting nitrogenous wastes and some salts without losing much water. As a result, insects can live in the driest habitats on Earth.

Annelid Metanephridia

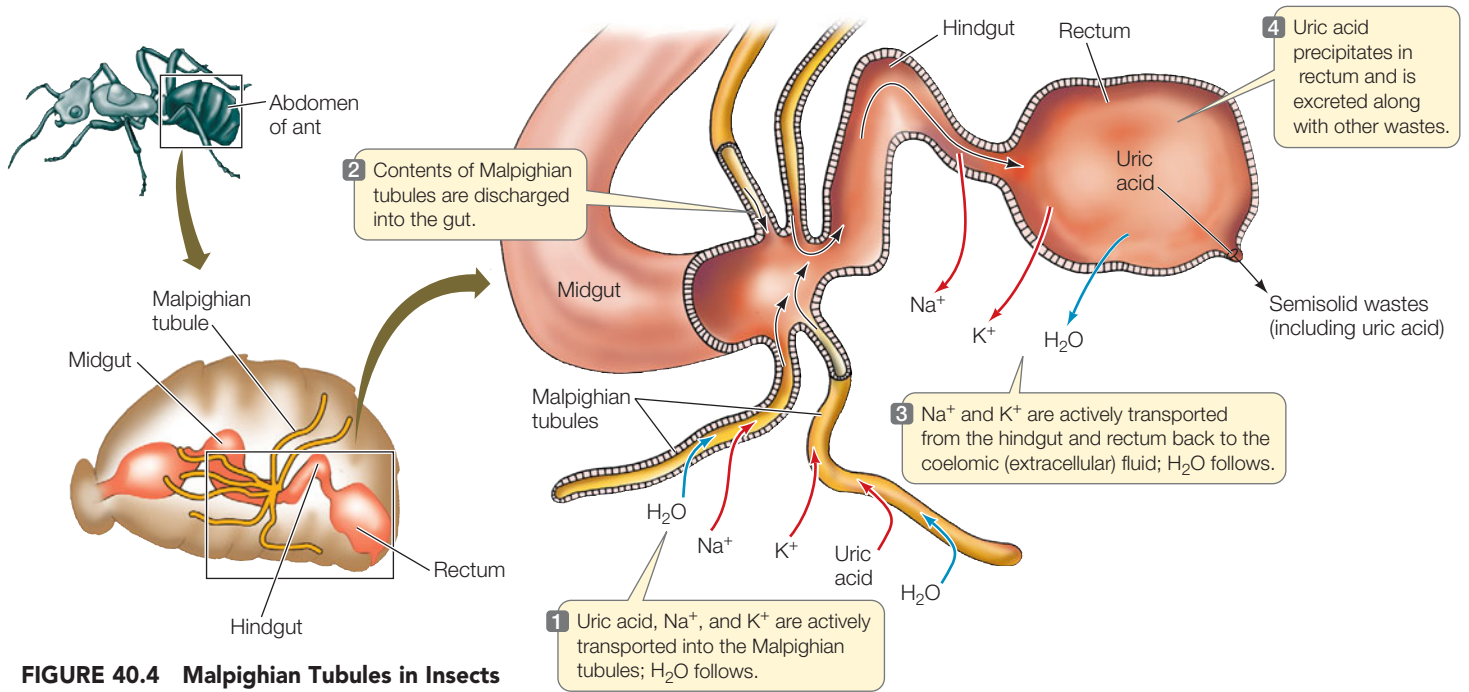

FIGURE 40.4 Malpighian Tubules in Insects
The blind, thin-walled Malpighian tubules are attached to the junction of the insect’s midgut and hindgut and project into the spaces containing extracellular fluid. This system makes it possible to excrete wastes with very little loss of water.

The vertebrate kidney is adapted for excretion of excess water

The main excretory organ of vertebrates is the **kidney**, and the functional unit of the kidney is the **nephron**. A nephron consists of a **renal tubule** and its surrounding blood vessels (FIGURE 40.5). Nephrons can filter large volumes of blood and can reabsorb large amounts of salts and glucose, making the vertebrate kidney well adapted for the excretion of excess water. Each human kidney has about 1 million nephrons.

A nephron begins with a ball-shaped structure called **Bowman’s capsule** that encloses a dense ball of capillaries called a **glomerulus** (plural *glomeruli*; FIGURE 40.6). The glomerulus sits within Bowman’s capsule much like a fist pushed into an inflated balloon. Blood enters the glomerulus via an *afferent arteriole* and leaves via an *efferent arteriole*. The glomerulus is highly permeable to water, ions, and small molecules but impermeable to cells and large molecules such as proteins.

Filtration takes place as blood pressure drives water and small solutes through *fenestrations* of the glomerular

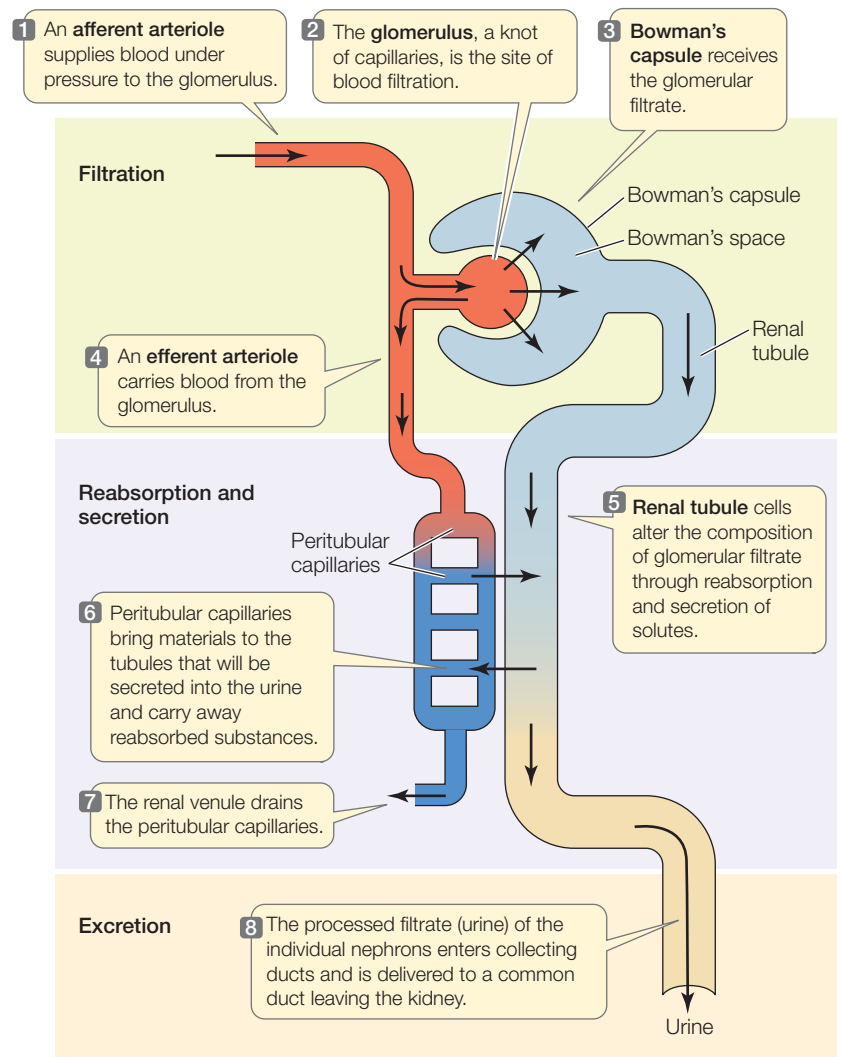

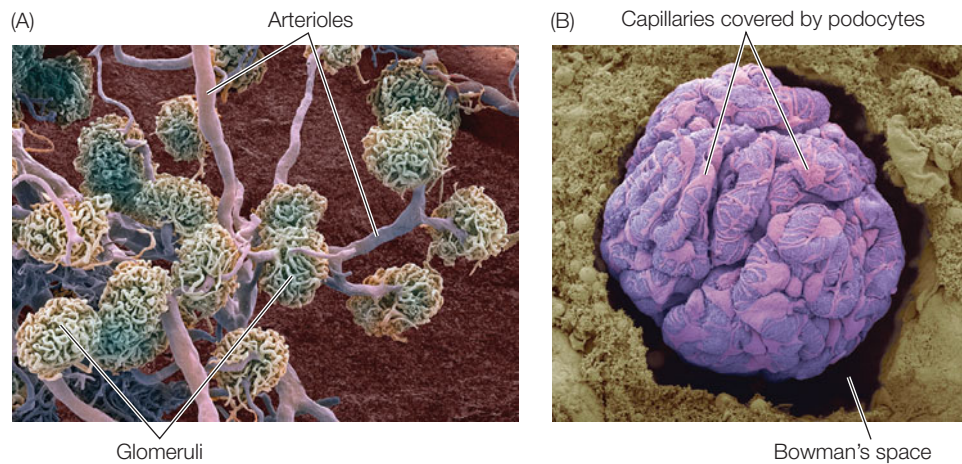

FIGURE 40.5 The Vertebrate Nephron The vertebrate nephron consists of a renal tubule closely associated with two capillary beds, the glomerulus and the peritubular capillaries.

FIGURE 40.6 A Tour of the Nephron Scanning electron micrographs illustrate the anatomical basis for blood filtration by the kidneys. (A) In a preparation showing only the blood vessels (tubular tissue has been digested away), the glomeruli appear as balls of capillaries served by arterioles. (B) This image of an intact glomerulus shows how it fits within Bowman's capsule.

capillaries (see Concept 38.5), through the basal lamina under the capillary cells, through slits between the cells of Bowman's capsule, and into the capsule's lumen (Bowman's space). *Filtration slits* in Bowman's capsule are formed by *podocytes*, specialized cells with numerous fingerlike projections that wrap around the glomerular capillaries. The rate at which the filtered fluid flows into Bowman's capsule is called the **glomerular filtration rate (GFR)**.

The filtrate that enters Bowman's capsule is similar to the blood plasma except that it lacks blood cells and large molecules. The composition of this fluid is then adjusted by reabsorption and secretion as it passes along the renal tubule. Cells of the tubule actively reabsorb certain molecules, such as glucose, amino acids, and most Na^+ and Cl^- , returning them to the capillaries surrounding the tubules—the *peritubular capillaries*. Other substances are actively secreted into the tubule fluid. An example is para-aminohippuric acid (PAH), which is produced in the liver from benzoic acid, a common food preservative.

Mechanisms to conserve water have evolved in several groups of vertebrates

Vertebrates probably evolved in fresh water, so it makes sense that they have an excretory system that can filter the blood, reabsorb essential molecules, and excrete a dilute urine to get rid of excess water. How, then, have modern vertebrates adapted to environments where water must be conserved and salts excreted? The answer to this question differs among vertebrate groups.

MARINE BONY FISHES Marine bony fishes maintain an osmolarity of one-third to one-half the osmolarity of seawater, which is around 1,000 mosm. Their only source of water is the sea around them, so they must conserve water and excrete excess solutes. Because marine bony fishes cannot produce urine that is more concentrated than their extracellular fluids (unlike mammals; see Concept 40.4), they minimize water loss by producing very little urine. How, then, do they get rid of the excess salts that they ingest with food? First, marine bony fishes do

APPLY THE CONCEPT

Excretory systems produce urine by filtration, reabsorption, and secretion

Kidney function can be quantitatively characterized by comparing concentrations of substances in the blood and in the urine, and by knowing the rate of urine production. The glomerular filtration rate (GFR)—the volume of fluid that passes into the kidney's Bowman's capsules per unit time—can be calculated by using a marker substance (such as the polyfructose inulin) that is filtered out of the blood, but not reabsorbed or secreted by the renal tubules. Thus the amount of the marker substance entering Bowman's capsules equals the amount leaving the body in the urine. If a different substance is secreted or reabsorbed by the renal tubules, the amount of that substance leaving the body in the urine will be either more than or less than the amount filtered. Remembering that the amount of a substance in a solution is equal to its concentration times the volume, consider the data in the table. The urine flow rate (V) is 1 ml/min.

SUBSTANCE	CONCENTRATION IN BLOOD	CONCENTRATION IN URINE
Inulin	1 mg/ml	125 mg/ml
Para-aminohippuric acid (PAH)	0.01 mg/ml	5.85 mg/ml
Na^+	140 mosm/L	70 mosm/L

1. What is the glomerular filtration rate (in ml/min)?
2. Is PAH secreted or reabsorbed, and at what rate (in mg/min)?
3. Is Na^+ secreted or reabsorbed, and at what rate (in mosm/min)?

not absorb from their guts some of the ions they ingest, especially divalent ions such as Mg^{2+} or SO_4^{2-} that are excreted in the feces. Second, bony fishes have an additional excretory organ besides the kidney: the gills. Na^+ is actively excreted across the gill membranes, with Cl^- following. As mentioned earlier, bony fishes can also lose their nitrogenous waste, ammonia, by diffusion across their gill membranes.

CARTILAGINOUS FISHES The cartilaginous fishes (sharks and rays) use a different strategy. They are osmoconformers but not ionic conformers. They convert nitrogenous wastes to urea and trimethylamine oxide, which they retain in large amounts in their body fluids. These species have adapted to a concentration of urea in the body fluids that would be toxic to other vertebrates. As a result, their body fluids have an osmolarity close to that of seawater, so they do not lose body water to the environment by osmosis. Excess $NaCl$ is eliminated by a rectal gland that actively secretes Na^+ (with Cl^- following) into the feces.

AMPHIBIANS Most amphibians live in fresh water or in humid environments. Like freshwater fishes, they produce large amounts of dilute urine and conserve salts. But a few amphibians have adaptations that allow them to live in dry habitats. For example, some of these amphibians have waxy substances in their skin that reduce evaporative water loss. Some frogs burrow into the ground during dry seasons, entering a state of low metabolic activity called **estivation**. These frogs have an enormous urinary bladder that they fill with dilute urine just before digging their burrows. This serves as a reservoir of water that is gradually reabsorbed into the blood during the long period of estivation.

REPTILES Many reptiles, including birds, have successfully adapted to extremely hot, dry habitats. In fact, snakes, lizards, and birds are among the most prominent members of many desert faunas. Three major adaptations have freed reptiles from a close association with water. First, reptiles are *amniotes* and do not need fresh water to reproduce; they use internal fertilization and lay eggs with shells that retard evaporative water loss. Second, they have a dry epidermis (skin) that also minimizes evaporative water loss. Third, they excrete nitrogenous wastes as uric acid semisolids, losing little water in the process.

LINK See Concept 23.6 for more on the adaptations that allowed amniotes to colonize dry environments

MAMMALS Mammals, like reptiles, are amniotes that do not need to deposit their eggs in external bodies of water. They also lose little water across the skin unless they are heat stressed and need to employ evaporative cooling. However, mammals excrete urea instead of uric acid, and since urea must be flushed out of the kidney with water, mammals tend to lose large amounts of water in their urine. As a result, the most challenging environments for mammals are those in which water is severely limited. A kidney has evolved in mammals, however, that enables them to produce urine several times more concentrated than their extracellular fluids.

Do You Understand Concept 40.3?

- Name the type of excretory system found in a fish, an earthworm, and a grasshopper. In each one, what is the site where extracellular fluid enters the excretory system?
- Comparing the three excretory systems that you named above, which one empties into the gut? Which filters extracellular fluid into the coelom? Which contains nephrons?
- You compare the kidneys of a marine and a freshwater bony fish species and discover that there is a huge difference in the numbers of nephrons in their kidneys. How would you explain this finding?

A variety of unique adaptations to conserve water have evolved in animals in terrestrial and saltwater habitats. In the next concept we will take a closer look at one of these adaptations: the ability of the mammalian kidney to produce urine that is more concentrated than extracellular fluids.

concept 40.4 The Mammalian Kidney Produces Concentrated Urine

Like other vertebrates, mammals have kidneys consisting of nephrons where the extracellular fluid is filtered into Bowman's capsules, followed by tubular reabsorption and secretion to form urine. However, mammals (and also birds) have an additional refinement: a long loop in the nephron called the **loop of Henle** that dips into the interior region of the kidney. Ions are transported in and out of this loop in such a way that a high-osmolarity region is created at the base of the loop. This high-osmolarity region allows water to be reabsorbed from the urine.

To understand this process, we first need to learn about the anatomy of the mammalian kidney and how the kidney transports ions. We will use the human kidney as an example.

A mammalian kidney has a cortex and a medulla

Humans (and all mammals) have two kidneys behind the abdominal cavity (**FIGURE 40.7A**). Each kidney filters blood, processes the filtrate into urine, and releases that urine into a duct called the **ureter**. The ureter of each kidney leads to the **urinary bladder**, where the urine is stored until it is excreted through the **urethra**, a short tube that opens to the outside of the body.

A kidney is shaped like a kidney bean (**FIGURE 40.7B**), with the ureter, a **renal artery**, and a **renal vein** entering or leaving on its concave side. If you slice a kidney open, you will see that it has two distinctly different regions: a granular outer **cortex** covering an interior **medulla** with a very different appearance. All of the glomeruli and Bowman's capsules are in the cortex. Leaving Bowman's capsule, the renal tubule is called the **proximal convoluted tubule**—"proximal" because it is closest to the

FIGURE 40.7 The Human Excretory System (A) The human kidneys lie behind the abdominal cavity, in the region of the middle back. (B) Certain parts of the nephrons are in the organ's outer region, called the cortex; other parts are in the internal region, called the medulla. (C) The glomeruli and the proximal and distal convoluted tubules are located in the cortex of the kidney. The loops of Henle run in parallel as straight sections down into the renal medulla and back up to the cortex. Collecting ducts run from the cortex to the inner surface of the medulla, where they open into the ureter. The vasa recta are peritubular capillaries that parallel the loops of Henle.

glomerulus, and “convoluted” because it is twisted—is also in the cortex (**FIGURE 40.7C**).

The tubule then straightens, descends directly down into the medulla, makes a hairpin turn, and ascends back to the cortex. This forms the loop of Henle. Some nephrons have loops that descend deep into the medulla; others have shorter loops (see the cortical nephron at the right in Figure 40.7C). The loop of Henle leads to the **distal convoluted tubule** in the cortex (“distal” because it is farther from the glomerulus). The distal convoluted tubules of many nephrons then join together to form a **collecting duct**. There are many collecting ducts, all

yourBioPortal.com
Go to **WEB ACTIVITY 40.3**
The Human Excretory System

of which descend straight down through the medulla, emptying the urine into a funnel-shaped space called a *pelvis*, which drains into the ureter (see Figure 40.7B).

The blood plasma that does not get filtered into Bowman's capsule (about 80%), along with the red blood cells, leaves the glomerulus in the *efferent arteriole* that feeds the peritubular capillaries surrounding the renal tubules. The peritubular capillaries run into the medulla in parallel with the loops of Henle and the collecting ducts, forming a vascular network called the **vasa recta** (see Figure 40.7C). These blood vessels play an important role in secretion and reabsorption and in maintaining the high-osmolarity region created by the loop of Henle.

The Mammalian Kidney and
WORKING WITH DATA 40.1

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule

The kidneys receive an impressive blood flow of about 1,500 liters of blood per day, more than many larger organs receive. This means that the entire blood volume of the body (about 5 liters in an average man) circulates through the kidneys over 300 times a day. Of this large volume, about 12 percent, or 180 liters of plasma per day, moves into Bowman's capsules. However, we only urinate about 2 to 3 liters per day, so the other 178 or so liters—98 percent of the original filtrate volume—must be returned to the blood somewhere along the length of the nephrons. Where and how is this enormous fluid volume reabsorbed?

The proximal convoluted tubule (PCT) is responsible for about 75 percent of the reabsorption. The cells of the PCT actively transport Na^+ (with Cl^- following), glucose, and amino acids out of the tubule and into the interstitial fluid. Water

follows osmotically. The water and solutes are then taken up by the peritubular capillaries.

The PCT changes the solute composition of the tubule fluid and reduces its volume but does not change its osmolarity; the fluid leaving the PCT still has the same osmolarity as the blood plasma. If urine were excreted at this concentration, it would result in a large loss of water, which most terrestrial vertebrates can ill afford. The next steps in urine processing in mammalian kidneys are (1) to reabsorb salts, leaving urea as the major solute in the urine, and (2) to set up the conditions that enable the production of a hypertonic urine.

The loops of Henle create a concentration gradient in the renal medulla

The concentrating ability of the mammalian kidney arises from a **countercurrent multiplier** mechanism made possible by the anatomical arrangement of the loops of Henle (FIGURE 40.8).

The term “countercurrent” refers to the opposing directions of flow of the two limbs of a loop of Henle. The term “multiplier” refers to the ability of this system to create a solute concentration gradient.

LINK Countercurrent mechanisms also contribute to the efficiency of gas exchange in fish gills; see Figure 37.3

The loops of Henle do not concentrate the urine that is passing through them; rather, they increase the osmolarity of the extracellular fluid in the medulla. In humans, for example, near the top of the medulla, next to the cortex, the extracellular fluid is about 300 mosm/L (the same as blood plasma). But deeper in the medulla, the extracellular fluid becomes more and more concentrated. At the hairpin turn of the loop of Henle, the osmolarity of the extracellular fluid is 1,200 mosm/L—*four times* more concentrated than the blood plasma. How do the loops generate this large concentration gradient running from the cortex to the bottom of the medulla?

The loop of Henle has three regions: the *thin descending limb*, the *thin ascending limb*, and the *thick ascending limb*, each of which differs in its permeability to water and its ability to transport NaCl. Most critical are the actions of the cells of the thick ascending limb that actively transport Na^+ and Cl^- from the tubule fluid to the interstitial fluid (see Figure 40.8, note 1). The thick ascending limb is relatively impermeable to water, so the reabsorption of Na^+ and Cl^- from the tubular fluid raises the concentration of those solutes in the surrounding interstitial fluid and decreases the concentration of the tubular fluid as it flows through the thick ascending limb and into the distal convoluted tubule.

The thin descending limb is permeable to water and to Na^+ and Cl^- . Since the local interstitial fluid has been made more concentrated by the actions of the thick ascending limb, water is drawn out from the thin descending limb by osmosis. Thus, the fluid flowing in the thin descending limb becomes more concentrated than the blood plasma and the filtrate that left the proximal convoluted tubule (see Figure 40.8, note 2).

An important change in the tubule cells occurs at the hairpin bend in the loop of Henle. The ascending limb of Henle is no longer permeable to water. As the fluid in the ascending limb flows toward the cortex, it encounters regions of the medulla where the interstitial fluid is less concentrated. As a result, Na^+ and Cl^- passively leave the tubule and enter the interstitial space. Thus, the overall action of the loop of Henle is to accumulate more and more solute in the lower part of the medulla, creating a concentration gradient.

As the tubule fluid passes through the thick portion of the ascending limb of Henle, more NaCl is removed by active transport. Thus the fluid flowing into the distal convoluted tubule is actually less concentrated than the fluid that entered the loop of Henle (see Figure 40.8, note 3). So the loop of Henle has not concentrated the urine, but it has created a concentration gradient in the interstitial fluid of the medulla. And it has had another important effect: because of the removal of much NaCl from the tubular fluid, the dominant solute in the tubular fluid entering the distal convoluted tubule is urea.

The distal convoluted tubule fine-tunes the composition of the urine

Next, fluid moves from the loop of Henle to the distal convoluted tubule. The urine entering the distal tubule is less concentrated than the surrounding interstitial fluid. If water is not reabsorbed as the urine flows through the distal tubule and the collecting duct, a hypotonic urine is created. But, if the distal tubule and collecting duct are permeable to water, water will be reabsorbed into the extracellular fluid, producing a hypertonic urine.

The distal tubule also fine-tunes the ionic composition of the urine (see Figure 40.8, note 3). For example, if a person is potassium depleted, potassium is reabsorbed in the distal convoluted tubule. But if a person has an excess of potassium, potassium is secreted in the distal convoluted tubule. Other ions also are adjusted in this way. The distal convoluted tubule contains dozens of different types of ion transporters. The fluid that leaves the distal convoluted tubule may be hypotonic or isotonic with the plasma, and its major solute is urea.

Urine is concentrated in the collecting duct

As the tubule fluid in the collecting duct goes down through the medulla, it passes directly through the high-osmolarity area created by the surrounding loops of Henle. Depending on the water permeability of the collecting duct, water may be osmotically drawn from the urine into the interstitial fluid (see Figure 40.8, notes 4 and 5). The urine can be concentrated up to the highest osmolarity that the loops of Henle were able to create in the interstitial fluid—in humans, up to 1,200 mosm/L, but in some desert dwelling rodents, much higher.

As we noted, the urine in the collecting duct has a solute *composition* that is considerably different from that of the blood plasma. The major solute in the tubular fluid is now urea, which is more than a 100 times more concentrated than it was in the glomerular filtrate. As water is withdrawn from the collecting duct, some of the urea is also transported out into the medullary interstitial fluid, adding to its osmotic potential (see Figure 40.8, note 6). This urea diffuses back into the loop of Henle and is returned to the collecting duct. The recycling of urea in the renal medulla contributes significantly to the osmotic concentration gradient in the medulla and assists in concentrating the urine.

Overall, the ability of a mammal to concentrate its urine is determined by the maximum concentration gradient it can establish in its renal medulla, which in turn is determined by the length of the loops of Henle. About 20 to 30 percent of human nephrons have long loops of Henle that go deep into the medulla; these long loops are the ones that enable us to concentrate our urine to four times the concentration of our blood plasma.

Kidney failure is treated with dialysis

Loss of kidney function, or *renal failure*, results in the retention of salts and water (hence high blood pressure), retention of

urea (uremic poisoning), and a decreasing pH (acidosis). A person who suffers complete renal failure will die within 2 weeks if not treated. The best treatment is kidney transplant, but few kidneys are available. So most patients with renal failure must undergo *dialysis* several times a week—cleansing of the blood with a machine referred to as an artificial kidney but that works completely differently than the kidney.

In a dialysis machine, the patient's blood flows through many small tubes made of semipermeable membranes. A dialysis solution flows on the other side of these membranes, through which small molecules can diffuse. Solutes always diffuse from higher concentration to lower concentration, so the composition of the dialysis fluid is crucial. Solutes that need to be conserved must be at the same concentration in the dialysis fluid as they are in the blood, while solutes that need to be removed from the blood must be near zero in the dialysis fluid. The total osmolarity of the dialysis fluid must equal that of the plasma, so that the patient does not lose or gain water.

FRONTIERS Researchers at the University of California in San Francisco, working with collaborators at 10 other institutions, recently built the first prototype implantable artificial kidney that would run off the body's own circulatory system and therefore not require electricity or pumps. The artificial kidney uses nanotechnology to filter the blood; the filtrate then flows over cultured kidney cells that can reabsorb glucose and essential salts before allowing the processed filtrate to leave the body. Nanotechnology has made it possible to shrink the functions of a huge dialysis machine into a very small package, but there is still the challenge to bioengineer the prototype for testing in animals and eventual implantation in humans.

Do You Understand Concept 40.4?

- Explain what is meant by a countercurrent multiplier in the kidney and how it enables the production of a hypertonic urine.
- Many diseases, including high blood pressure and heart failure, result in water accumulation in the body. Drugs called diuretics are frequently used to increase the loss of water in these patients. One drug, bumetanide, decreases the activity of the Na^+ transporters in the thick ascending limb of Henle. How would this drug cause increased water loss?
- Explain the difference in how the kidney excretes metabolic wastes and how that function is carried out by a dialysis machine.

The kidney contributes to homeostasis in many critical ways, such as regulating the water content of the body, as well as the solute concentration and composition of the extracellular fluid. As we will see next, the kidneys also play a major role in regulating blood pressure.

concept 40.5

The Kidney Is Regulated to Maintain Blood Pressure, Blood Volume, and Blood Composition

The ability of the kidneys to filter blood depends on a constant glomerular filtration rate (GFR), which in turn depends on an adequate blood supply to the kidneys at an adequate blood pressure. If blood pressure in the glomeruli falls, several *autoregulatory mechanisms* (i.e., initiated by the kidneys themselves) activate to correct the problem. In addition, several hormones released by other organs also help regulate the kidneys to maintain normal blood pressure, blood volume, and blood composition. We will discuss these mechanisms separately, but keep in mind that they are always working together.

The renin-angiotensin-aldosterone system raises blood pressure

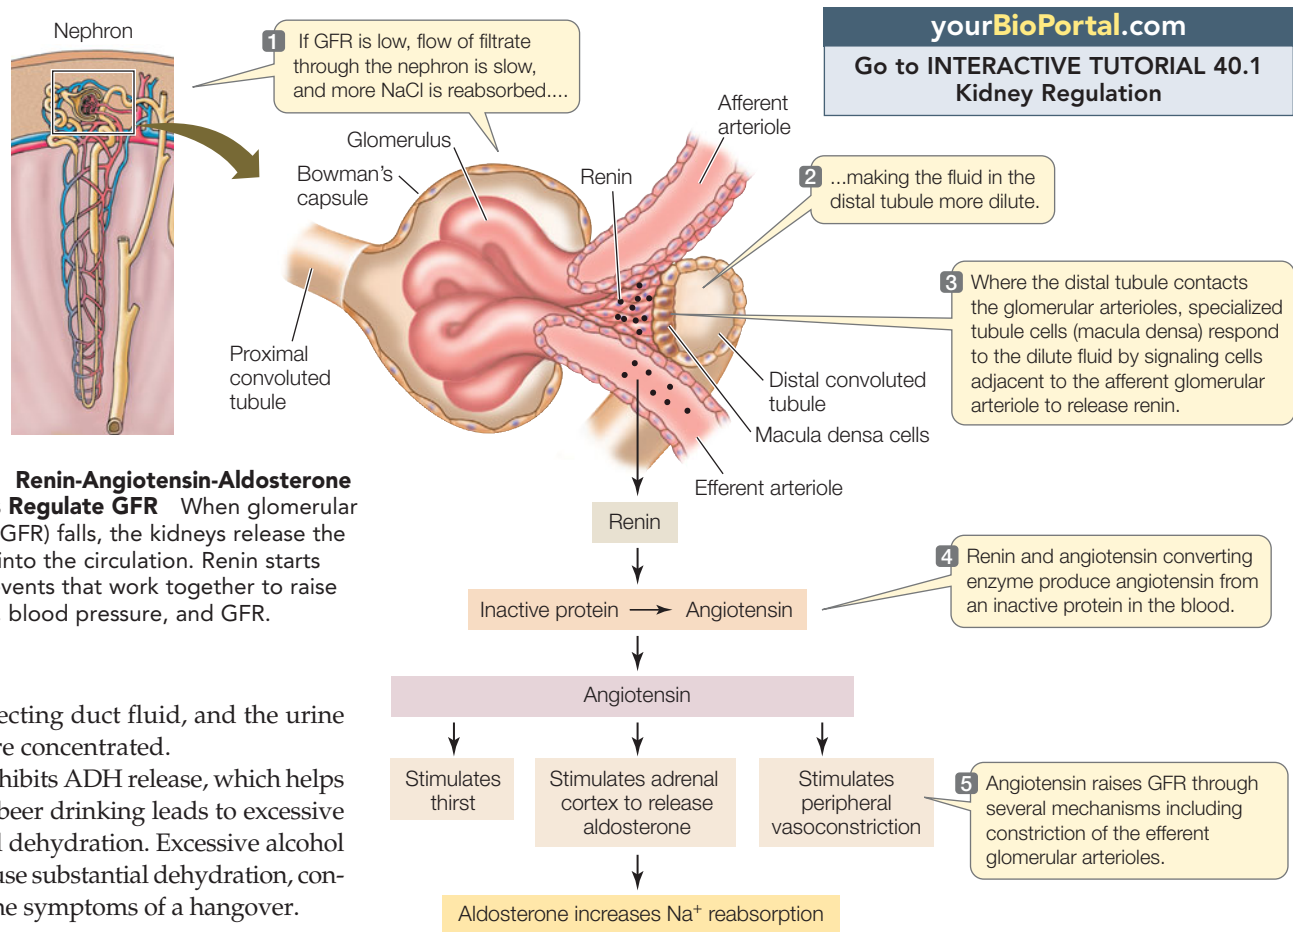

If GFR begins to fall, the first autoregulatory response is dilation (expansion) of the afferent renal arterioles, decreasing resistance and increasing local blood pressure in the glomerulus. But if arteriole dilation does not bring the GFR back to normal, the kidneys release an enzyme, **renin**, into the blood. Renin, along with an enzyme in the lungs called ACE (for *angiotensin converting enzyme*), converts an inactive protein in the blood into the hormone **angiotensin** (FIGURE 40.9), which increases blood pressure by several mechanisms:

- It constricts the efferent renal arterioles, elevating local blood pressure in the glomerular capillaries.
- It constricts peripheral blood vessels all over the body, elevating blood pressure throughout the body.
- It stimulates thirst. Increased water intake then increases blood volume and increases blood pressure.
- It stimulates the adrenal cortex to release the steroid hormone **aldosterone**. Aldosterone stimulates Na^+ reabsorption by the kidneys. Water follows the Na^+ , so more water is reabsorbed, helping maintain blood volume and therefore blood pressure.

Thus the renin-angiotensin-aldosterone system is a powerful regulatory mechanism that raises blood pressure throughout the body, not just in the kidneys (see Figure 38.16).

ADH decreases excretion of water

When serum osmolality rises, hypothalamic osmoreceptors are stimulated to produce, among other responses, thirst. In addition, the release of *antidiuretic hormone* (ADH, also called vasopressin) is triggered by osmoreceptor stimulation. An antidiuretic is any substance that reduces the volume of urine. ADH causes cells of the collecting duct to insert *aquaporins* (water channels; see Concept 5.2, especially Figure 5.5) into their plasma membranes, increasing their permeability to water (FIGURE 40.10). Therefore, more water is reabsorbed

from the collecting duct fluid, and the urine becomes more concentrated.

Alcohol inhibits ADH release, which helps explain why beer drinking leads to excessive urination and dehydration. Excessive alcohol intake can cause substantial dehydration, contributing to the symptoms of a hangover.

The heart produces a hormone that helps lower blood pressure

You may not think of the heart as an endocrine organ, but it is. When there is excess body fluid volume, the heart must contract with greater force, and that puts strain on the heart. Under these conditions, the increased venous return stretches the atria of the heart. This causes atrial cells to release a peptide hormone called **atrial natriuretic peptide (ANP)**. This peptide hormone enters the circulation, and in the kidneys it decreases the reabsorption of Na^+ . If less Na^+ is reabsorbed, less water is reabsorbed, and a more voluminous and dilute urine is produced. Thus ANP has the effect of lowering blood volume and therefore blood pressure.

Do You Understand Concept 40.5?

- Name four hormones involved in kidney function. Briefly describe the function of each one.
- Angiotensin converting enzyme (ACE) inhibitors are used to treat high blood pressure. By what actions would these drugs have their effect?
- Suppose you sweat a great deal on a hot day, losing both salt and water, so that your blood volume, and hence your blood pressure, decrease sharply without your blood osmolarity changing much. Which hormone levels will change in response to this situation, and why?

How do excretory systems of animals maintain homeostasis of the interstitial fluid in the face of extreme challenges?

ANSWER The active transport of Na^+ plays many roles in excretory systems. The transport of Na^+ , usually with Cl^- following, creates osmotic concentration gradients that move water across the membranes of tubules. In the evolution of the desert rodents, selection exploited the role of NaCl transport in the countercurrent multiplier to the extreme (Concept 40.4). The loops of Henle in these species are so long relative to the size of the kidney that the medulla sticks way out of the kidney and into the ureter and produces a huge concentration gradient. These animals can produce urine with a concentration over 5,000 mosm/L. Crystals appear in the urine as it leaves the body of the animal.

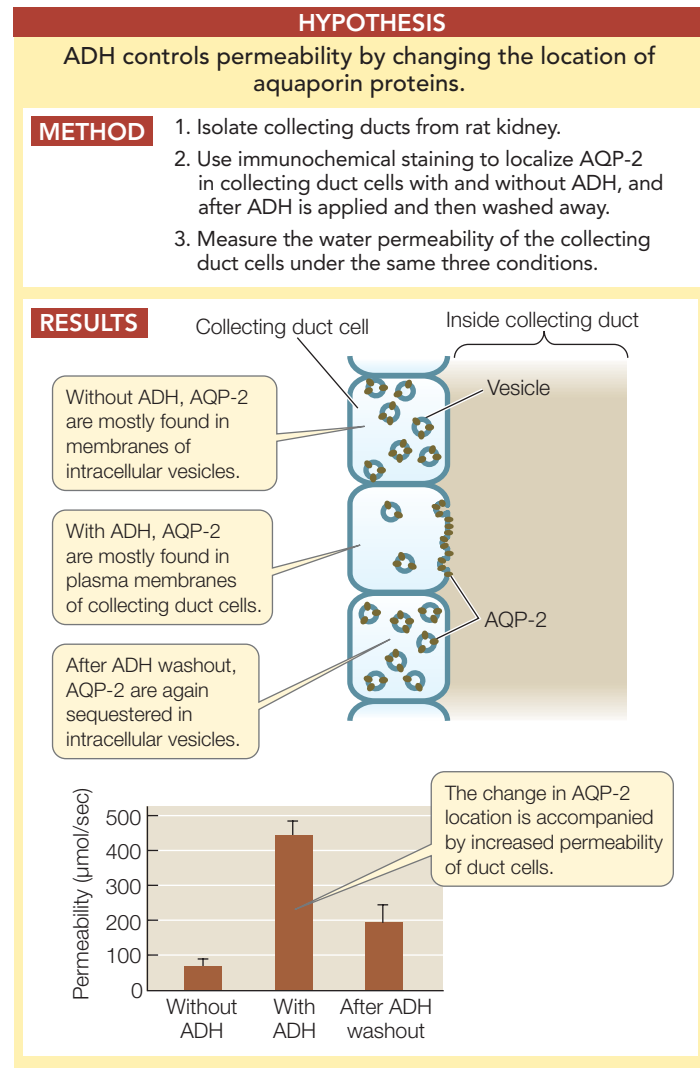

Freshwater animals use the transport ability of their renal tubules to conserve NaCl and to provide secondary active transport to reabsorb other solutes. They have short loops of Henle and produce only dilute urine.

The albatross and many other marine birds that are mostly at sea and take in large amounts of salt with their food have a special salt-secreting organ above the eyes that uses NaCl transporters. These salt glands consist of tubules that take up NaCl from the interstitial fluid (similar to our tear glands). The

INVESTIGATION

FIGURE 40.10 ADH Induces Insertion of Aquaporins into Plasma Membranes Aquaporin proteins make some regions of renal tubules permeable to water. One aquaporin, AQP-2, is

responsible for the permeability of the collecting duct cells. How does antidiuretic hormone (ADH) act on these proteins to control the level of permeability in renal cells?

CONCLUSION

In the absence of ADH, AQP-2 is sequestered intracellularly. When ADH is present, these water channels are inserted into the plasma membranes, making the cells more permeable to water.

ANALYZE THE DATA

The results showed that ADH controls the location of AQP-2 in collecting duct cells, but does it also affect the amount of AQP-2? The Brattleboro strain of rats does not produce ADH, and the DI strain of mice has a defect in the signaling pathway of the ADH receptor. The amount of AQP-2 produced in response to ADH and an ADH receptor antagonist was studied in these animals. Values were normalized to baseline amounts in normal animals.

Treatment	Amount of AQP-2			
	Normal rat	Brattleboro rat	Normal mouse	DI mouse
Baseline	1.0	0.5	1.0	0.1
ADH	1.0	1.5	1.0	0.1
ADH receptor antagonist	0.5	0.5	0.5	0.1

- How does ADH affect the amount of AQP-2 in normal and Brattleboro rats? Explain the difference in the responses of the two rat strains.
- Why does ADH not have an effect on the amount of AQP-2 in DI mice?
- Considering these data as a whole, construct a hypothesis to explain why Brattleboro mice can maintain AQP-2 levels at 50% of normal. How would you test your hypothesis?

SUMMARY

concept 40.1 Excretory Systems Maintain Homeostasis of the Extracellular Fluid

- **Excretory systems** maintain the volume, concentration, and composition of the extracellular fluids and eliminate nitrogenous wastes. **Urine** is the output of excretory systems.
- **Osmolarity** is the overall solute concentration of a fluid. Animals must maintain the osmolarity of their extracellular fluids within an acceptable range.
- Animals can be **osmoconformers** or **osmoregulators**. Terrestrial and freshwater animals must be osmoregulators. Most marine invertebrates are osmoconformers, but most marine vertebrates are osmoregulators. **Review Figure 40.1**
- In addition to regulating the overall osmolarity of the extracellular fluid, most animals also regulate the concentrations of specific ions.
- The mammalian kidney reabsorbs bicarbonate ions from the urine and returns them to the blood, where they act as a pH buffer to absorb excess H^+ ions.

concept 40.2 Excretory Systems Eliminate Nitrogenous Wastes

- Metabolism of proteins and nucleic acids produces toxic **nitrogenous wastes**, which must be eliminated from the body. The most common nitrogenous waste is **ammonia**. **Review Figure 40.2**
- **Ammonotelic** animals produce ammonia as their primary nitrogenous waste. They are typically water-breathing aquatic animals that eliminate ammonia by diffusion across their gill membranes.
- **Ureotelic** animals detoxify ammonia by converting it to **urea** before excretion, and then flush the urea out with water. These animals include mammals, most amphibians, and cartilaginous fishes.
- **Uricotelic** animals convert ammonia to **uric acid**. They include insects, some amphibians, and birds and other reptiles. Uric acid can be excreted without much loss of water.
- Most species produce more than one kind of nitrogenous waste.

concept 40.3 Excretory Systems Produce Urine by Filtration, Reabsorption, and Secretion

- Excretory systems produce urine through the processes of filtration, reabsorption, and secretion.
- Water cannot be actively transported against its concentration gradient, so it must be moved across membranes by a difference in either osmolarity or pressure.
- In annelid worms, blood pressure causes filtration of the blood across capillary walls and into the coelom, where it is taken up by **metanephridia**, which adjust the composition of the filtrate by active transport. **Review Figure 40.3 and WEB ACTIVITY 40.1**
- The **Malpighian tubules** of insects receive ions and nitrogenous wastes by active transport across the tubule cells. Water follows by osmosis. Ions and water are reabsorbed from the hindgut and rectum, so the insect excretes semisolid wastes. **Review Figure 40.4**
- The functional unit of the vertebrate **kidney** is the **nephron**. A nephron consists of a ball of capillaries called a **glomerulus**, from which the blood is filtered, a **renal tubule**, which processes the

filtrate into urine to be excreted, and a system of peritubular capillaries, which surround the tubule and assist with secretion and reabsorption. The vertebrate kidney is adapted for ridding the body of excess water. **Review Figures 40.5 and 40.6 and WEB ACTIVITY 40.2**

- The rate at which the filtrate flows into Bowman's capsule is called the **glomerular filtration rate (GFR)**.
- Several groups of vertebrates have evolved different mechanisms for conserving water. Marine bony fishes produce little urine. Cartilaginous fishes retain urea so that the osmolarity of their body fluids remains close to that of seawater. Most amphibians produce large amounts of dilute urine. Reptiles lose little water in urine because they excrete nitrogenous wastes as uric acid. Mammals must lose some water to flush out urea, but they can produce urine more concentrated than their extracellular fluids.

concept 40.4 The Mammalian Kidney Produces Concentrated Urine

- The glomeruli, Bowman's capsules, and **proximal and distal convoluted tubules** are located in the **cortex** of the kidney. Straight sections of renal tubules called **loops of Henle** and **collecting ducts** are arranged in parallel in the **medulla** of the kidney. **Review Figure 40.7 and WEB ACTIVITY 40.3**
- The proximal convoluted tubule reabsorbs water, NaCl, and certain solutes, reducing the renal filtrate's volume without appreciably changing its osmolarity.
- The loops of Henle create a concentration gradient in the interstitial fluid of the renal medulla by a **countercurrent multiplier** mechanism. Urine flowing down the collecting ducts is concentrated by the osmotic reabsorption of water caused by the concentration gradient in the surrounding interstitial fluid. **Review Figure 40.8, ANIMATED TUTORIAL 40.1, and WORKING WITH DATA 40.1**

concept 40.5 The Kidney Is Regulated to Maintain Blood Pressure, Blood Volume, and Blood Composition

- Kidney function in mammals is controlled by autoregulatory mechanisms that maintain a constant high GFR even if blood pressure varies.
- The kidneys release **renin** if GFR falls. Renin activates **angiotensin**, which causes the constriction of efferent glomerular arterioles and peripheral blood vessels, causes the release of **aldosterone** (which enhances water reabsorption), and stimulates thirst. **Review Figure 40.9 and INTERACTIVE TUTORIAL 40.1**
- A fall in blood pressure or a rise in blood osmolarity increases the release of antidiuretic hormone (ADH) from the posterior pituitary. ADH increases the permeability of the collecting duct to water and therefore increases the reabsorption of water from the urine.
- If the volume of blood returning to the heart increases and stretches the atrial walls, heart cells release **atrial natriuretic peptide (ANP)**. ANP increases excretion of salt and water, reducing blood volume and blood pressure.

See **WEB ACTIVITY 40.4** for a review of the major human organ systems.

Animal Behavior

41

Many behaviors of many species are so stereotypic that they can frequently be used to identify the species. An example is spider webs; different species of spiders spin webs of different designs. Web spinning involves thousands of movements performed in the right sequence, and each time a spider builds a web, the sequence is largely the same, even though it has to accommodate different physical environments. Yet in many species there is no opportunity for a spider to learn how to build a web from another spider because the adults die before their eggs hatch. How do spiders know how to build a complicated and precise web? It has to be programmed into their genome.

Circumstances favoring genetic programming of behavior are easy to understand: (1) there may be no opportunities to learn (no adults to teach offspring), (2) mistakes may be costly, as in predator avoidance (no second chances), and (3) potential mates of the correct species must be identified.

The mating behavior of fruit flies (*Drosophila*) exemplifies all three of these reasons. Flies emerging from pupation in a piece of rotting fruit are ready to mate in about 8 hours. There may be no adult flies around to provide lessons in mating behavior. There may be other species hatching out from that piece of rotting fruit. Making a mistake in selecting a partner can be costly in terms of energy investment (especially for the females) and loss of opportunity (especially for the males, as the availability of virgin females falls rapidly).

Stereotypical, complex courtship rituals guarantee that mating pairs are of the same species. The male fruit fly chases after the female and taps her body with his forelegs. The common female response is to run away, but if she does not, the male will extend one wing and vibrate it to produce a courtship song, and if the female

still does not run away, he will lick her genitals and attempt to copulate.

Mutations of single genes can disrupt the fruit fly courting ritual. The gene *per* (for period) was discovered because it altered the daily rhythms of the flies, but it also altered the frequency of the wing beat and therefore the courtship song. That was enough to cause receptive females to break off courtship. Another gene mutation called *fru* (for fruitless) results in the inability of males to discriminate between males and females. Groups of males with the *fru* mutation form mating circles, with each male trying to mate with the one in front of it. Obviously none has mating success even though their displays are perfect.

In fruit flies and many other species, mating is the culmination of an elaborate, genetically determined series of behaviors.

How can a single gene be responsible for a complex behavior?

KEY CONCEPTS

concept 41.1 Behavior Has Proximate and Ultimate Causes

The study of behavior involves all biology subject areas covered in this book, from the molecular to the ecological and evolutionary. Molecular, cellular, and physiological mechanisms underlie specific behaviors. Behaviors develop, they have genetic determinants, and they evolve in response to selective pressures imposed by the social and physical environment. Scientists have taken different approaches to studying behavior, depending on their orientations: laboratory versus field, genetic determinism versus learning, physiology versus ecology, and so on. In this chapter we will explore several behaviors from these different perspectives.

Biologists ask four questions about a behavior

Niko Tinbergen, a prominent naturalist, ecologist, and animal behavioral biologist in the mid-1900s, proposed that scientists investigate behavior as four questions:

- **Causation:** What is the immediate stimulus for the behavior?
- **Development:** How does the behavior change with age and with learning, and what experiences are necessary for it to be displayed?
- **Function:** How does the behavior affect the animal's chances for survival and reproduction?
- **Evolution:** How does the behavior compare with similar behaviors in related species, and how might it have evolved?

The first two questions refer to the **proximate causes** of behavior: the immediate genetic, physiological, neurological, and developmental mechanisms that determine how an individual is behaving at time scales ranging from milliseconds to the entire life span. The third and fourth questions refer to the **ultimate causes** of behavior: the evolutionary processes that produced the animal's capacity and tendency to behave in particular ways over many generations of natural selection.

Questions about proximate causes lead to mechanistic approaches

Two classical schools of animal behavior focused on proximate causes. One, **behaviorism**, derived from the famous discoveries of the physiologist Ivan Pavlov, who discovered that neural reflexes controlling digestive processes (including salivation) could be modified by experience to respond to an unnatural stimulus rather than the sight or smell of food. This, of course, was the famous conditioned reflex (**FIGURE 41.1**) that became a paradigm for laboratory studies of learning and memory, mostly in rats.

Another classical school of animal behavior, **ethology**, focused on behavior patterns ethologists called "fixed

action patterns." These are not learned, and in fact are resistant to modification by learning. Fixed action patterns are characteristically triggered by very simple stimuli such as color, smell, or sound. Such triggers are called **releasers**. For example, Tinbergen studied the begging behavior of gull chicks. In some species of gulls, adults have a red dot on their bills. When a parent gull returns to the nest to feed its chicks, the chicks peck on the red dot, which stimulates the parent to regurgitate food (**FIGURE 41.2A**). To determine what stimulated chicks to peck their parents' bills, experimenters showed to newly hatched, naïve gull chicks models of gull heads of different shapes and colors (**FIGURE 41.2B**), as well as models of a beak without a head. The results showed that the red dot was necessary for the release of chick pecking behavior. In fact, a pencil with a

FIGURE 41.1 The Conditioned Reflex Ivan Pavlov discovered that when a normal response is paired with an artificial stimulus, an animal learns to produce the response even when only the artificial stimulus is presented.

FIGURE 41.2 Releasing a Fixed Action Pattern

(A) Gull chicks instinctively peck at the red dot on the parent's bill, a behavior that induces the parent to regurgitate food into the chick's mouth. (B) Tinbergen's work showed that the red dot on the parent's bill is the critical component that releases the pecking response.

red eraser elicited a more robust pecking response than did an accurate model of a gull head without a red dot.

Ethologists concluded that fixed action patterns are adaptive in situations where learning is not possible or where mistakes could be costly. But to become genetically programmed, releasers have to be rather simple subsets of information encountered by the animal.

Modern studies of the proximate causes of animal behavior cover a wide range of approaches ranging from molecular genetics to neurophysiology. It is recognized that most behaviors have genetic determinants as well as the capacity to be modified by experience; however, the balance differs for different species and different behaviors.

Questions about ultimate causes lead to ecological/evolutionary approaches

Behavioral ecologists seek answers to why particular behaviors have evolved in a species by trying to understand how those behaviors affect the reproductive fitness of the individuals in the population. To do this, they have to understand the selective pressures placed on the individuals by the environment. Obvious environmental conditions that animals face include availability of food, mates, and good nesting sites, as well as challenges from predators, competitors, and weather. Many behaviors involve making choices: where to build a nest, whom to choose as a mate, when to aggressively defend a territory or a food source, and so on. Experiments frequently involve studying animals under different conditions or manipulating conditions to see how the animals respond.

In the concepts that follow we will see many examples of how the evolution of behaviors is investigated by efforts to understand how the behaviors contribute to the reproductive fitness of the individuals of the population.

Do You Understand Concept 41.1?

- Questions about proximate and ultimate causes of behavior are called how and why questions, respectively. Explain.
- When a male robin is in reproductive condition, it has bright red breast feathers. It aggressively attacks other male robins, but it will also attack a simple tuft of red feathers on a stick. How does this seemingly maladaptive behavior relate to concepts of fixed action patterns and releasers?
- African sunbirds, which are nectar feeders, defend their feeding territories in some habitats but not in others. What selective pressures might have shaped these behavioral choices?

Early work on animal behavior left no doubt that behavior can be genetically determined. But genes code for proteins, and behaviors are highly complex traits involving sensory inputs and intricate patterns of responses. How are genes and behavior connected?

concept 41.2 Behaviors Can Have Genetic Determinants

Behaviors are complex traits. Nevertheless, evidence from multiple approaches shows that alterations in single genes can result in discrete behavioral phenotypes subject to natural selection.

Breeding experiments can reveal genetic determinants of a behavior

Breeding experiments can be used to reveal whether or not a specific behavior has a genetic determinant. If a behavior is variably expressed in a population and follows a Mendelian inheritance pattern (see Concept 8.1), then that trait is likely to be controlled

by a small number of genes. A classic example is the genetics of hive cleaning by honey bees.

A honey bee colony consists of a reproductive queen and a huge number of nonreproductive workers. The worker bees build the honeycomb, and the queen lays eggs in cells of that honeycomb. The workers feed the larvae that hatch from those eggs. When the larvae pupate, the workers cap and seal their cells. If a pupa dies, workers uncap the cell and drag the carcass outside the hive. This *hygienic* behavior decreases the probability of pathogens spreading to other larvae in the hive. *Nonhygienic* hives do not show this behavior and are more susceptible to the spread of the disease.

When a nonhygienic queen bee was crossed with a hygienic male, the offspring (the F_1 generation) were all nonhygienic, indicating that the genetic determinant of nonhygienic behavior is dominant (FIGURE 41.3). (Note that in bees, only females are diploid; the males are haploid and thus have only one copy of each gene instead of two.) When these nonhygienic F_1 females were backcrossed to hygienic males, however, four phenotypes were produced: one hygienic, one nonhygienic, and two intermediates that were very interesting. Workers with one intermediate phenotype opened the cells of dead pupae but did not remove them. Workers with the other intermediate phenotype did not open cells, but if a cell was already open, they would dispose of the dead pupa. Thus it was concluded that the hygienic behavior had at least two components controlled by separate genes. (Compare these experiments with those of Mendel's on the color and shape of pea seeds; see Figure 8.5.) But breeding experiments alone cannot identify which genes influence behavior and how they do so. Molecular genetic approaches are used to answer these questions.

Studies of mutants can reveal the roles of specific genes

Molecular genetic studies of a behavior can begin with naturally occurring mutants or mutants created in the laboratory through exposure to chemicals or radiation. If a behavioral trait is altered in the mutant, then efforts can be made to localize and identify the gene involved.

An example is the *Drosophila* mutant *fruitless* (*fru*), described in the chapter opener. Mutant males do not have the ability to discriminate males from females and are just as likely to court either sex. Cloning and sequencing the *fruitless* gene led to many studies advancing knowledge of its regulation and its roles in male sexual behavior. Targeted alterations in the gene resulted in a variety of effects on the sexual behavior of the male *Drosophila*. Some of these engineered mutants had subtle differences in their courtship displays; others showed no courtship behavior at all. It was found that the *fru* gene is selectively expressed in cells in the fly's nervous system that are involved in sexual differentiation and sexual behavior, and that the gene

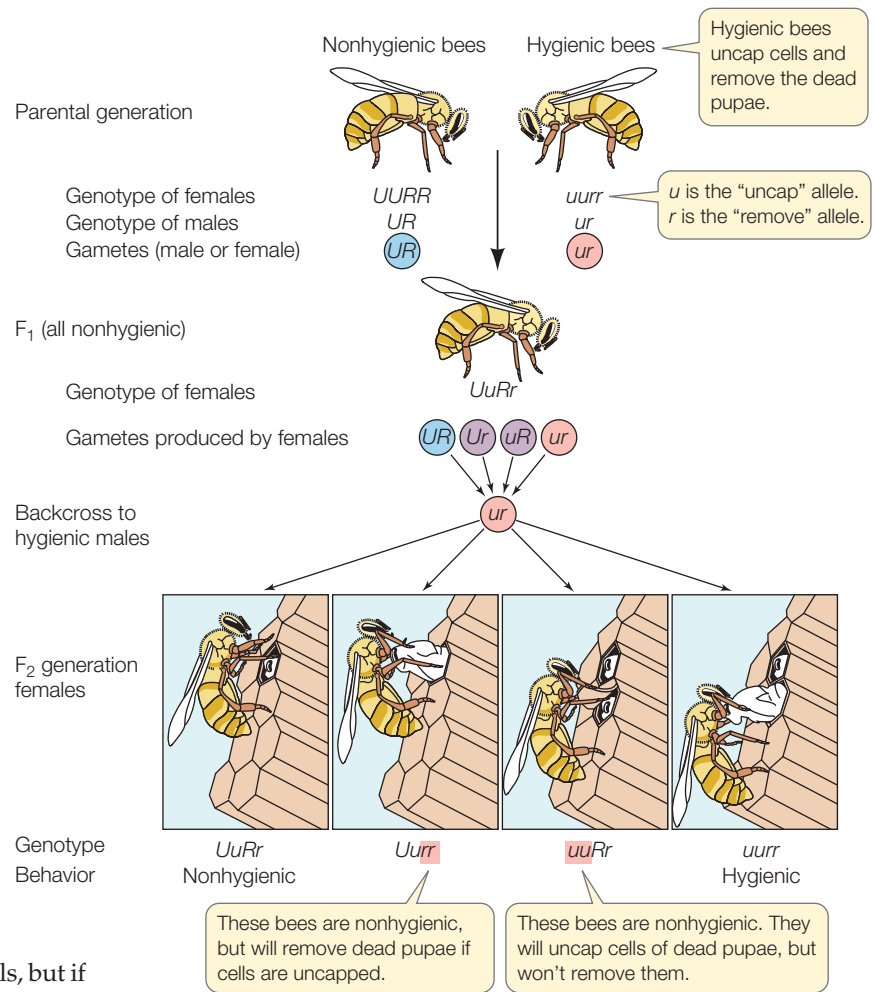

FIGURE 41.3 Genes and Hygienic Behavior Some worker honey bees remove carcasses of dead pupae from their hive. Two components of this behavior—cell uncapping and removal of the carcass—are under the control of separate recessive alleles, designated u and r .

product is a transcription factor that can control the expression of many other genes. Modifications in any one of those genes or their expression can alter behavior. Thus, even though no behavior is coded for by a single gene, alterations in single genes can influence behavior in ways that affect an animal's fitness. Genes frequently function in gene cascades, which creates many opportunities for a change in a single gene to alter even complex behaviors.

LINK Because of the gene cascades involved in development, single genes can also cause profound changes in morphology; see Concepts 14.4 and 14.5

Gene knockouts can reveal the roles of specific genes

Once a gene has been identified, molecular genetic methods can be used to eliminate it or silence it to see what effects the loss of that gene has on behavior. One method is to genetically engineer an animal that lacks the gene—a gene knockout (see Figure 13.8). Knocking out genes involved in sensory pathways can have pronounced effects on behavior. One example is a

INVESTIGATION

FIGURE 41.4 The Mouse Vomeronasal Organ Identifies Gender The mouse VNO is located adjacent to the nasal passages. It contains pheromone receptors whose input travels to a specific region of the olfactory bulb (the accessory olfactory bulb). Dulac used knockout mice to demonstrate that pheromone receptors in the VNO are involved in stimulating mating behaviors in male mice (pursuit of females and aggression toward other males).

HYPOTHESIS

When the receptors in a male's VNO bind to sex pheromones produced by other mice, the receptors stimulate mating behavior.

METHOD

1. Create knockout mice in which the a gene necessary for VNO receptor signaling is inactivated.
2. Place knockout male mice with wild-type females and wild-type males and observe their behavior.

RESULTS

CONCLUSION

Properly functioning VNO receptors appear to be essential not for sexual attraction, but for gender identification.

ANALYZE THE DATA

Mice have two pheromone receptors in the VNO, VN1 and VN2. Knockout males in which either the VN1 or VN2 receptor was inactivated were exposed to either a wild-type male, a castrated male, or a female. The results are shown in the table. M indicates that the test male tried to mate with the introduced individual, O means that he did not react to the individuals, and A indicates that he was aggressive towards that individual.

Introduced individual	Genotype of resident male		
	Wild type	VN1 knockout	VN2 knockout
Male	A	O	M
Castrated male	O	O	M
Female	M	M	M

- What behavioral trait is dependent on a functional VN1 receptor?
- What behavioral trait is dependent on a functional VN2 receptor?
- If a male mouse lacked both a VN1 receptor and a VN2 receptor, how would he react to an introduced wild-type male?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

gene for a specific olfactory receptor in mice.

Mice have two olfactory organs: the nasal olfactory epithelium common to all mammals, and a small organ adjacent to the nasal passages, called the *vomeronasal organ*, or VNO. Catherine Dulac at Harvard University discovered that pheromone receptors were expressed in the VNO and used gene knockouts to demonstrate that the receptors are involved in stimulating mating behavior (FIGURE 41.4). Pheromones are signaling molecules released into the environment; see Concept 35.2.)

Do You Understand Concept 41.2?

- How did breeding experiments on honey bees reveal that two genes playing major roles in hygienic behavior? Would you expect the two genes to be linked or to be inherited by independent assortment? Why?
- After the *fru* gene was cloned and sequenced in *Drosophila*, what evidence was obtained to support the conclusion that the product of this gene controlled gene expression cascades specifically involved in sexual behavior?
- How was Catherine Dulac able to conclude that the pheromone receptor she was investigating in mice was specifically responsible for gender identification? What results would have been obtained if her original hypothesis was correct that the receptor controlled mating behavior?

How can the genetic cascades that underlie complex behaviors be programmed to respond selectively to specific sets of stimuli? How can their expression be limited to appropriate times in an animal's life? The answers to these questions can be found by studying how behaviors develop over the life span.

concept 41.3 Developmental Processes Shape Behavior

The emergence of behavior as an animal develops and matures depends on the development of the nervous system as well as on the growth and maturation of other body systems. A bird cannot fly until its wings grow and its muscles and flight feathers mature. But even with anatomical and physiological competence, specific behaviors may not be expressed. Behaviors that are adaptive at one stage in an animal's life may not be adaptive at other stages. Behaviors typical of juvenile animals, such as begging for food, may disappear and new behavior patterns of a mature individual, such as courtship displays, appear.

Hormones can determine behavioral potential and timing

Hormones can determine the development of a behavioral potential at an early age and the expression of that behavior at a later age. An excellent example of this is sexual behavior in rats (FIGURE 41.5). Normally, adult male and female rats exhibit different patterns of sexual behavior: females adopt a sexually receptive posture, called *lordosis*, in the presence of males, and males copulate with receptive females. Neither sex, however, expresses these behaviors until the animals have reached adulthood. Experiments in which newborn and adult rats were neutered (to remove the influence of sex hormones naturally produced by their gonads) and artificially treated with hormones led to the following conclusions:

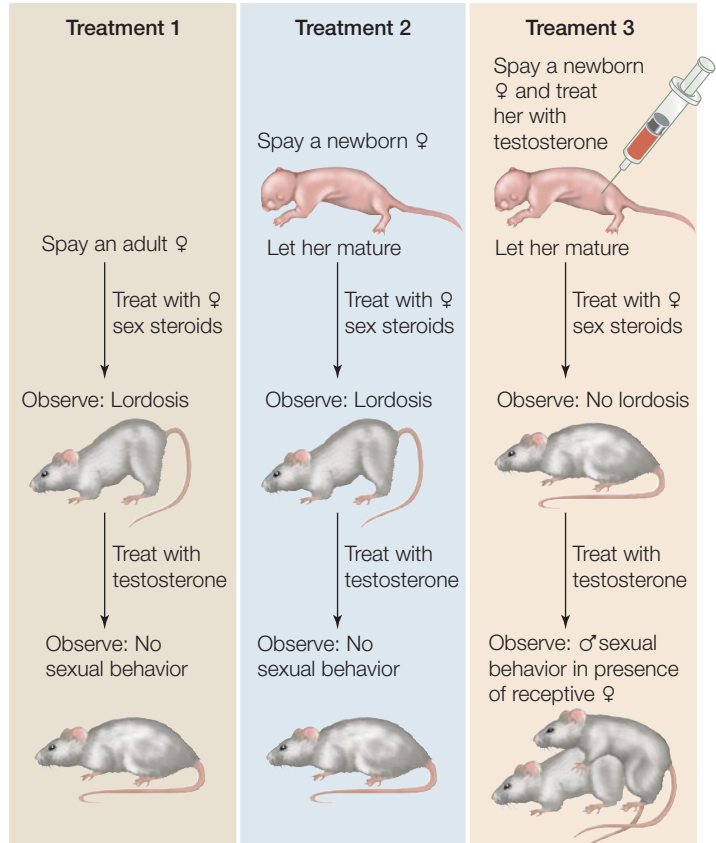

- Development of male sexual behavior requires that the brain of the newborn rat be exposed to testosterone, but development of female sexual behavior does not require exposure to estrogen.
- Testosterone masculinizes the nervous systems of both genetic males and genetic females.
- Exposure to sex steroids in adulthood is necessary for the expression of sexual behavior, but testosterone produces male sexual behavior only in adult rats whose brains were masculinized when they were newborns, and estrogen produces female sexual behavior only in adult rats whose brains were *not* masculinized when they were newborns.

Thus the sex steroid hormones that are present around the time of birth determine which pattern of behavior develops, and the sex steroids that are present in adulthood determine when that pattern is expressed.

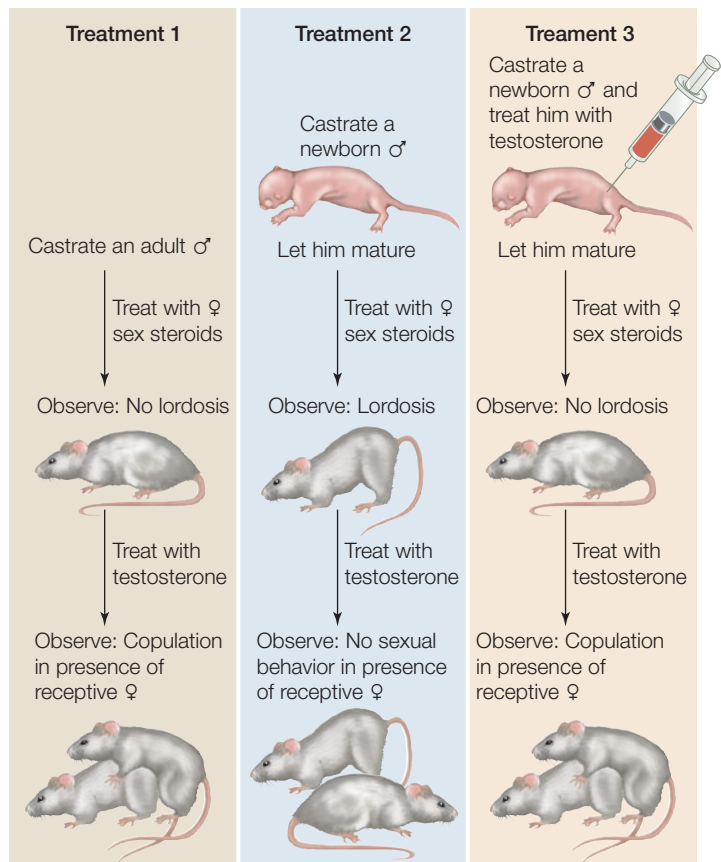

FIGURE 41.5 Hormonal Control of Sexual Behavior

Experimental hormonal treatments of rats demonstrated that the sex steroids present during early development determine what sexual behavior patterns develop, but the sex steroids present in adulthood control the expression of those patterns.

(A) Female rats

(B) Male rats

Some behaviors can be acquired only at certain times

Responsiveness to simple releasers is sufficient for certain behaviors such as begging behavior in gull chicks, but more complete information that cannot be genetically programmed is required for other behaviors. An example is parent–offspring recognition. When animals live in close proximity to other individuals, as in a herd or a nesting colony, it is important for a mother and her offspring to learn each other’s identity soon after birth so they will be able to find each other in a crowded situation. In many such cases, a parent–offspring bond is formed by **imprinting**. What characterizes imprinting is that an animal learns a specific set of stimuli during a limited time called a **critical period** or **sensitive period**.

Imprinting requires only a brief exposure, but its effects are strong and long-lasting. Emperor penguins reproduce during the coldest, darkest time of year in Antarctica. The parents walk up to 150 kilometers inland to form a dense colony, where the female lays her egg. She then walks back to the ocean to feed while her mate incubates the egg. By the time she returns, the chick has hatched. She then takes over its care and feeding, and the father walks back to the ocean to feed. Generally, he is away so long that the mother must leave to find food as well to avoid starvation. Thus after being away for weeks, the father must find his chick in a crowded, milling colony of chicks, all calling for their parents. Yet he can unerringly locate his own offspring by recognizing its call, which he learned before he left to feed.

The critical, or sensitive, period for imprinting may be determined by a brief developmental or hormonal state. For example, if a mother goat does not nuzzle and lick her newborn within 10 minutes after its birth, she will not recognize it as her own offspring later. For goats, the sensitive period is associated with peaking levels of the hormone oxytocin in the mother’s circulatory system at the time she gives birth and is sensing the olfactory cues emanating from her newborn kid. A female goat rendered incapable of smelling before giving birth is unable to differentiate between her own kid and other kids after giving birth.

Bird song learning involves genetics, imprinting, and hormonal timing

Male songbirds use species-specific song to claim and advertise a breeding territory, compete with other males, and declare dominance. They also use song to attract females, which

recognize the song of their species even though they do not sing it. For males of many species, learning is an essential step in the acquisition of song. *What* they learn seems to be influenced by genes, and *when* they learn by a limited *developmental time frame* for learning. For example, a male white-crowned sparrow hatchling hears his father and other white-crowned sparrows singing. He also hears the songs of many other bird species. But he does not sing until he approaches sexual maturity almost a year later, and when he does, he sings his father’s type of song.

Studies of song learning in white-crowned sparrows were initiated in the 1960s by Peter Marler, who hand-reared hatchlings in the laboratory, where he could expose them to different recorded songs at different times in their development. He discovered that male birds cannot produce their species-specific song as adults unless they hear it as nestlings in the first 2 months of their lives (**FIGURE 41.6**). The hatchlings also have to be able to hear themselves as they approach sexual maturity and begin practicing their singing. If a bird is deafened just before he begins to sing, he will not be able to match his own song with his stored song memory. If he is deafened *after* he sings his correct species-specific song, however, he will continue to sing like a normal bird. We say that at this point the song behavior pattern is *crystallized*. Thus there are two critical periods for song learning: the first in the nestling stage, when a song memory is imprinted; the second as the bird approaches sexual maturity, when he learns to match that song memory.

To learn why birds learn only the song of their own species, Marler played tape recordings of other species’ songs to

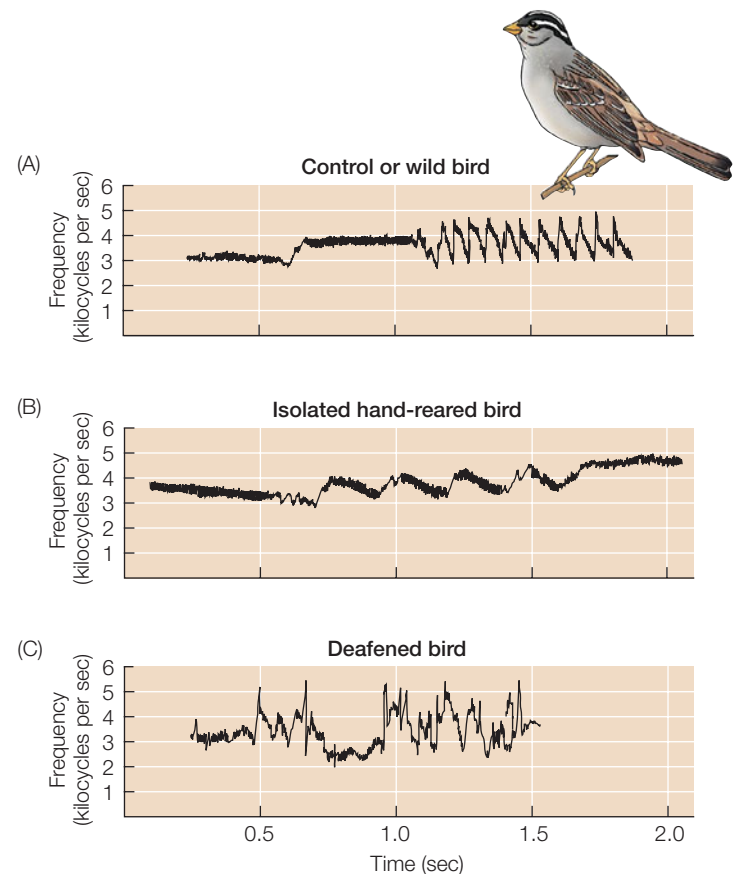

FIGURE 41.6 Sensitive Periods for Song Learning (A) Sonogram showing the species-specific song of an adult male white-crowned sparrow (*Zonotrichia leucophrys*). (B) Song of an adult male raised in isolation (never having heard the song as a nestling). (C) Song of an adult male that heard the song as a nestling but was deafened prior to ever singing himself. Marler’s experiments showed the bird must first acquire a song memory by hearing the song as a nestling, and must then be able to hear himself as he attempts to match his singing to that song memory.

the white-crowned sparrow hatchlings in his laboratory. The young male sparrows did not learn the songs of other species, even if they heard them many times, but hearing songs of their own species just a few times was sufficient for imprinting. Thus the male sparrows seem to have a genetic predisposition to learn their own song and not the songs of other species. Marler called this phenomenon “an instinct to learn.”

Since Marler’s pioneering work, more investigations have revealed additional complexity in white-crowned sparrow song learning capacity. In nature, for example, the sparrows are occasionally heard singing the songs of other species. Further laboratory experiments suggested why. Hand-reared nestlings were exposed to the sight and sound of a related species in an adjacent cage while recordings of their own species’ song were played in the background (sound only). When these sparrows matured, they sang the song of the other species. Thus social experience (sight plus sound) has a powerful effect on what the young bird can and will learn.

The timing and expression of bird song are under hormonal control

As we have seen, both male and female songbirds hear their species-specific song as nestlings, but only the males of most species sing as adults, and they do so only in spring. Hormones underlie both the difference in song expression between male and female songbirds and the timing of song expression.

When investigators injected adult female songbirds with testosterone in spring, the females sang a rough version of their species-specific song. Apparently females form a memory of their species-specific song and have the physical capacity to sing, but under normal circumstances they lack the hormonal stimulation. This memory, however, may be important in their mate selection.

How does testosterone cause a songbird to sing? A remarkable study revealed that each spring, an increase in circulating testosterone levels causes certain parts of the male’s brain necessary for singing to grow larger. Individual neurons in those regions of the brain increase in size and grow longer extensions, and the number of neurons in those regions increases. These results demonstrated that, contrary to the once widely held belief that new neurons are not produced in the brains of adult vertebrates, hormones can control behavior by changing brain structure as well as brain function, both developmentally and in response to environmental cues.

FRONTIERS To determine what triggers the release of testosterone in birds in response to the onset of spring, Takashi Yoshimura conducted a DNA microarray analysis of Japanese quail brains. He examined the responses of 32,000 transcripts to increases in day length. Fourteen hours after dawn on the first day that reached the critical day length for induction of singing, genes in the brain that code for thyroid-stimulating hormone were switched on, initiating a cascade of hormonal controls that stimulate the growth of the testes and the production of testosterone.

Do You Understand Concept 41.3?

- We say that female reproductive behavior is the default developmental pattern in rats. Explain what that means and why it happens.
- What is the adaptive value of imprinting?
- Describe the series of events necessary for a male white-crowned sparrow to sing its species-specific song in spring.

Complex behaviors result from the interactions of genetic, physiological, and environmental factors. Studying these proximate causes of behavior reveals the mechanisms responsible for the behavioral abilities of animals and the differences between species.

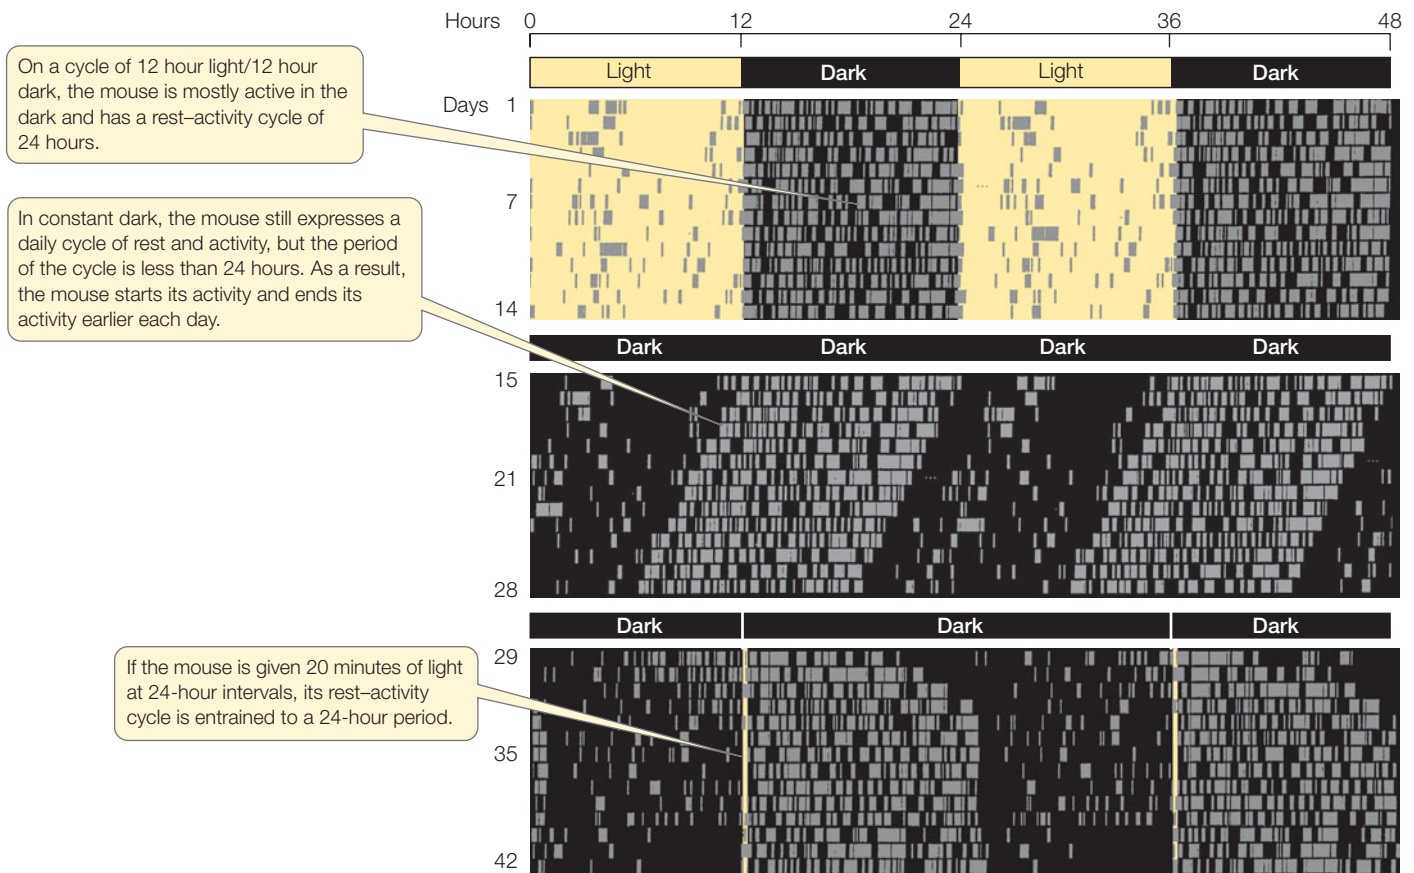

concept 41.4 Physiological Mechanisms Underlie Behavior

Control of behavior involves the nervous and endocrine systems. Execution of most behavior involves the musculoskeletal system. All of the physiological systems we have covered in this book have behavioral aspects. Therefore, the field of behavioral physiology is enormous; here we will dig deeper into just three different phenomena studied by behavioral physiologists: the timing of behavior, navigation, and communication.

Biological rhythms coordinate behavior with environmental cycles

Earth turns on its axis once every 24 hours, generating daily cycles of light and dark, temperature, humidity, and tides. In addition, Earth is tilted on its axis, so the light–dark cycle changes as Earth revolves around the sun. These daily and seasonal cycles profoundly influence the physiology and behavior of animals. Animals tend to be either day-active (diurnal) or night-active (nocturnal), and have appropriate sensory capabilities. Therefore it is adaptive to organize behavior on a cycle that corresponds with the environmental cycle of light and dark. Similarly, a behavior that is adaptive at one time of year may not be adaptive at other times. Thus it is important for animals to be able to time their behavior to appropriate times of the day or year and to be able to anticipate those times.

Experimental animals kept in constant darkness and at a constant temperature, with food and water available all the time, still demonstrate daily cycles of activities such as sleeping, eating, drinking, and just about anything else that can be measured. The persistence of these daily cycles in the absence of environmental time cues suggests that animals have an internal clock. Because these daily cycles are not exactly 24 hours long, they are known as **circadian rhythms** (*circa*, “about,” and *dies*, “day”).

As described in Concept 26.4, any biological rhythm can be viewed as a series of cycles, and the length of one of those cycles is the *period* of the rhythm. Any point in the cycle is a *phase* of that cycle. Hence, when two rhythms completely match, they are *in phase*, and if a rhythm is shifted (as in the resetting of a clock) it is *phase-advanced* or *phase-delayed*. Because the period of a circadian rhythm is not exactly 24 hours, it must be phase-advanced or phase-delayed each day to remain in phase with the daily cycle of the environment. In other words, the rhythm has to be **entrained** to the cycle of light and dark in the environment.

An animal kept under constant conditions will not be entrained to the light–dark cycle of the environment, and its circadian clock will run according to its natural period—it will be *free-running*. If the period is less than 24 hours, the animal will begin its activity a little earlier each day (FIGURE 41.7). The period of the free-running circadian rhythm is under genetic control. Different species may have different average periods, and within a species, mutations can lead to different period lengths.

Under natural conditions, environmental time cues, such as the onset of light or dark, entrain the free-running rhythm to the light–dark cycle of the environment. In the laboratory, it is possible to entrain the circadian rhythms of free-running animals with short pulses of light or dark administered every 24 hours (see the bottom panel of Figure 41.7).

FIGURE 41.7 Circadian Rhythms Are Entrained by Environmental Cues The activity–rest cycle of a laboratory mouse (a nocturnal animal) responds to the light–dark cycle under which it is kept. The gray bars indicate times when the mouse is running on an activity wheel. Two days of activity are recorded on each horizontal line; the data for each day are plotted twice—once on the *right* half of each line (hours 24–48) and again on the *left* half of the line below it (hours 0–24). This double plotting is merely to make the pattern easier to see.

yourBioPortal.com

Go to ANIMATED TUTORIAL 41.1
Circadian Rhythms

In mammals, the master circadian “clock” consists of two clusters of neurons just above the optic chiasm (the area of the brain where the optic nerves come together and some fibers cross to the opposite side of the brain). These structures are called the **suprachiasmatic nuclei (SCN)**. If they are destroyed, the animal becomes *arrhythmic*: it is just as likely to eat, drink, sleep, or wake at any time of day.

The molecular mechanism of the circadian clock involves negative feedback loops. When certain *clock genes* are expressed in SCN cells, the mRNA enters the cytoplasm and is translated. The resulting proteins dimerize and reenter the nucleus, where they act as a transcription factor that shuts off the expression of the clock genes. The period of this cycle of gene activation and inactivation is about a day.

APPLY THE CONCEPT

Physiological mechanisms underlie behavior

Martin Ralph and colleagues used artificial selection to produce two strains of hamsters: one with a short circadian period and one with a long circadian period. When the SCNs in some of these adult hamsters were destroyed, the animals became arrhythmic. After several weeks, the scientists transplanted SCN tissue from fetal hamsters into the brains of the adult hamsters whose own SCNs had been destroyed. Long-period adult hamsters received tissue from short-period fetuses, and short-period adults received tissue from long-period fetuses. The effects of these treatments on the hamsters' circadian periods are shown in the table.

RECIPIENT	NONE	SCN DESTROYED	TREATMENT	
			SCN DESTROYED AND SHORT-PERIOD TRANSPLANT	SCN DESTROYED AND LONG-PERIOD TRANSPLANT
Short-period adult	Short-period	Arrhythmic	Not done	Long-period
Long-period adult	Long-period	Arrhythmic	Short-period	Not done

A. Why did destroying the SCN make the adult hamsters arrhythmic?

2. What result would you expect if SCN tissue from a long-period fetal hamster were transplanted into a long-period adult whose own SCN was destroyed?
3. What do the results of the transplantation experiments tell you about where in the body the circadian rhythm phenotype (long versus short) is expressed?

Animals must find their way around their environment

To locate suitable habitats, find food and mates, and escape from predators and bad weather, an animal needs to be able to find its way around its environment. Within its local habitat, an animal can organize its behavior spatially by orienting to landmarks. But what about destinations farther away?

PILOTING: ORIENTATION BY LANDMARKS Most animals find their way by knowing and remembering the structure of their environment. This form of navigation is called **piloting**. Gray whales, for example, migrate seasonally between the Bering Sea and the coastal lagoons of Mexico (**FIGURE 41.8**). They find their way in part by following the west coast of North America. Coastlines, mountain chains, rivers, water currents, and wind patterns can all serve as piloting cues. But some remarkable cases of long-distance orientation and movement cannot be explained by piloting.

HOMING: RETURN TO A SPECIFIC LOCATION The ability to return to a nest site, burrow, or other specific location is called **homing**. Homing can be accomplished by piloting in a known environment, but some animals that travel long distances through unfamiliar territory perform much more sophisticated homing. The ability of pigeons to return to their home loft even after being transported to remote sites is well known. Pigeons use the sun as a compass (see Figure 41.9), but they can still find their way home when the sun is not visible. Other experiments have shown that pigeons equipped with frosted contact lenses can find their way home, suggesting that visual cues, though sufficient, are not necessary. Most amazing is that pigeons can detect Earth's magnetic field and orient to it much as a human

orients with a compass. Taken together, the studies of homing by pigeons suggest that they can use multiple, redundant sources of directional information and can switch among those sources depending on the circumstances.

FIGURE 41.8 Piloting Gray whales (*Eschrichtius robustus*) migrate south in winter from the Bering Sea to the coast of Baja California by piloting, in part by following the western coast of North America.

MIGRATION AND NAVIGATION OVER GREAT DISTANCES Many homing and migrating species are able to take direct routes to their destinations through environments they have never experienced because they use mechanisms of navigation other than piloting. Humans use two major forms of navigation:

- *Distance–direction navigation* (dead reckoning) requires knowing in what direction and how far away the destination is. With a compass to determine direction and a means of measuring distance, humans can navigate.
- *Bicoordinate navigation*, also known as *true navigation*, requires knowing the latitude and longitude (the map coordinates) of both the current position and the destination, as well as a compass to determine direction.

Animals, of course, do not carry compasses or GPS receivers, but many of them have a *compass sense* that allows them to use environmental cues to determine direction, and some appear to have a *map sense* that allows them to determine their position.

A compass sense is not difficult to explain. If you know what time it is—remember the circadian clock described above—you can use the position of the sun to indicate compass direction. A *time-compensated solar compass* was demonstrated in pigeons by placing them in an outdoor circular cage that enabled them to see the sun and sky, but no other visual cues (**FIGURE 41.9**). Food bins were arranged around the sides of the cage, and the birds were trained to expect food in the bin at one particular compass point in the cage—south, in this case. The birds were then moved indoors and placed in rooms with controlled photoperiods that were different than in the outside environment. In a week or so, their circadian rhythms entrained to the new photoperiods—just like you recover from jet lag. When the birds were then returned to the outdoor cage, they remembered to seek food at a particular compass point in their cage, but they showed an error in that directional selectivity that

matched their shifted circadian rhythms. For example, if the birds were shifted by 6 hours so their internal clocks said noon when it was really 6:00 A.M., when they were returned to the outdoor cage they searched for food in the direction of the sun. But at sunrise that was in the east, not the south. Similar experiments have shown that many species can orient by means of a time-compensated solar compass.

Time-Compensated Solar Compass and
INTERACTIVE TUTORIAL 41.1

Birds that migrate at night could use a time-compensated star map for directional orientation, but a simpler source of directional information is available in the night time sky. Because of the rotation of Earth, the star pattern rotates around fixed points in the sky that lie over the North or South Poles. Steve Emlen at Cornell University raised birds in a planetarium, rotated the sky around different constellations, and showed that birds from the Northern Hemisphere learn to identify the fixed point in the sky as north. It did not matter which star in which constellation was used as that fixed point.

There is no clear demonstration of true bicoordinate navigational mechanisms in animals, but many behave as if they have such capabilities. For example, gray-headed albatrosses breed on small islands in the Southern Hemisphere. After young birds leave their nests, they wander widely over the southern oceans for 8 or 9 years before reaching reproductive maturity (**FIGURE 41.10**). Then they fly back to the island where they hatched to find a mate and breed. It is difficult to imagine how they could locate such a specific locality in the vast southern oceans after years of wandering unless they were able to know the map coordinates of where they are and where they need to go.

FIGURE 41.9 A Time-Compensated Solar Compass The circadian clocks of pigeons factor into their ability to judge direction correctly based on the sun's position. (A) Pigeons placed in cages can be trained to expect food at a particular compass point, which they determine solely from the sun's position. (B) Phase-shifted pigeons make orientation errors that match their circadian phase shift. For example, a 6-hour phase shift produces a 90-degree orientation error.

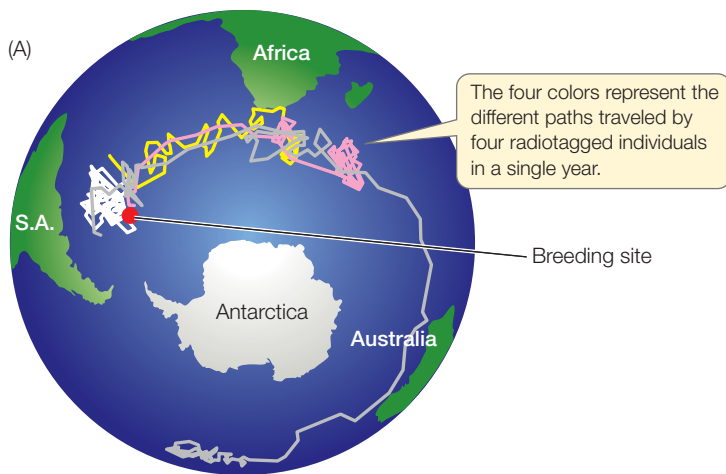

FIGURE 41.10 Coming Home (A) Gray-headed albatrosses are born on islands in the subantarctic oceans. Young birds roam widely over the southern oceans for 8 or 9 years. (B) Once they reach maturity, the birds return to the island where they were born to mate and raise their own young. A courting couple is shown here.

(B) *Thalassarche chrystoma*

themselves: species, individual identity, reproductive status, size (indicated by the height of the marking), and how recently the animal has been in the area (indicated by the strength of the scent). Pheromones are especially effective for exchanging species-specific information because the recipient must have the proper receptor to detect the pheromone; thus predators do not easily intercept the signal.

Animals use multiple modalities to communicate

As individual animals interact, they exchange information; therefore, animal behaviors can evolve into systems of information exchange, or **communication**. Specific behaviors can evolve into communication systems if they convey information that benefits both the sender and the receiver. For example, consider bird song, which we discussed in Concept 41.3. Natural selection has favored male singing displays because they communicate the male's sex, his reproductive condition, and even his possession of a territory that would provide a good nest site and food supply. Natural selection has favored females' responses to singing displays that convey information about the male's qualities as a potential mate and father. Thus this communication signal contributes to the reproductive success of both the male and the female.

Animals communicate using a variety of sensory modalities that vary in the nature of the signal produced, the specificity of the information conveyed, the speed and persistence of the signal, and its suitability in different environments.

PHEROMONES Odorants used for communication are called *pheromones*. Pheromones vary in their volatility (ease of vaporization) and diffusibility, which in turn determine their range and persistence. Pheromones that act as alarm signals, for example, are highly volatile and diffusible, so their messages spread rapidly but disappear rapidly. Territory-marking and trail-marking pheromones have low volatilities and diffusibilities and stay effective for a long time. Sex pheromones, such as that of the silkworm moths (see Figure 35.4), are intermediate in these properties; they spread a long distance but do not disappear rapidly.

Because of the potential diversity of their molecular structures, pheromones can communicate very specific, information-rich messages. Mammals that mark their territories with pheromones reveal a great deal of information about

VISUAL SIGNALS Visual signals offer the advantage of rapid delivery of information over considerable distances (depending on the environment and the visual acuity of the receiver). Visual signals convey without ambiguity the position of the signaler. Visual signals also can provide information about the signaler's sex, species, vigor, health, social status, and reproductive state. Unlike pheromones, effective visual signals require sufficient light, and the receiver must be looking directly at the signaler. Thus visual communication is not particularly useful at night or in dark environments, such as caves and ocean depths. Some species have overcome this constraint with light-emitting mechanisms. Fireflies, for example, use an enzymatic mechanism to create flashes of light. By emitting flashes in species-specific patterns, fireflies advertise for mates at night.

Another drawback of visual signals is that they can be intercepted by other species. There are predatory firefly species, for example, that mimic the flash pattern of females of other species. A male that approaches the mimicking "female" becomes a meal rather than a mate.

ACOUSTIC SIGNALS Sound cannot convey complex information as rapidly as visual signals can. But acoustic signals, unlike visual signals, can be used in dark environments. They can also be transmitted in complex environments, such as forests, that might hinder visual signals. Acoustic signals are often better than visual signals at getting the attention of a receiver because the receiver does not have to be looking at the signaler. Sounds are also useful for communicating over long distances—loud sounds can transmit information over longer distances than visual signals can. The complex songs of humpback whales, for example, can be heard up to hundreds of kilometers away. In this way, humpback whales can locate one another across vast expanses of ocean.

The information content of acoustic signals can be increased by varying their frequency, as in the species-specific songs of

FIGURE 41.11 The Waggle Dance of the Honey Bee (A) A honey bee runs straight up on the vertical surface of the honeycomb in the dark hive while wagging her abdomen to tell her hive-mates that there is a food source in the direction of the sun. (B) When the waggle runs are at an angle from the vertical, the other bees know that the same angle separates the direction of the food source from the direction of the sun.

yourBioPortal.com

Honey Bee Dance Communication

birds shown in Figure 41.6 (and in our own speech). However, acoustic signals place the signaler at risk for detection by predators, which can be minimized by adjustments of frequency and signal structure that decrease the directional information the receiver can extract from the signal. Alarm calls tend to be pure tones (a single frequency) without much temporal structure, which are difficult to localize. By contrast, territorial calls or mating calls tend to cover a broad frequency range and have temporal structure. These calls are easy to localize. Acoustic signals are also adapted to specific habitats: pure tones at lower frequencies carry better in forests, and more complex calls at higher frequencies carry well in open habitats.

MECHANOSENSORY SIGNALS Animals in close contact with one another communicate by touch, especially under conditions where visual communication is difficult. The best-studied use of mechanosensory communication is the dance of honey bees, first described by Karl von Frisch. Honey bees can reliably communicate the location of food sources as far as 2.5 kilometers away from their hive. When a forager bee finds

food, she returns to the hive and communicates her discovery to her hive-mates by dancing on the vertical surface of the honeycomb.

The returning forager performs a *waggle dance* (FIGURE 41.11), a repeating figure-eight pattern on the honeycomb. She alternates half-circles to the left and right with vigorous wagging of her abdomen in a short, straight run between turns. The angle of the straight run indicates the direction of the food source relative to the sun's azimuth (the position of the sun projected down to the horizon). The directional information in the straight runs becomes more accurate as the distance to the food increases. Researchers used to think that the bees had a separate dance to indicate nearby food, but it turned out to be just a larger variation of the waggle dance. Even under partially cloudy conditions that obscure the sun, the forager can provide directions to the food source because bees can see polarized light in a clear patch of sky and infer the position of the sun from the pattern of polarization. The honey bee's internal clock allows the dancer to adjust her dance to take into account the sun's movement during her return flight—another example of a time-compensated solar compass. The dance also indicates the distance to the food source: the farther away it is, the longer the duration of each waggle run. The odor on the dancer's body indicates the flower to be looked for, and she shares some nectar with hive-mates to demonstrate the quality of the food source. When the food source is close, the distance and direction information is less critical because other workers excited by the food smell and the dancer's level of arousal can simply follow her back to the food source.

COMMUNICATION IN MULTIPLE SENSORY MODALITIES Specificity is a high priority in any signaling system and can be enhanced by using multiple sensory modalities. Courtship behavior in fruit flies, as we saw in the opener to this chapter, involves tactile, chemical, visual, and acoustic signals. The male fruit fly identifies the female by her pheromones (chemical), taps her body with his foreleg (touch), and vibrates his wing to produce his "courtship song" (acoustic). The male then extends his mouthparts to taste the female's genitalia (chemical and tactile); if she is receptive, he initiates copulation. If at any point sensory feedback indicates to either the male or the female that their pairing is inappropriate, the courtship abruptly ends.

Do You Understand Concept 41.4?

- What is meant by a "free-running" rhythm? How is it entrained to the 24-hour environmental cycle?
- Experimenters captured young starlings in the Netherlands and transported them to Switzerland. Normally these young starlings would migrate to western France, but instead they flew to Spain. Adult starlings used in the same experiment flew correctly from Switzerland to western France. Explain the different navigational systems that could have been used by juvenile and adult birds to yield these results.
- Draw a table that lists at least one advantage and one disadvantage of visual, acoustic, and chemical communication.

We have just explored three fields of behavior in which researchers primarily focus on physiological mechanisms underlying behaviors and also seek to understand how those mechanisms are adapted to specific environmental variables. Another approach to studying behavior is to investigate how the environment influences the fitness of individuals and thereby shapes the evolution of their behavior.

concept 41.5 Individual Behavior Is Shaped by Natural Selection

Environmental conditions are highly variable over both time and space. Animal behaviors are also variable within and between species. Behavioral ecologists strive to discover the relationships between behavior and environment that lead to the evolution of specific behaviors.

Animals must make choices

Over an animal's lifetime, its behavior is largely a series of choices: where and when to move, where to build a nest, what to eat, when to fight and when to flee, with whom to associate, with whom to mate. Making wrong choices reduces fitness.

The choice of a place to live, for example, is one that has many consequences. In most cases a **habitat**—the environment in which an animal lives—provides not only shelter but also food and access to mates. The environmental cues animals use to make their habitat choices can be quite simple. For example, seabirds select cliffs or offshore rocks for nesting because those sites offer protection from predators. Animals with very specialized food requirements obviously select habitats where those foods are abundant. The general hypothesis that guides behavioral ecologists is that the cues animals use for habitat selection are those that over evolutionary time have been reliable correlates of good fitness outcomes.

Behaviors have costs and benefits

Behavioral ecologists often use a cost–benefit approach to investigate the relationship between behavior, environment, and fitness. A **cost–benefit approach** assumes that an animal has only a limited amount of time and energy, and therefore cannot afford to engage in behaviors that cost more to perform than they bring in benefits.

LINK A cost–benefit approach can also be used to analyze life history trade-offs during evolution; see Concept 43.3

The benefits of a behavior can be measured in terms of the enhancement in fitness an animal accrues by performing the behavior. The cost of a behavior typically has three components:

- **Energetic cost** is the energy the animal expends performing the behavior.
- **Risk cost** is the increased chance of being injured or killed as a result of performing the behavior.

- **Opportunity cost** is the benefit the animal forgoes by not being able to perform other behaviors during the same time interval.

Cost–benefit analysis has been used extensively in the study of **territorial behavior**: aggressive behavior used by an animal to actively deny other animals access to a habitat or resource. Optimal habitats and resources are frequently in short supply, so individuals of the same species must compete for them. Many individual animals—usually males—defend all-purpose territories that provide shelter, food, and access to mates. Through territorial behavior, the males obtain the resources they need for reproductive success, but they also pay a price.

Territorial behavior requires considerable expenditure of energy, makes a male more vulnerable to predation, and detracts from time spent feeding or engaging in parental behavior. Michael Moore and Catherine Marler at Arizona State University investigated the costs incurred by males when defending a territory (**FIGURE 41.12**). Yarrow's spiny lizards (*Sceloporus jarrovi*) defend territories that include the habitats of several females. Their territorial behavior is normally most intense during September and October, when their circulating testosterone levels are high and the females are most receptive to mating. The researchers varied the intensity of the lizards' territorial behavior by implanting testosterone capsules in some males in summer, when they are not normally highly territorial.

Testosterone-treated males spent more time patrolling their territories, performed more displays, and expended about one-third more energy than control males (an energetic cost). As a result, they had less time to feed (an opportunity cost), captured fewer insects, stored less energy, and had a higher death rate (a risk cost). In summer, when females are not normally receptive, these high costs of vigorous territorial defense outweigh the reproductive benefits of territoriality. Thus natural selection has favored seasonal variation in the level of the hormone controlling territorial behavior in this species.

The cost–benefit approach explains the diversity of territorial behaviors seen in different species. Even if a resource is absolutely essential to an animal, if it cannot be defended economically, the animal will not engage in territorial behavior. For example, the open ocean where seabirds feed cannot be defended. But safe nest sites on islands or rocky cliffs are in short supply, and they can be defended. Thus the territories of seabirds may be no larger than the distance the birds can reach while sitting on their nests and are defended only while offspring are present.

In some cases the resource that is defended is the mate itself. Elephant seals spend most of their lives and collect all of their food at sea, but females come to land at traditional beach sites to give birth to their pups. Male elephant seals arrive at these sites ahead of time and stake out territories through vigorous fighting. When the females arrive, they enter the territories of the males. As long as the male territory holder can fend off challengers, he will be able to mate with all the females using his piece of the beach.

INVESTIGATION

FIGURE 41.12 The Costs of Defending a Territory

By using testosterone implants to increase territorial behavior, Moore and Marler measured the costs to male Yarrow's spiny

lizards (*Sceloporus jarrovi*) of defending a territory during the summer, when they do not normally do so.

HYPOTHESIS

Yarrow's spiny lizards do not defend a territory during summer because the energetic costs of territorial behavior in that season outweigh the benefits.

METHOD

1. During the summer, when female lizards are not sexually receptive, insert testosterone capsules under the skin of some males; leave other males untreated as controls.
2. Observe the patterns of territorial behavior and the survival rate of the two groups of males.

RESULTS

CONCLUSION

For these lizards, the cost of defending territories during summer significantly reduces their survival rate without increasing their reproductive success.

ANALYZE THE DATA

Given the trade-off between time spent in territorial behavior and time available for foraging, researchers hypothesized that the cost of territoriality should be reflected in decreased growth rates. Two measures of body size in a lizard are length (tip of snout to urogenital vent) and weight. Lizards were captured and implanted with testosterone capsules or empty capsules. The individual lizards varied widely in size at the time of capture, but the average size was the same for the two treatment groups. Three months later the lizards were recaptured and their sizes measured (see table).

Controls		Testosterone implants	
Weight (g)	Length (mm)	Weight (g)	Length (mm)
3.9	73	3.1	73
4.9	78	3.2	76
5.1	78	3.2	79
4.3	80	4.2	78
4.8	80	4.1	79
4.6	82	4.8	80
5.8	84	3.5	82
5.2	85	4.5	84
8.2	86	4.2	87
5.5	90	7.5	102
6.9	90		
6.4	91		
8.1	93		
7.0	94		
7.0	96		

- For each treatment, calculate the mean and standard deviation for the two size measures.
- Using statistical tests from Appendix B, what can you conclude from these data?
- Since the lizards varied greatly in size at the beginning of the experiment, how could you use regression analysis to compare the two experimental groups?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

The most unusual form of male territorial behavior arises in a situation where neither food, nest sites, nor females are defended. A **lek** is an area where males gather to engage in communal displays of their territorial prowess for the purpose of attracting mates. Even though space is not limited, each male defends a small piece of real estate on which he performs a display. Those pieces of territory closest to the center of the lek are the prime sites, and males compete intensely for those locations. The females stroll into the lek,

observe the males, and generally mate with the males holding the prime sites. The benefit of this system to the female is that she is inseminated by a successful competitor, and therefore her offspring will carry the genes that contributed to his success. The costs of lekking to males are high, as they engage in continuous, intense territorial behavior that precludes eating, drinking, and sleeping until they are displaced. The benefit is the chance to maximize their fitness by mating with many females.

yourBioPortal.com

Go to ANIMATED TUTORIAL 41.3
The Costs of Defending a Territory

Cost–benefit analysis can be applied to many aspects of behavior. For example, foraging behavior can be analyzed in terms of energy and time expended versus energy obtained. Is it more beneficial to exploit a readily abundant food source with low energy content or a more dispersed food source with higher energy content? Is it more beneficial to pursue a high-quality food source for which there is fierce competition or a low-quality food source that is free for the taking?

yourBioPortal.com

Go to ANIMATED TUTORIAL 41.4
Foraging Behavior

Of course, there are other considerations than energy in the evolution of feeding behavior. Essential minerals, for example, are in short supply in some animals' diets, and those animals may incur large energetic costs and risks to obtain them. Foods may also be chosen for their medicinal value. Chimpanzees, for example, have been observed eating the pith of a plant called *Vernonia amygdalina*. The pith contains very small quantities of a compound called vernonioside B1, which is toxic to chimps at high concentrations, but at low concentrations it can kill their intestinal parasites. Chimps that consume this pith have fewer parasites. Thus the behavioral ecologist must be cognizant of all aspects of an animal's behavior that could influence its reproductive fitness.

Do You Understand Concept 41.5?

- List at least five types of behavioral choices that an animal must make in its life.
- Some bird species defend all-purpose territories that provide nest sites and all the food needed to raise their young, but other species defend much smaller territories that cannot provide all of the food they will need. What factors could influence the evolution of these different territorial strategies?
- In lek species the male provides no resources or help to the female with which he mates. What are the advantages to the female of selecting a mate that is in the center of the lek?

In this concept we focused on the behavioral choices made by individual animals and how those behaviors can influence the fitness of the individual. However, in nature, species can display complex social behaviors that are not as easy to analyze in terms of the reproductive success of the individual.

concept
41.6

Social Behavior and Social Systems Are Shaped by Natural Selection

The evolution of social behavior became a field of study in 1975, with the publication of E. O. Wilson's landmark book, *Sociobiology*. A minimal social system is the reproductive behavior of a single male and female, but even here there is diversity. Species differ in the number of mates each individual has (ranging from monogamous to promiscuous); the amount of parental care they give their young; and the degree to which the male contributes to raising the young. Beyond these relatively simple mating systems, larger numbers of reproductive individuals may associate in *polygynous* mating systems, in which a male has more than one mate, or *polyandrous* mating systems, in which a female has more than one mate. Even more complex interactions include extended families that participate in raising young, and societies such as honey bee colonies in which large numbers of nonreproductive individuals assist a single reproductive individual. Sociobiology proposes that the evolution of all these variations can be understood by asking how social behavior contributes to the fitness of the *individuals* involved.

Mating systems maximize the fitness of both partners

Voles are small rodents, and there are many species of voles living in very different habitats. Prairie voles (*Microtus ochrogaster*) are *monogamous*; they form strong pair bonds that last for life, and both parents participate in rearing the young. In contrast, montane voles (*M. montanus*) are *promiscuous*: males mate with many females, and the young are raised by the females alone. The proximate mechanisms behind these stark behavioral differences involve differences in the release of oxytocin during mating and the distribution of the oxytocin receptors in the brains of the two species. Because of this role of oxytocin in pair bonding, it has been called the “cuddle hormone.” The ultimate question is why two such different mating systems evolved in two species that are so closely related.

To answer this question, we begin with the premise that there is an asymmetry in the contributions of male and female animals to their offspring at the time of fertilization. As we learned in Concept 33.1, females produce a limited number of eggs, and each egg is generously stocked with resources. Males produce an almost infinite number of sperm that contain almost no resources. So the energetic and opportunity costs of reproduction are greater for the female than for the male. In mammals, this asymmetry increases throughout gestation as the female bears most of the costs. Under these circumstances, the main way for the female to maximize her fitness is to make sure her young are healthy and survive to pass on her genes. Females that invest heavily in current offspring may be favored over those that “skimp” and produce weaker offspring, because the weaker young are unlikely to be as successful in their reproductive efforts.

The male has different options for maximizing his fitness. He can simply move on after inseminating the female and seek additional mates as a means of maximizing his reproductive success—as in the case of the montane vole. Or he can stay with the female he inseminated, protect her, and help care for their young—as in the case of the prairie vole. Which strategy maximizes his fitness depends on a number of factors that are influenced by the species' environment, such as the likelihood that a female and her offspring will survive without a male's help, and a male's likelihood of finding another fertile female. Sociobiologists seek to quantify these factors in nature as a means of explaining observed differences in mating systems.

POLYGYNY **Polygynous** mating systems, in which a male has more than one mate, involve a different asymmetry. If a male can sequester a group of females from other males, he can increase his fitness by increasing the number of females in his group. As we mentioned in Concept 41.5, male elephant seals accomplish this by protecting an area of beach where females give birth. Male baboons do so by herding females. Male red-winged blackbirds may acquire more than one mate by defending high-quality nesting territories, building more than one nest, and attracting females to that desirable real estate. Since sex ratios in all these species are close to 50:50, a large differential in male fitness is established: some males have high reproductive success while many males have none. Selection favors males that are successful in competing with other males to obtain and protect access to many females. In general, bigger, stronger males are the winners, and sexual dimorphism in body size evolves. The elephant seal is an extreme example: males may weigh more than three times as much as females. When species with polygynous mating systems are compared, there is a strong correlation between the number of females a male controls and the degree of sexual dimorphism.

Why do females participate in these polygynous mating systems? In some cases they have no choice. A female elephant seal is most likely to successfully raise her pup if she gives birth on a safe beach, and to do so she must enter the territory of a male. A female red-winged blackbird is more likely to have a successful brood if she accepts a mate that defends a nesting site that is safest from predators and provides access to a good food supply. To achieve this end, she may have to share the attentions of the territory's owner with other females. Even if a female has a choice of mates, she can maximize her fitness by mating with a strong dominant male so her sons are also likely to be strong and dominant, thereby maximizing her number of grandchildren. Strong dominant males may be able to protect more than one female.

POLYANDRY **Polyandry**—one female with multiple mates—is a relatively rare mating system seen in some birds and a few mammals in which paternal care for the young can have a large effect on fitness. An example is the golden lion tamarin (*Leontopithecus rosalia*), a primate native to the Brazilian tropical forests (FIGURE 41.13). Compared with other primates, adult tamarins are tiny—under 1 kilogram—so they face high predation

Leontopithecus rosalia

FIGURE 41.13 Polyandry in a Small Primate The endangered golden lion tamarins of Brazil are small primates whose unique life history has given rise to polyandry in some groups, with males playing a major role in rearing the young.

pressure. Females usually give birth to twins and thus newborns constitute a higher percentage of maternal weight than in other primates. They also grow faster, so nursing costs are high. For all these reasons, young tamarins cared for by their mother alone are unlikely to survive.

A male tamarin helps guarantee his reproductive success by watching out for predators and gathering food for the female and her young. Tamarin mothers with twins in tow spend 92 percent of their time resting, compared with only 58 percent of the time when they are not carrying young. When a male is present, however, he carries the young about one-third of the time, so the mother has much more time for foraging and feeding.

If one male is helpful in protecting and raising young, then two should be even more helpful. Some females can attract a second mate by being sexually receptive to him. Neither male can be sure that any eventual offspring are his, so it is in the best interest of both to help in their rearing. Of the social groups of golden lion tamarins observed in field studies, only 22 percent had one male and one female, whereas 61 percent had multiple males and one female.

Fitness can be enhanced through the reproductive success of related individuals

As humans, we readily understand the concept of extended family—brothers, sisters, aunts, uncles, nieces, nephews, and so forth. Extended families are a form of social organization in other species as well. Members of these families may cooperate in territory defense, predator avoidance, foraging, and rearing of young. If behavior is favored when it increases the fitness of the individual performing it, how can we explain the evolution

FIGURE 41.14 Helpers at the Nest Young Florida scrub jays (*Aphelocoma coerulescens*) often forego reproduction in their first few years of adulthood to help their parents raise their siblings. These young birds help their parents feed the nestlings, defend the territory, and protect the nest from predators.

of social behaviors that do not lead to the performer having more offspring? How can we explain behaviors that appear to be **altruistic**—benefiting another individual at a cost to the performer?

Having offspring increases an individual's fitness because those offspring carry the parent's genes into the next generation. Fitness gained by producing offspring is referred to as **individual fitness**. However, an individual's genes can be carried into the next generation by other routes. In diploid organisms, two offspring of the same parents share, on average, 50 percent of the same alleles, and an individual is likely to share 25 percent of its alleles with its sibling's offspring. Therefore, by helping parents and other relatives raise their offspring, an individual increases the transmission of those shared alleles to the next generation. **Inclusive fitness** is the fitness derived from an individual's own reproductive success plus that derived through the reproductive success of its relatives.

Maximization of inclusive fitness is the mechanism behind **kin selection**: selection for behaviors that increase the reproductive success of relatives even when they come at a cost to the performer. An example is the phenomenon of *helping at the nest*, which was extensively studied in Florida scrub jays by Glen Woolfenden. Scrub jay pairs mate for life and establish large territories, which they defend aggressively. The mating pair may be assisted in rearing their young by three to five helpers (**FIGURE 41.14**). The helpers guard against predators, feed the young, clean the nest, and fly with fledglings to protect them. Why are these birds helping others rather than rearing their own young? Through a long-term study, Woolfenden was able to establish a number of important facts:

- The helpers are prior offspring of the mating pair and are usually 1 to 3 years old.
- Young birds that attempt to set up their own territories and breed have almost zero reproductive success.
- Mating pairs with helpers have approximately three times the reproductive success of those without helpers.
- When birds that have been helpers eventually establish their own nests, they fledge more offspring than birds that have never been helpers. Thus experience pays off.

These results support the conclusion that helper scrub jays are maximizing their inclusive fitness by helping their parents

raise siblings until the helpers are mature enough to have a reasonable probability of successfully raising their own offspring.

The concept of kin selection was formalized by W. D. Hamilton in what has become known as **Hamilton's rule**. He argued that for an apparent altruistic behavior to be adaptive, the cost to the performer must be less than the benefit to the recipient times the degree of relatedness between the performer and the recipient. This relationship was clearly stated years before by the eminent geneticist J. B. S. Haldane, who said during an argument about altruism that he would not be willing to risk his life to save his brother—but for two brothers or eight cousins, he would consider it.

Eusociality is the extreme result of kin selection

The social groups of **eusocial** species include nonreproductive workers. Prime examples are wasps, bees, and ants—members of the large insect order Hymenoptera. In a honey bee colony, a single reproductive female—the queen—occasionally produces a few male offspring, but most of the thousands of other individuals in the colony—all her offspring—are sterile female workers. One theory for explaining the evolution of eusociality in hymenopterans focuses on their sex determination mechanism, called **haplodiploidy** because diploid individuals are female and haploid individuals are male. The queen carries a lifetime supply of sperm obtained during her single mating flight, and she controls whether her eggs are fertilized or not. An unfertilized egg develops into a male, a fertilized egg develops into a female.

If a queen copulates with only one male, all the sperm she receives are identical because a haploid male has only one set of chromosomes, all of which are transmitted to every sperm cell. Therefore, the queen's daughters share all of their father's genes and, on average, half of their mother's genes. As a result, the workers in the hive—all sisters—share, on average, 75 percent of their alleles. Were they to reproduce, they would share only 50 percent of their alleles with their own female offspring. Thus they can potentially increase their inclusive fitness more per individual raised by caring for their sisters than by producing and caring for their own offspring.

Heterocephalus glaber

Haplodiploidy is not essential for eusociality to evolve. This social system may also arise if it is costly or dangerous to establish new colonies. Nearly all eusocial animals construct elaborate nests or burrow systems within which their offspring are reared. Such a structure represents an enormous investment of resources. Naked mole-rats—the most eusocial mammals—live in elaborate underground tunnel systems that can extend as much as 5 kilometers in cumulative length (FIGURE 41.15). A colony includes 70 to 80 individuals but only 1 reproductive female and a few reproductive males. The other colony members—all offspring of the single reproductive female—are sterile workers that dig and maintain the tunnels, guard against intruders, harvest food (tubers), and use their feces to feed

FIGURE 41.15 A Eusocial Mammal Naked mole-rats live in a large colony with only one reproductive female (shown here nursing her young) and a few reproductive males. They live in an elaborate tunnel system excavated by the colony over time.

the queen and her offspring. Individuals attempting to found new colonies have a high risk of failing or being captured by predators. When chances of individual reproductive success are practically zero, an individual can best maximize its inclusive fitness by staying with and helping maintain the colony.

Group living has benefits and costs

The cost–benefit approach of behavioral ecology is relevant to understanding the evolution of social behavior. An obvious benefit of group living is improved foraging efficiency. By hunting in packs, for example, wolves employ cooperative strategies that enable them to bring down larger prey than could a single wolf. Living in a group can also reduce the risk of the members' becoming prey themselves. One investigator found that a trained goshawk's success in capturing a pigeon in a flock decreased as the number of pigeons in the flock increased (FIGURE 41.16A). The larger the flock, the sooner some individual in the flock spotted the hawk and flew away. This escape behavior stimulated other individuals in the flock to take flight as well.

Alarm calling is another means of reducing predation risk, but the caller incurs a risk cost by calling attention to itself. Belding's ground squirrels live in large colonies in open meadows. When one squirrel announces the presence of a predator with loud, sharp barks, all the nearby squirrels dive into their burrows (FIGURE 41.16B). Paul Sherman and others showed that this altruistic behavior, which doubles the caller's risk of

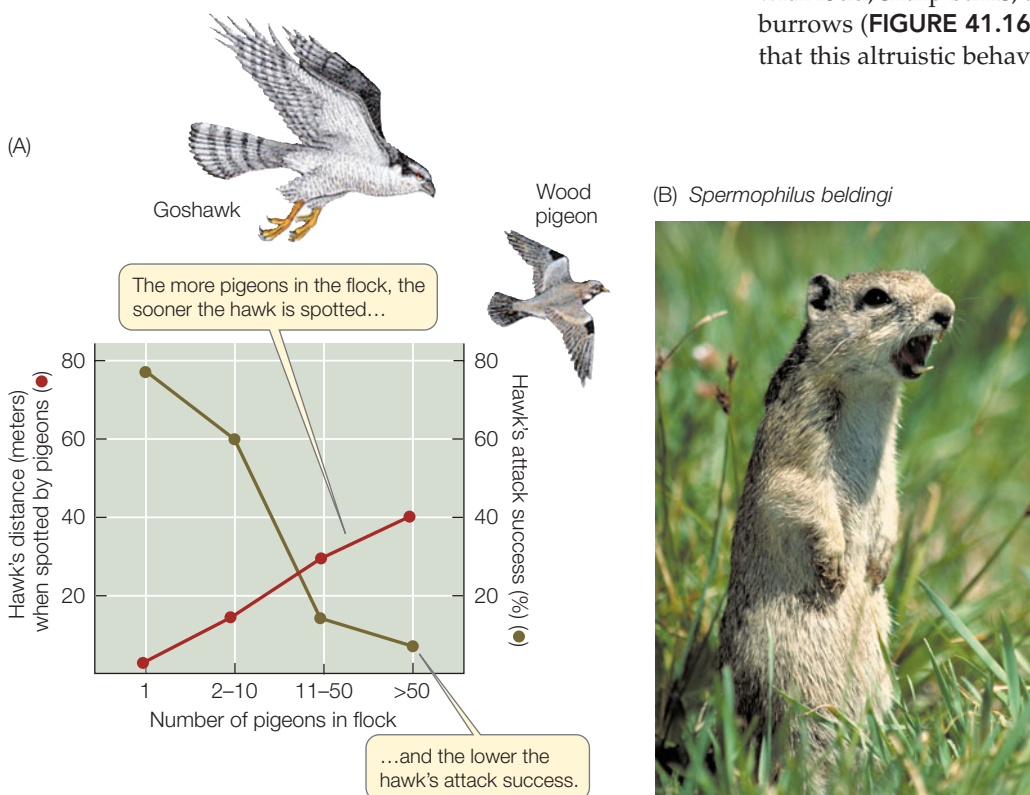

FIGURE 41.16 Group Living Provides Protection from Predators Animals that live in groups can spread the cost of looking out for predators. (A) The larger the number of pigeons in a flock, the greater the chances that one of the pigeons will spot a hawk before it attacks, and the lower the chances that the hawk will capture one of the pigeons. (B) A young male Belding's ground squirrel gives an alarm call upon spotting a predator. Although this behavior increases the squirrel's individual risk of becoming prey, it increases the survival chances of many of his close relatives.

being preyed on, is a product of kin selection. In this polygynous species, males establish large territories in the spring that include the territories of several females, which they inseminate. Female offspring settle near their mothers, so neighboring females in a colony tend to be sisters, and they defend each other's young. Sherman showed that males are much less likely to give alarm calls than females, and that females are more likely to give alarm calls when related individuals are nearby.

Social behavior has many costs as well as benefits. Foraging in a group may reduce the amount of food available to each individual, and the foraging individuals may interfere with one another's foraging activities. Individuals living in groups may face more competition for mates, as well as for food, than solitary individuals would. A large group may actually attract the attention of predators. And living at high population densities can increase the risk of disease transmission. The behavioral ecologist employing cost-benefit analysis must take these various factors into consideration.

Do You Understand Concept 41.6?

- Explain how differential parental investment can favor the evolution of either monogamy or promiscuity.
- Explain the evolutionary relationship between sexual dimorphism in body size and degree of polygyny (female to male ratio) in a species.
- Describe the differences in the selective pressures producing eusocial behavior in bees and naked mole-rats.

Knowledge of the behavior of particular species—how they use the environment, how they obtain food, how they organize their activities spatially and temporally—is essential for understanding how species interact in nature. These interactions are one focus of the science of ecology, the subject of Part 7 of this book.

How can a single gene be responsible for a complex behavior?

ANSWER A gene cannot code for a behavior. Genes code for proteins, and proteins play many roles—structural, functional, and signaling. By interfering with any of these roles, a gene can have an effect on a behavior (Concept 41.2). We saw a simple example in the gene critical for the function of a pheromone receptor in mice. An alteration in this single gene destroyed the ability of the male mouse to tell a male from a female—an essential component of territorial and mating behaviors. Another example is the prairie (monogamous) and the montane (polygynous) voles (Concept 41.6). Both species of voles release oxytocin when copulating, but the expression pattern of the oxytocin receptor is different in the brains of the two species. Notably, the receptor is heavily expressed in a particular area of the brain (the nucleus accumbens) of the prairie vole, but not in the montane vole. The nucleus accumbens is associated with sensations of pleasure and reward, so we can hypothesize that its stimulation could play a role in forming a strong bond between two young voles mating for the first time. The role of hormones in stimulating neurogenesis in songbirds or in causing the development of neural circuitry responsible for masculinization of the newborn rat brain are other examples where genes can influence developmental and functional processes that underlie behavior (Concept 41.3). A signaling role for a gene in behavior was seen in the fruit fly example in the chapter opener. The development and expression of male and female sexual behavior in fruit flies is under control of a gene cascade that differs in males and females because of different splicing patterns of gene products early in the cascade. As a result, one gene, *fruitless*, produces a slightly different protein in males and females. This protein serves as a transcription factor and controls the expression of downstream genes that make the difference between male and female behavior. It is easy to see how elimination or alteration of this one gene could have large effects on courtship behavior of this species even though that behavior is really under the control of many genes.

It is fair to say that we have many examples of single genes affecting behavior and that we understand why that result occurs. However, we are a long way from understanding how spider webs are coded in the genome.

41

SUMMARY

concept 41.1 Behavior Has Proximate and Ultimate Causes

- Questions about animal behavior can be grouped into four inter-related categories: causation, development, function, and evolution. The first two refer to **proximal causes** of behavior and the later two to **ultimate causes** of behavior.
- **Behaviorism** originated in the study of conditioned reflexes and focused on this phenomenon as a mechanism of learning. By contrast, **ethology** focused on fixed action patterns and the nature of stimuli, called **releasers**, that trigger those genetically inherited behavior patterns. **Review Figures 41.4 and 41.2**

concept 41.2 Behaviors Can Have Genetic Determinants

- Breeding experiments can reveal whether a behavioral phenotype is inherited. A simple Mendelian ratio of traits in offspring indicates a small number of responsible genes for a behavioral difference. **Review Figure 41.3**
- Induced mutations can reveal genetic determinants of a behavior. However, a mutation may affect a behavior because it is a transcription factor influencing the expression of many genes, or because it is a gene in a cascade of gene expression that underlies a behavior.
- Gene knockout experiments can reveal the roles of specific genes underlying a behavior. An example is the knockout of genes responsible for pheromone detection in mice. **Review Figure 41.4**

concept 41.3 Developmental Processes Shape Behavior

- Hormones can determine the pattern of behavior that develops and the timing of its expression. **Review Figure 41.5**
- **Imprinting** is a process by which an animal learns a specific set of stimuli during a limited **critical**, or **sensitive, period**. That critical period may be determined by hormones.
- The development and expression of song in white-crowned sparrows involves a genetic predisposition to learn the species-specific song, a critical period for imprinting of a song memory, and hormonally controlled timing of song expression. Social interactions may also play a role. **Review Figure 41.6**

concept 41.4 Physiological Mechanisms Underlie Behavior

- **Circadian rhythms** control the daily cycle of behavior. Without environmental time cues, circadian rhythms free-run with a period that is genetically programmed. They are normally **entrained** to the light–dark cycle by environmental cues. **Review Figure 41.7 and ANIMATED TUTORIAL 41.1**
- Two forms of navigation used by animals to find their way in the environment are piloting (orienting to landmarks) and distance–direction navigation. Bicoordinate navigation may also be used by some animals. Navigation mechanisms include celestial navigation and a time-compensated solar compass. **Review Figures 41.8–41.10, ANIMATED TUTORIAL 41.2, and INTERACTIVE TUTORIAL 41.1**
- The behaviors of individuals may become communication systems if the transmission of information benefits both the sender and the receiver.

- Chemical communication signals (pheromones) can be highly specific and have different time courses depending on their volatility and diffusibility. Visual signals can convey complex messages rapidly, but the recipient must be looking at the sender. Acoustic signals travel well over distances, do not require a focused recipient, and can be modified to reveal or conceal directional information. Tactile signals are used by animals in close proximity and can convey complex messages. **Review Figure 41.11 and WEB ACTIVITY 41.1**

concept 41.5 Individual Behavior Is Shaped by Natural Selection

- An animal's behavior is a series of choices that influence its fitness. To make these choices, animals use environmental cues that are reliable predictors of the potential effects of their choices on their fitness.
- The **cost–benefit approach** can be used to investigate the fitness value of specific behaviors. The cost of a behavior typically has three components: **energetic cost**, **risk cost**, and **opportunity cost**.
- Different types of territorial behavior can be understood in terms of the costs and benefits of defending resources, among them nesting sites, food, and even mates. **Review Figure 41.12 and ANIMATED TUTORIALS 41.3 and 41.4**

concept 41.6 Social Behavior and Social Systems Are Shaped by Natural Selection

- The evolution of mating systems can be understood by looking at the fitness costs and benefits incurred by each partner in the species' environment. **Polygynous** mating systems, in which one male controls and mates with many females, can result in great variation in male reproductive success. **Polyandry**—a female mating with multiple males—can evolve in circumstances in which a male can make a substantial contribution to the survival of his offspring. **Review Figure 41.13**
- The fitness an individual gains by producing offspring (**individual fitness**) plus the fitness it gains by increasing the reproductive success of relatives with whom it shares alleles is called **inclusive fitness**. **Kin selection** may favor **altruistic** behavior toward relatives, despite its cost to the performer, if it increases the performer's inclusive fitness. **Review Figure 41.14**
- As a result of **haplodiploidy**, the sex determination mechanism of the Hymenoptera, nonreproductive workers share more alleles with one another than females share with their own offspring. Haplodiploidy has probably facilitated the evolution of **eusocial behavior** in this group through kin selection. Eusocial behavior has also risen in diploid species in which chances of individual reproductive success are extremely low. **Review Figure 41.15**
- Group living confers benefits such as greater foraging efficiency and protection from predators, but it also has costs, such as increased competition for food and ease of transmission of diseases. **Review Figure 41.16**

See **WEB ACTIVITY 41.2** for a concept review of this chapter.

Ecology

Organisms in Their Environment

42

The U.S.–Mexico Borderlands of southern Arizona have a colorful “Wild West” history peopled by Spanish explorers and missionaries, cowboys and Indians, cavalry, outlaws and sheriffs, miners and ranchers, cattle rustlers, and railroad tycoons. Today most of this history is seen only in a few monuments and historic buildings. One period, however, left a lasting legacy on the grasslands of the Borderlands: the cattle boom of the 1880s.

The first herds of cattle appeared in the Borderlands in 1687, when Spanish missions and associated settlements were established. Livestock numbers fluctuated as conflicts between settlers and Indians waxed and waned, but remained below 40,000 head until the 1880s. At that time, several events—the end of the Indian Wars, the completion of transcontinental railroads that opened up huge markets for beef, and an influx of investment capital—combined to bring 1.5 million animals to fatten on the free grass of Arizona’s “open range.” Within a few years, the cattle grazed to the ground the sea of grass that had once grown “as high as the belly of a horse.”

The cattle boom did not last long. A drought in 1892 and 1893 killed 75 percent of the animals, leaving such a density of carcasses that one could walk across the San Simon Valley, it is said, without setting foot on the ground. Prickly, unpalatable shrubs such as mesquite (*Prosopis* spp.) gained a toehold in the denuded landscape when torrential rains returned in the late 1890s and washed away the soil. Rich grassland had been turned into unprofitable shrubland.

A cow grazes in the mesquite-dominated “pasture” of southern Arizona. Modern range management techniques have failed to restore this region’s grassland ecosystem.

Soon thereafter, state and federal governments closed the “open range,” substituting a lease system that would allow them to better manage public rangelands. They tried to restore the grass using a method that had worked for thousands of years in the pastures of Europe: adjusting the number of cattle up or down depending on pasture condition. This technique assumes that the primary effect of grazing is to deplete palatable grasses and favor unpalatable ones, and that reducing the number of cattle will allow the palatable species to recover and restore the productive capacity of the pasture. Alas, “resting the range” did not work in the arid Borderlands: shrubs continued to spread, and grasses did not increase measurably.

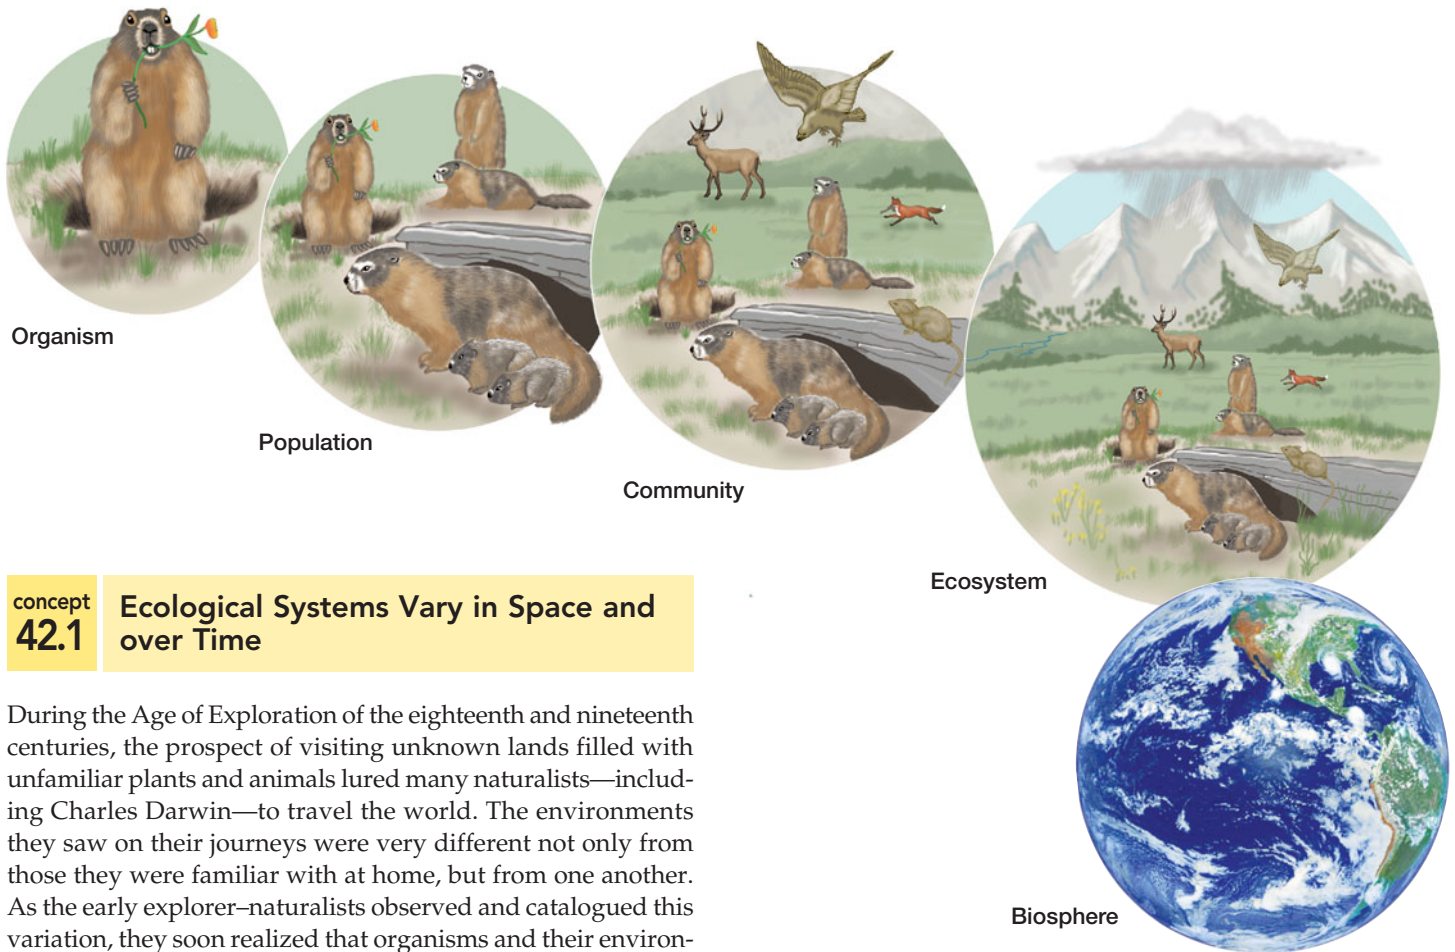

Why did the rangeland restoration method that worked in Europe fail to work in the Borderlands?

*You will find the answer to this question on page 840.

concept
42.1 Ecological Systems Vary in Space and over Time

During the Age of Exploration of the eighteenth and nineteenth centuries, the prospect of visiting unknown lands filled with unfamiliar plants and animals lured many naturalists—including Charles Darwin—to travel the world. The environments they saw on their journeys were very different not only from those they were familiar with at home, but from one another. As the early explorer–naturalists observed and catalogued this variation, they soon realized that organisms and their environments are closely linked. Their work laid the foundations for two new fields of study: **physical geography**, the study of the distributions of Earth’s climates and surface features; and **biogeography**, the study of the distributions of organisms.

Ecological systems comprise organisms plus their external environment

All organisms, humans included, are surrounded by and interact with their external environment. That external environment is made up of nonliving, or **abiotic**, components and living, or **biotic**, components. We can think of one or more organisms plus the external environment with which they interact as an **ecological system**.

The term “ecological” derives from **ecology**, a word that the German biologist Ernst Haeckel constructed in 1866 from the Greek roots *oikos*, “house,” and *logia*, “study of.” By “house” he meant “the total relations of the animal both to its inorganic [abiotic] and its organic [biotic] environment.” Haeckel’s new word referred to a very old subject, for even the earliest humans knew a great deal about their food, their enemies, and natural hazards—indeed, the earliest available religious texts and scholarly writings are full of ecological topics. By coining the term “ecology,” however, Haeckel helped to establish “all those complex interrelations referred to by Darwin as ‘the conditions of the struggle for existence’” as a legitimate subject for scientific study. Furthermore, he emphasized that ecology is relevant to evolution because ecological interactions drive natural selection.

FIGURE 42.1 The Hierarchy of Ecological Systems Ecological systems can include any part of the biological hierarchy from the individual to the biosphere. Each successive level brings in new interacting biotic and abiotic elements and involves progressively larger spatial scales.

The term “system” derives from the Greek *systema*, meaning “organized whole.” Nicolas Léonard Sadi Carnot, a nineteenth-century French physicist who is considered the father of thermodynamics, first introduced the idea of a system as a whole comprising a set of interacting parts in which neither the parts nor the whole can be understood without taking account of the interactions.

Ecological systems can be small or large

A system is defined by the interacting parts it contains. But scientists have a great deal of freedom to choose the set of interacting parts they wish to study (see Figure 1.6). In the case of ecological systems, a boundary can be drawn around any part of the biological hierarchy from the individual on up (**FIGURE 42.1**). Each successive level of the hierarchy brings in new interacting parts at progressively larger spatial scales.

At the smallest scale is the fundamental ecological unit: the individual organism and its immediate environment. Individuals remove materials and energy from the environment, convert those materials and energy into forms that can be used by other organisms, and by their presence and activities, modify the

physical environment. In aggregate, these humble exchanges between individuals and their immediate surroundings drive vast fluxes of energy and materials, as we will see in Chapter 46.

The individual organism is part of a **population**: a group of individuals of the same species that live, interact, and interbreed in a particular geographic area at the same time. When individuals reproduce or die, they contribute to changes in the size (number of individuals) of the population of which they are a part. The role a population plays in its ecological system is determined by the average individual's rate of interaction or exchange with its environment, multiplied by the population size.

LINK The population is the unit of evolution; review Concepts 15.2 and 15.3

The assemblage of interacting populations of different species within a particular geographic area forms a biological **community**. As we expand the geographic area we include within the boundary of our ecological system, we include multiple communities in **landscapes** until, at the largest scale, we include all the organisms and environments of the planet—the entire **biosphere**.

In 1935 the British ecologist Sir Arthur Tansley first introduced the idea of an ecological system. He called it an **ecosystem**. Although Tansley's original use of this term referred to all levels of the biological hierarchy from individuals to communities plus their abiotic environment, in modern ecology this term is mostly used to refer to communities plus their physical environment. It was at the community level that the concept was first applied in a concrete way by Raymond Lindeman. In an influential paper published in 1942, Lindeman showed that properties of the community in a freshwater lake resulted from exchanges of matter and energy within and between the biotic and abiotic components of the system. In this chapter we use "ecosystem" more in Tansley's broad sense, as a contraction of "ecological system." In Chapter 46 we consider ecosystems in the modern sense: as communities plus their abiotic environments.

Large ecological systems tend to be more complex than small ones, not only because they contain more interacting parts, but also because those parts interact over a greater range of spatial and temporal scales. The components of the biosphere, for example, are linked not only by the rapid and localized exchanges between individual organisms and their surroundings, but also by slower and more extensive migrations of organisms, great cycles of air and water movement, and the geological churning of Earth's crust.

INVESTIGATION

FIGURE 42.2 The Microbial Community of the Human Gut Depends on the Host's Diet To treat certain digestive disorders, doctors try to increase the relative abundance of beneficial *Bifidobacterium* bacteria in the human gut. This manipulation of the nutritional environment as a way of adjusting the species composition of the gut community is known as *prebiotic therapy*.

HYPOTHESIS

The abundance of beneficial *Bifidobacterium* bacteria in the human gut can be increased relative to pathogenic bacteria by including oligofructose in the diet.

METHOD

1. Feed 8 healthy human subjects a standardized experimental diet for 45 days. On days 1–15 supplement the diet with 15 g sucrose/day ("Sucrose 1"); on days 16–30, substitute 15 g oligofructose for the sucrose; on days 31–45 return to 15 g sucrose ("Sucrose 2").
2. Collect stool samples during each 15-day period and assay for bacterial composition and energy content.

RESULTS

Type of bacteria	Number of bacteria (\log_{10} /g stool; mean \pm SD)		
	Sucrose 1	Oligofructose	Sucrose 2
Bifidobacteria	8.8 \pm 0.5	9.5 \pm 0.7^a	8.9 \pm 0.9^b
Lactobacilli	6.8 \pm 1.2	7.0 \pm 1.4	7.1 \pm 1.0
Coliforms	6.0 \pm 1.2	5.9 \pm 0.7	5.8 \pm 1.0
Gram-positive cocci	5.8 \pm 1.0	5.8 \pm 0.9	5.5 \pm 0.8
Bacteroides	9.4 \pm 0.8	8.8 \pm 1.1 ^a	8.9 \pm 0.9 ^c
Fusobacteria	8.5 \pm 0.7	7.7 \pm 0.9 ^a	8.1 \pm 0.8 ^c
Clostridia	8.0 \pm 1.2	7.5 \pm 0.9 ^c	7.7 \pm 0.7

^aSignificantly different from sucrose 1 ($P < 0.01$).

^bSignificantly different from oligofructose ($P < 0.01$).

^cSignificantly different from sucrose 1 ($P < 0.05$).

The number of bifidobacteria was highest on the oligofructose diet.

The numbers of these potentially pathogenic bacteria were lowest on the oligofructose diet.

CONCLUSION

Oligofructose stimulated the growth of bifidobacteria at the expense of potentially pathogenic bacteria.

ANALYZE THE DATA

Researchers measured the energy content of the subjects' stools and compared it with the energy content of the ingested oligofructose. The stools contained no oligofructose because it had been fermented—converted into bacterial biomass and waste heat.

	Energy (kJ/day)
Ingested as oligofructose	240
Excreted in stools	77

- A. Was all of the oligofructose energy excreted?
- B. What happened to the energy that wasn't excreted?
- C. What do these observations suggest about the role of gut bacteria in host nutrition?
- D. Why did the researchers follow the oligofructose diet with "Sucrose 2"? (Hint: If the microbial community in Sucrose 2 had not moved back toward its composition in Sucrose 1, would the Conclusion be different?)

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

LINK Scientists can analyze complex microbial ecosystems by sequencing DNA present in environmental samples; see Figure 12.7

Even very small systems, however, can be complex. Consider the ecosystem within each of us. The human large intestine is one of the most densely populated ecosystems on Earth. It contains hundreds of microbial species, and on the order of 10^{12} individual microbes per gram of fecal material. The bacterial cells in our bodies vastly outnumber our own trillion or so human cells, and their combined metabolism rivals that of an organ such as the liver.

It's no surprise that bacteria thrive in the mammalian gut. That environment is regulated within narrow physiological limits, and there is a steady input of nutrients, in the form of food ingested by the host. The gut bacteria interact with their environment as any other organism does. They metabolize food materials that the host cannot digest, and they excrete waste products, some of which are used by other bacterial species or the host. The gut bacteria modify the water and acid content of their environment, provide their host with products such as B vitamins, suppress populations of other, potentially pathogenic bacteria, and interact with epithelial cells to "educate" the immune system.

Each ecological system at each time is potentially unique

The properties of ecological systems depend on their interacting components—biotic and abiotic—and the patterns, strengths, and rates of the interactions among them. Because these components and interactions are distributed unevenly in space and change over time, each system, at any given time, is potentially unique.

The ecosystem of the human gut exemplifies this uniqueness. Even though our knowledge of this particular system is in its infancy, what is emerging from recent studies is that the species of bacteria in the gut are highly diverse (hundreds of species) and vary from person to person and with diet. These observations suggest that both the host's genotype and inputs from the host's diet affect the gut environment from the bacterial point of view. The gut bacteria, in turn, influence their environment, which includes the host. The composition of the gut bacterial community is associated with the presence or absence of various health problems in the host, such as gastric ulcers, irritable bowel syndrome, and obesity. These interactions between the bacterial community and the host affect the properties of the entire system. For example, bacteria in the genus *Bifidobacterium* are human gut microbes that are particularly adept at fermenting oligofructose—a carbohydrate that humans can't digest. Bifidobacteria are also beneficial because they suppress pathogenic bacteria and supply nutrients.

Researchers are actively investigating whether certain health disorders can be treated by manipulating the "ecosystem within." Administering live bifidobacteria by mouth—a strategy called *probiotic therapy*—met with limited success because few bacteria survived the low pH of the stomach to reach the gut. Scientists then tested an alternative strategy known as *prebiotic therapy*: stimulating growth of an already-resident *Bifidobacterium* population by including oligofructose in the patient's diet (FIGURE 42.2).

Do You Understand Concept 42.1?

- What two components make up the external environment of organisms?
- Explain why ecological systems at large scales tend to be more complex than smaller-scale systems.
- How might advances in medicine arise from considering the human gut as an ecosystem?

Variation over space and time can be seen in ecosystems at all scales, from the human gut to the entire biosphere. Next we turn to some of the physical factors that underlie this heterogeneity at the biosphere scale: Earth's climates and topography.

concept 42.2 Climate and Topography Shape Earth's Physical Environments

Variation in Earth's physical environments results from patterns of circulation in the atmosphere and the oceans and from the geological processes that sculpt the surface of the planet. It is these processes that determine whether a particular place is hot or cold, moist or dry, aquatic or terrestrial.

Latitudinal gradients in solar energy input drive climate patterns

Atmospheric conditions—temperature, humidity, precipitation (rainfall or snowfall), and wind direction and speed—are important features of terrestrial environments. We refer to the state of atmospheric conditions in a particular place at a particular time as **weather**, and to their average state and pattern of variation over longer periods as **climate**. In other words, climate is what you expect; weather is what you get. The responses of organisms to weather are usually short-term; for example, animals may seek shelter from a sudden rainstorm, and plants may close their stomata on a hot summer day. Responses to climate, on the other hand, tend to involve adaptations that prepare organisms for expected weather patterns. Organisms in hot climates have high thermal tolerances; those that inhabit seasonal climates use cues such as day length to prepare for an impending cold or dry season.

Globally, air temperatures decrease from low latitudes (near the equator) to high latitudes (near the poles). Averaged over the course of the year, air temperature decreases by about 0.8°C with every degree of latitude (about 110 km) north or south of the equator. High latitudes also experience more pronounced **seasonality**—that is, greater fluctuations in temperature over the course of a year—than low latitudes. These global climatic patterns are the result of uneven input of solar radiation. That uneven input is caused by the shape of Earth and by the orientation of the axis around which it spins relative to Earth's orbit around the sun.

FIGURE 42.3 Solar Energy Input Varies with Latitude

The angle of incoming sunlight affects the amount of solar energy that reaches a given area of Earth's surface. On average, sunlight strikes Earth's surface at a steeper angle at low than at high latitudes. This results in greater input of energy at low (i.e., equatorial) latitudes because (1) the energy is spread over a smaller area and (2) sunlight passes through less atmosphere.

Because Earth is spherical, the sun's rays strike Earth's surface at a steeper angle near the equator than near the poles (FIGURE 42.3). This difference results in more solar energy input per unit of surface area at low latitudes than at high latitudes, for two reasons. First, the energy of perpendicular rays of sunlight is spread over a smaller surface area. Second, perpendicular rays of sunlight pass through less of Earth's atmosphere, so less of their energy is absorbed and reflected by the atmosphere before it reaches the ground.

Seasonality occurs because Earth's axis of rotation is tilted at an angle of approximately 23.5 degrees relative to its orbit around the sun. This tilt causes different latitudes to receive their greatest solar energy input at different times during the

yearly orbit, in a yearly cycle of solstice and equinox (FIGURE 42.4). In late June of every year, the North Pole tilts toward the sun, and the sun is directly over the Tropic of Cancer (latitude 23.5°N). At this time the Northern Hemisphere is basking in the long, warm days of summer, and the Southern Hemisphere is shivering in the long, cold nights of winter. In late December of every year, the North Pole points away from the sun, and the Tropic of Capricorn (latitude 23.5°S) receives the greatest solar input; then it is winter in the Northern Hemisphere and summer in the Southern Hemisphere. In late March and late September, the sun is directly above the equator, and both hemispheres experience equal lengths of day and night.

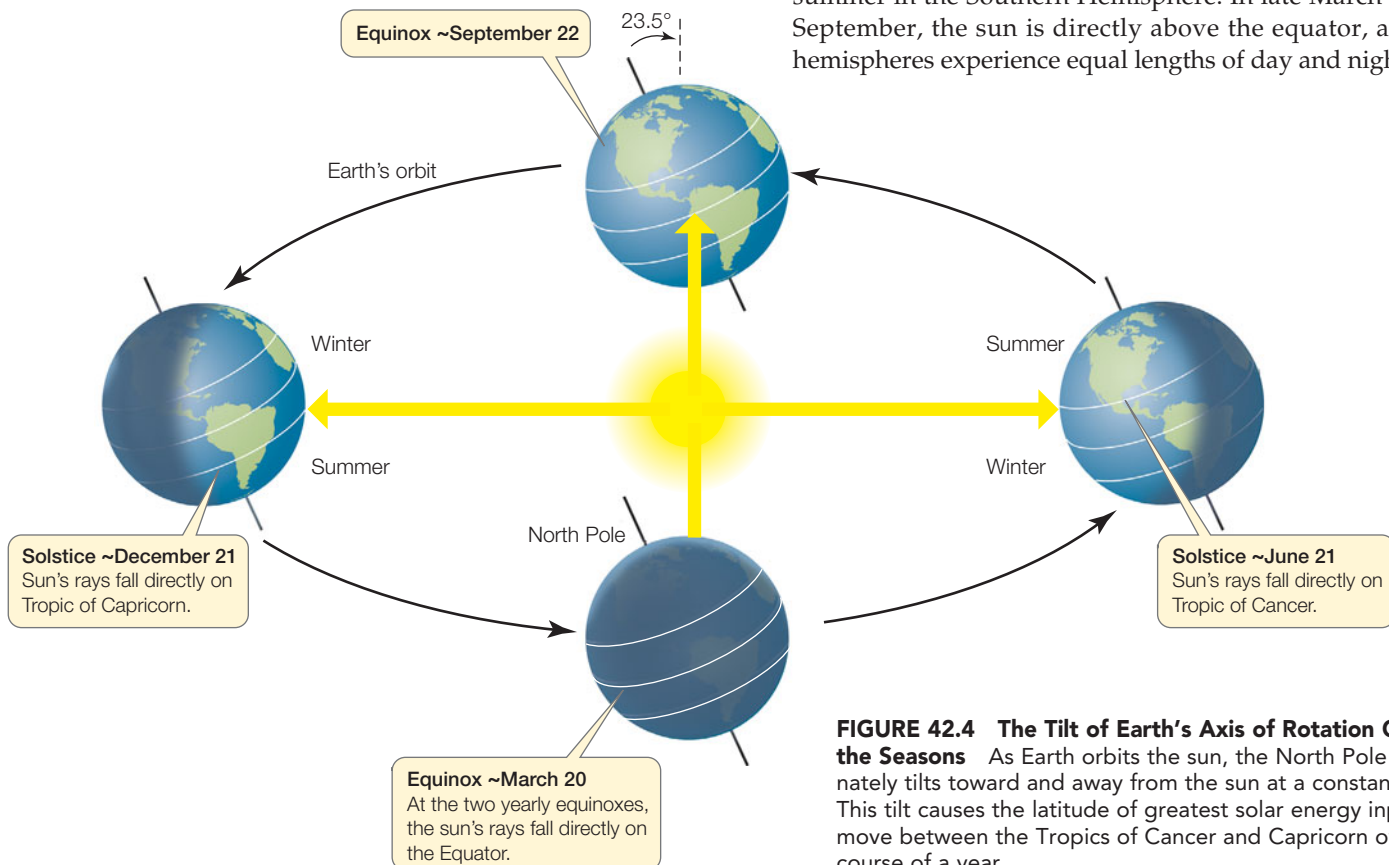

FIGURE 42.4 The Tilt of Earth's Axis of Rotation Causes the Seasons As Earth orbits the sun, the North Pole alternately tilts toward and away from the sun at a constant angle. This tilt causes the latitude of greatest solar energy input to move between the Tropics of Cancer and Capricorn over the course of a year.

Solar energy drives global air circulation patterns

Regardless of seasonal latitudinal shifts in solar input, the total input of solar energy is always greatest between the two Tropics (see Figure 42.3). This solar energy drives a vast global pattern of atmospheric circulation that defines broad latitudinal patterns of surface winds and precipitation.

As the sun beats down on the tropics, the air there absorbs radiant energy and heats up—that is, its molecules move faster (recall that temperature is a measure of disordered molecular motion), colliding and pushing one another farther apart. The heated air expands, becoming less dense and more buoyant, and rises. As it rises, it continues to expand and cool **adiabatically** (this is the principle on which an air conditioner works: when compressed gas is allowed to expand, it cools), until it reaches the same low temperature and density as the surrounding air, high in the atmosphere. Because tropical air is the warmest, it boils up to greater altitudes before it stops rising than does high-latitude air.

This rising tropical air is replaced by cooler, denser surface air that flows in from the north and south. As that air heats, expands, and rises, it pushes the cool air high above the tropics away from the equator. No longer buoyed by rising tropical air, the air aloft eventually sinks back toward Earth. As it descends, it is compressed by overlying atmosphere and warms adiabatically. It reaches Earth's surface at latitudes of roughly 30°N and 30°S, at which point some of it flows back toward the equator to replace air that is rising in the tropics. Thus it completes two patterns of vertical atmospheric circulation—one north and one south of the equator—that we call **Hadley cells**. The Hadley cells give rise to similar air circulation patterns at higher latitudes (FIGURE 42.5). Some of the air that descends at 30°N and 30°S flows poleward. At about 60°N and 60°S, this poleward-flowing surface air rises again and flows aloft either toward the equator or poleward. At the poles, where there is little solar energy input, cold air descends and flows toward

the equator. Because of these three latitudinal circulation cells, surface air flows toward the equator between 30°N and 30°S latitudes, toward the poles between 30° and 60°N and S, and again toward the equator above 60°N and 60°S latitude.

These vertical atmospheric circulation cells influence latitudinal patterns of precipitation as well as surface winds. As water molecules absorb the intense tropical sunlight, they evaporate and the tropical air becomes rich in the resulting water vapor. As this warm, moist tropical air expands, rises, and cools, fewer water molecules bounce apart after they collide. Instead they form droplets of liquid water (or ice crystals), which grow and—when they become massive enough—fall to the ground as precipitation. Thus the warm, rising air of the Hadley cells drops most of its moisture on the tropics as rain. The high-altitude air that eventually descends at about 30°N and 30°S is largely depleted of water vapor; moreover, because it warms as it descends and is compressed, the little water that remains stays in a gaseous state. Earth's great deserts are located at these dry subtropical latitudes.

The prevailing wind patterns at Earth's surface reflect Earth's counterclockwise rotation as seen from the North Pole (see Figure 42.3), as well as the north–south atmospheric circulation (see Figure 42.5). Because Earth is a sphere, the rotation of its surface is fastest at the equator, where its circumference is greatest, and slowest at the poles. Air that is not moving north or south has the same speed of eastward rotation as the surface beneath it. But as an air mass moves toward the equator, it lags behind the faster-moving surface beneath it and is therefore deflected to the west. Conversely, the rotational movement of an air mass moving poleward is faster than that of Earth beneath it, and it is deflected to the east. This *Coriolis effect* causes prevailing surface winds to blow from east to west in the tropics

FIGURE 42.5 Global Atmospheric Circulation Latitudinal differences in solar energy input drive global patterns of atmospheric circulation and precipitation.

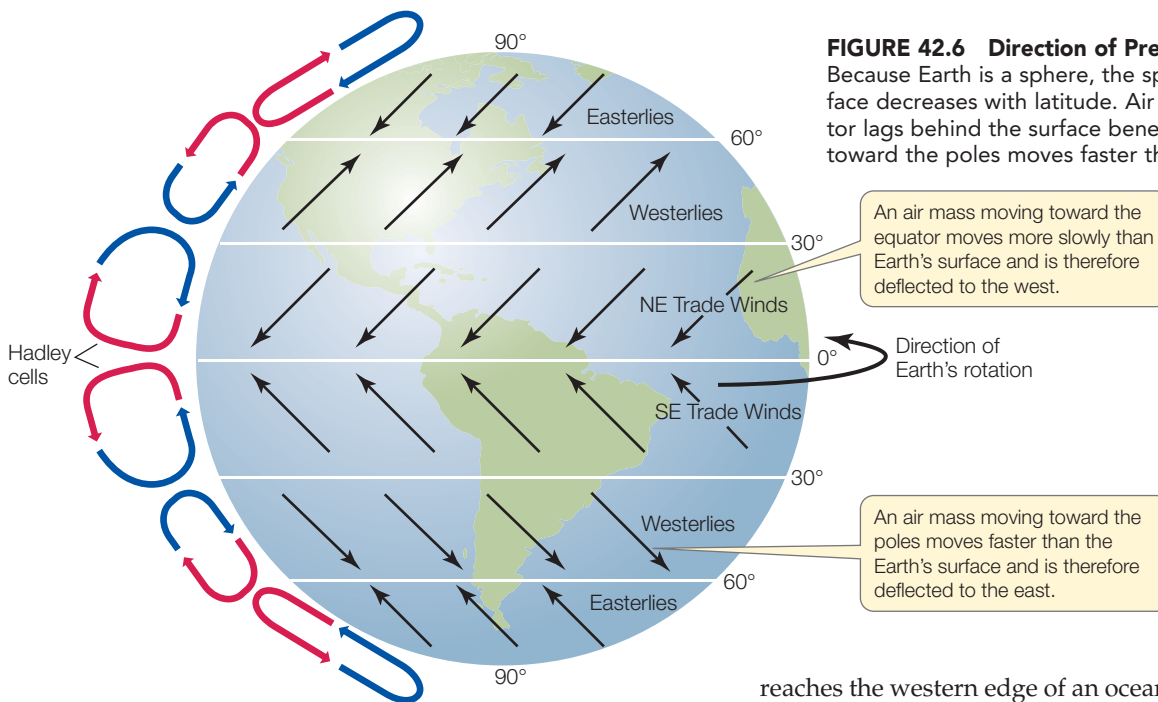

FIGURE 42.6 Direction of Prevailing Surface Winds

Because Earth is a sphere, the speed of rotation of its surface decreases with latitude. Air flowing toward the equator lags behind the surface beneath it, whereas air flowing toward the poles moves faster than the surface below.

An air mass moving toward the equator moves more slowly than Earth's surface and is therefore deflected to the west.

Direction of Earth's rotation

An air mass moving toward the poles moves faster than the Earth's surface and is therefore deflected to the east.

(the northeast or southeast *trade winds*), from west to east in the mid-latitudes (the *westerlies*), and from east to west again above 60°N or 60°S latitude (the *easterlies*; **FIGURE 42.6**).

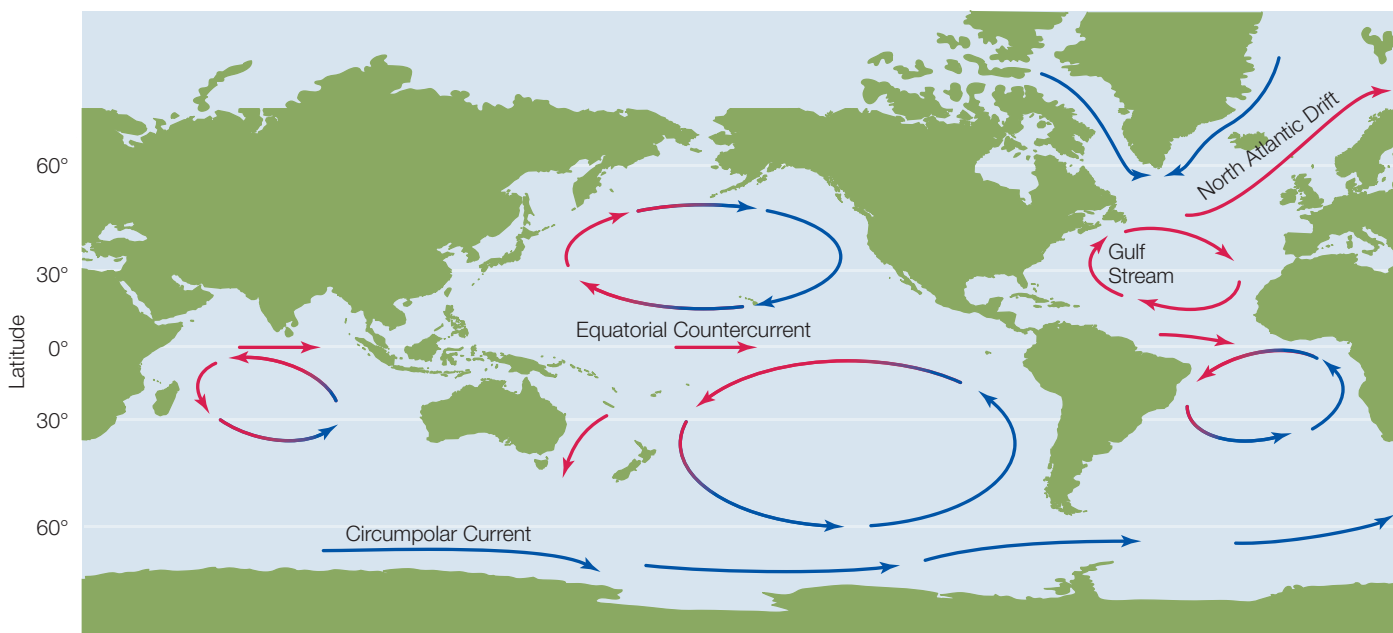

The spatial arrangement of continents and oceans influences climate

The prevailing winds drive massive circulation patterns in the surface waters of the oceans, known as **currents** (**FIGURE 42.7**). Winds move the water over which they blow by frictional drag. In the tropics, for example, the northeast trade winds drag surface waters to the west. When this westward-moving water

reaches the western edge of an oceanic basin and encounters a continent, most of it flows northward until the westerlies of the northern temperate zone drag it eastward again, completing a circuit. The water that doesn't flow north slushes back to the east near the equator because the trade winds have pushed it to a higher sea level, and it flows downhill. The pattern in the Southern Hemisphere is essentially a mirror image of that just described.

Surface currents are not the whole story. Gradients in water density caused by latitudinal variation in temperature and salinity cause surface waters to sink in certain regions, forming deep currents. These deep currents regain the surface in areas

FIGURE 42.7 Ocean Currents Ocean surface currents are driven by prevailing winds (see Figure 42.6) and are deflected by continents.

of upwelling, completing a vertical ocean circulation. Thus ocean circulation is complex and three-dimensional.

Oceans and large lakes moderate Earth's terrestrial climates because water has a high heat capacity, as we saw in Chapter 2. This means that the temperature of water changes relatively slowly as it exchanges heat with the air it contacts and as it absorbs or emits radiant energy. As a result, water temperatures fluctuate less with the seasons and with the day–night cycle than do land temperatures, and the air over land close to oceans or lakes also shows less daily and seasonal temperature fluctuation.

Furthermore, poleward-flowing ocean currents carry heat from the tropics toward the poles, moderating the climates of higher latitudes. The Gulf Stream and North Atlantic Drift, for example, bring warm water from the tropical Atlantic Ocean and the Gulf of Mexico north and east across the Atlantic, warming the air above the North Atlantic (see Figure 42.7). Prevailing westerlies then carry this warmed air across northern Europe, moderating temperatures there.

Walter climate diagrams summarize climate in an ecologically relevant way

The climate at any location can be summarized in a **climate diagram**. Modern climate diagrams were devised by the German biogeographer Heinrich Walter as a way of graphically summarizing the climate in a given location. Recognizing that ecological processes are jointly influenced by temperature and moisture, Walter superimposed graphs of average monthly temperature and precipitation through the year. He scaled the axes of the two graphs to incorporate the rule of thumb that plant growth requires at least 20 mm of precipitation per 10°C of temperature above 0°C. This scaling makes it easy to see when conditions allow terrestrial plant growth—when temperature is greater than 0°C and the precipitation line is above the temperature line—and when it is not (FIGURE 42.8).

FIGURE 42.8 Walter Climate Diagrams Summarize Climate in an Ecologically Relevant Way Walter diagrams traditionally combine the average temperature (left-hand axis) and precipitation (right-hand axis) throughout the year, as shown here for Perth, Western Australia. The summer solstice (December in Perth) is placed at the center of the diagram. The axes are scaled so that precipitation is adequate for plant growth when the precipitation line is above the temperature line. This *growing season* spans those months (shaded) with above-freezing temperature and adequate precipitation.

APPLY THE CONCEPT

Climate shapes Earth's physical environments

Shown below are the Walter climate diagrams for three different locations. Using the information in these diagrams and what you've learned about the various factors that determine a location's climate, answer the following questions and explain the logic that led to your answer.

1. Which location is near the equator?
2. Which location is close to 30°N?
3. Which location has the greatest seasonality?
4. Which location has the longest growing season?

Topography produces additional environmental heterogeneity

Earth's surface is not flat; it is rumped and crumpled into mountains, valleys, and ocean basins. This variation in the elevation of Earth's surface, known as **topography**, affects the physical environment.

Mountains, for example, are “weather formers.” Because rising air cools adiabatically, temperatures become cooler as elevation (distance above sea level) increases. If you climb a mountain, you will find that the temperature drops by about 1°C for each 220 m of elevation gained. Where prevailing winds blow over a mountain range, the mountains force the air to rise, cool, and drop its moisture as precipitation. Abundant precipitation on the windward side (the side facing into the wind) of a mountain range may lead to the growth of lush vegetation. On the leeward side (the side away from the wind), air descends and warms, and little precipitation falls (**FIGURE 42.9**). The resulting dry area on the leeward side of a mountain range is known as a “rain shadow.”

Topography also influences physical conditions in aquatic environments. The velocity of water flow, for example, is dictated by topography: water flows rapidly down steep slopes, more slowly down gradual slopes, and pools as lakes, ponds, or oceans in depressions. The depth of a water-filled depression determines gradients of many abiotic factors, including temperature, pressure, light penetration, and water movement (see Figure 42.13).

FIGURE 42.9 A Rain Shadow Precipitation tends to be lower on the leeward side of a mountain range than on the windward side, particularly when oceans lie upwind of mountain ranges.

Rain Shadow

Do You Understand Concept 42.2?

- What is the difference between weather and climate?
- Outside of the tropics, in the Northern Hemisphere we find plants adapted to warmer and drier conditions on the south-facing slopes of hills and mountains. In the Southern Hemisphere, however, such plants are found on north-facing slopes. Why?
- How would the climate of Earth differ if the axis of rotation were not tilted relative to the plane of the solar system?

How do the physical conditions imposed by variations in solar energy input and in topography influence the distributions of organisms? The physical conditions in any particular place, and their range of variation, determine which organisms can live there.

concept 42.3 Physical Geography Provides the Template for Biogeography

An organism's physiology, morphology, and behavior affect how well it can tolerate a particular physical environment. A lizard that needs to bask in the sun to raise its body temperature to an operative level, for example, cannot persist in shady environments or be active at night. Similarly, a plant that has no means of conserving water during droughts cannot thrive in a desert. As a consequence, species are found only in environments they can tolerate. Moreover, we expect species that occur in the same physical environment to have evolved means of coping with the challenges that environment presents.

LINK Some adaptations of plants to challenging climatic conditions are described in Concept 28.3

Similarities in terrestrial vegetation led to the biome concept

The naturalist–explorers of the eighteenth and nineteenth centuries laid the foundations for understanding how the distribution of Earth's physical environments shapes the distribution of organisms. The German explorer Alexander von Humboldt was particularly influential in this regard because he explicitly related his observations on the distributions of plants to his painstaking measurements of physical conditions, including latitudinal and elevational gradients in temperature. Humboldt's observations, and those of other naturalists, eventually revealed a striking convergence in the characteristics of the vegetation found in similar climates around the world.

This convergence led to the concept of a **biome**: a distinct physical environment that is inhabited by ecologically similar organisms with similar adaptations. Often the species that occupy the same biome in geographically separate regions

FIGURE 42.10 Temperature and Precipitation Gradients Determine Terrestrial Biomes Average annual temperature and precipitation determine terrestrial vegetation structure of a given locality.

The distribution of terrestrial biomes is broadly determined by annual patterns of temperature and precipitation (FIGURE 42.10). Latitudinal gradients in average temperature and its seasonal fluctuation separate tropical, subtropical, temperate, boreal, and polar biomes. Within those broad temperature zones, average annual precipitation and its seasonal fluctuation define biome types. In tropical biomes, for example, the length of the dry season determines whether tropical rainforest, tropical seasonal forest, or savanna develops. Elevational gradients in temperature also determine the distribution of biomes; for example, tundra can be found on mountaintops even in the tropics (FIGURE 42.11).

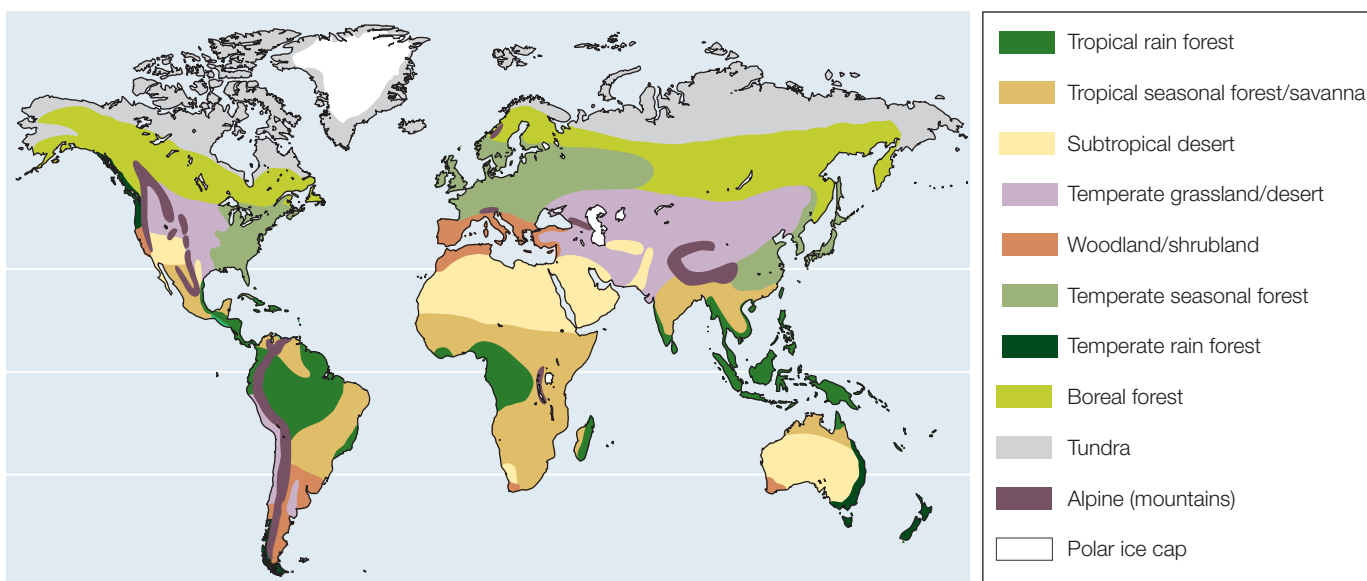

Since biomes were first recognized, ecologists have compared the attributes of organisms within and among biomes to understand how the physical environment influences their adaptations. This approach has led to the discovery that features of the physical environment other than climate—particularly soil characteristics—interact with climate to influence the character of vegetation. Southwestern Australia, for example, is one of a number of places around the world with a Mediterranean

are not closely related phylogenetically. Their morphological, physiological, or behavioral similarities therefore reflect *convergent evolution* in response to similar natural selection (see Concept 16.1). Terrestrial biomes are generally distinguished by the characteristics of their vegetation—whether the dominant plants are woody trees or shrubs, grasses, or broad-leaved herbaceous plants, and whether their leaves are big or small, deciduous (dropped seasonally) or evergreen. The attributes of other organisms vary among biomes as well, however, since other organisms are directly affected by climate, as well as manifesting indirect effects in response to the climatic adaptations of vegetation.

FIGURE 42.11 Global Terrestrial Biomes The global distribution of terrestrial biomes reflects latitudinal and elevational gradients in temperature and precipitation. The same biomes can be found in widely separated locations.

FIGURE 42.12 Same Biome, Different Continents The Mediterranean climate (described by the climate diagram in Figure 42.8) produces a convergent woodland/shrubland vegetation that is found throughout the world. (A) Southwestern Australia's Fitzgerald River National Park. (B) "Maritime" shrubland on the windward side of a California mountain, North America. (C) The region bordering the Mediterranean Sea gave this climate type its name; this "bloom of broom" is in Croatia. (D) A unique flora known as *fynbos* is found in the Cape region of South Africa.

climate in which summers are hot and dry and winters are cool and moist (see Figure 42.8). This climate supports woodland/shrubland vegetation (**FIGURE 42.12**). Succulent plants, which are well adapted to summer drought, are common in many of these places but not in southwestern Australia. What is responsible for this difference?

Southwestern Australia has extremely nutrient-poor soils. The lack of nitrogen in these soils makes it expensive for plants to construct the nitrogen-rich photosynthetic machinery of new leaves. As a result, the leaves of many plants in the region are long-lived, and they are defended against herbivores by chemical compounds that do not contain nitrogen. These defensive compounds include tough, indigestible components of plant cell walls such as lignin or silica, compounds such as tannins that reduce the nutritional quality of leaves, and toxic oils and

resins (see Concept 28.2). These defensive compounds make plant material not only very slow to decompose, so that it accumulates in the ecosystem, but also highly flammable. Plant material produced during the winter rains dries out during the summer drought and fuels intense fires that periodically sweep across the landscape. As a result, succulent plants, which are easily killed by fires, are rare in southwestern Australia.

FRONTIERS Plant scientists have formed a global consortium called Glopnet to gather and make digitally available new information about patterns in the chemical, structural, and physiological traits of leaves. The hope is that understanding how climate interacts with the adaptive characteristics of leaves will allow them to predict how biome boundaries will change with changing land use and climate.

The biome concept can be extended to aquatic environments

The biome concept can be applied to aquatic environments as well as terrestrial ones (**TABLE 42.1**). Like terrestrial organisms, aquatic organisms show convergent adaptations to similar physical environments. In aquatic environments, however,

TABLE 42.1 Major Aquatic Biomes

BIOME ^a	DESCRIPTION
FRESHWATER	
Rivers and streams	Flowing water. Many fast-flowing, small <i>source streams</i> form on high ground, feeding into networks of ever larger, slower-flowing streams and rivers. Biota adapted to constantly moving water.
Wetlands	Glades, swamps, and marshes. Rich biota adapted to water-saturated soil and/or standing fresh water.
Ponds and lakes	Significant bodies of standing fresh water. Ponds are smaller and shallower, subject to drying. Biotic zones determined by distance from shore and light penetration (see Figure 42.13A).
ESTUARIES^b	
Salt marshes	Cool-temperate stands of salt-tolerant grasses, herbaceous plants, and low-growing shrubs. Crucial to nutrient cycling and coastal protection; rich habitat supporting diverse aquatic and terrestrial life.
Mangrove forests	Tropical and warm subtropical coasts and river deltas. Dominated by mangrove trees with aerial roots (see Figure 28.11A). Rich in animal life; protect against coastal erosion.
MARINE	
Intertidal	Sandy or rocky coastlines subject to rising and falling tides; organisms adapted to withstand both submerged and dry conditions, as well as the force of waves and moving water.
Kelp forests	Found in shallow coastal waters of temperate and cold regions. Dominated by large, leaflike brown algae (kelp) that support a wide variety of marine life.
Seagrass beds	"Meadows" of monocot grasses (see Figure 21.29C) found in shallow, light-filled temperate and tropical waters.
Coral reefs	Rich, highly endangered ecosystems of shallow tropical waters. Dependent on cnidarian corals (see Figure 23.9C) and their photosynthetic endosymbionts (see Concept 20.4).
Open ocean	The <i>pelagic zone</i> (see Figure 42.13B) is rich in photosynthetic planktonic organisms that support a host of marine animals. Below the level of light penetration, the <i>abyssal zone</i> supports a fauna largely dependent on detritus that sinks down from pelagic regions.
Hydrothermal vents	Abyssal ecosystems warmed by volcanic emissions. Chemolithotrophic prokaryotes (see Concept 19.3) nourish large annelid worms (see Figure 23.17B) and other invertebrates.

^a A *benthic* region—silt, sand, or other substrate and the organisms encompassed there—occurs in all three biome types.

^b *Estuaries* are coastal biomes where the water is brackish (i.e., fresh and salt water mix).

there is no structurally dominant group of organisms like terrestrial plants that can be used to distinguish biomes, and climate is less of a distinguishing physical factor than are other abiotic factors such as water depth and movement, temperature, pressure, salinity, and characteristics of the substrate.

The primary distinction among aquatic biomes is salinity, which distinguishes freshwater (streams, ponds, and lakes), saltwater (salt lakes and oceans), and estuarine (at river mouths where fresh and salt water mix) biomes. Salinity determines what organisms are found in a biome because the salt concentration in an aquatic organism's external environment strongly affects its ability to osmoregulate (see Concept 40.1).

Freshwater biomes can be categorized by water movement. Streams form wherever precipitation exceeds evaporation, as water that does not penetrate the soil flows downhill. These streams may be small initially, but they grow as they join other streams, forming rivers that eventually reach a lake or ocean. Within streams, the velocity of the water's flow determines the strength of the current against which fish must swim and the amount of force that can dislodge bottom-dwelling organisms from the streambed. It also affects the characteristics of the stream bottom. Rapid water flow scours away sediment, exposing rocky surfaces to which organisms cling. As water slows, it deposits sediment, forming a soft bottom in which organisms can burrow.

Still-water biomes such as lakes and oceans can be divided into water-depth zones (**FIGURE 42.13**). The nearshore regions of lakes (**littoral zone**) and oceans (littoral or **intertidal zone**) are shallow, affected by wave action, and periodically exposed to air by fluctuations in water level. There is often conspicuous vertical zonation of species here according to their tolerance of heat, desiccation, and wave energy.

Because only the surface water is in contact with air, dissolved oxygen concentrations are highest in surface waters. Light, too, penetrates only a short distance into water. Photosynthetic organisms are confined to this zone of light penetration, called the **photic zone**. Aquatic vascular plants and their multicellular algal equivalents (as well as corals with their photosynthetic algal symbionts) grow where the photic zone extends to the bottom, sometimes forming communities with a complex vertical structure much like that of terrestrial plant communities. In the open-water **limnetic zone** of lakes and the **pelagic zone** of oceans beyond the continental shelf, the prominent photosynthesizers are phytoplankton.

No photosynthetic organisms occur in the **aphotic zone**, below the reach of light, which as a consequence is sparsely populated. The lake bottom or ocean floor is called the **benthic zone**. Water is heavy, and pressure increases with water depth. Temperature generally decreases with depth, because cold water is denser than warm water and sinks. Organisms that dwell

FIGURE 42.13 Water-Depth Zones Freshwater (A) and marine (B) environments can be divided into water-depth zones.

in the deepest **abyssal zone** of the oceans experience very high pressures, low oxygen levels, and (except near hydrothermal vents) cold temperatures.

Do You Understand Concept 42.3?

- What is meant by a *biome*?
- What conditions limit the distribution of photosynthetic organisms in aquatic biomes? In terrestrial biomes?
- Is it legitimate to consider the human gut a biome? Explain your answer.

We have just seen how climate, topography, and other abiotic factors influence the distributions of species. But those factors

have changed over Earth's history. How have those changes affected the distributions of species?

concept 42.4 Geological History Has Shaped the Distributions of Organisms

The naturalist–explorers of the eighteenth and nineteenth centuries showed that the physical environment shapes the distributions of organisms. But it soon became clear to them that there were other factors at work as well. The observations of one explorer suggested an important role for geological history in the distributions of organisms.

Barriers to dispersal affect the distributions of species

Alfred Russel Wallace—who, along with Charles Darwin, advanced the idea that natural selection could account for the evolution of life's diversity (see Concept 15.1)—first noticed an odd pattern of species distributions during a seven-year exploration of the Malay Archipelago. He observed that dramatically different bird faunas inhabited two neighboring islands, Bali and Lombok. Wallace pointed out that these differences could not be explained by climate or by soil characteristics, because in those respects the two islands are equivalent. Instead, Wallace suggested that the Malay Archipelago was divided into two distinct halves by a line (now known as Wallace's line) that follows a deep-water channel separating Bali and Lombok (**FIGURE 42.14**). This channel is so deep that it would have remained full of water—and thus would have been a barrier to the movement of terrestrial animals—even during the glaciations of the Pleistocene era, when sea level dropped more than 100 m and Bali and the islands to its west were connected to the Asian mainland. As a consequence, the faunas on either side of Wallace's line evolved mostly in isolation over a long period.

The movement of continents accounts for biogeographic regions

Wallace's observations of animal distributions led him to divide the world into six continental-scale areas called **biogeographic regions**. Each biogeographic region encompasses multiple biomes and contains a distinct assemblage of species, many of which are phylogenetically related. Although Wallace based his region's boundaries on animal distributions, those based on plants have similar boundaries, and the biogeographic regions as we define them today have changed little from those first proposed by Wallace (**FIGURE 42.15**). Many of the boundaries correspond to geographic barriers to movement. These include bodies of water (for terrestrial organisms); areas with extreme climates; and physical barriers such as mountain ranges. At Wallace's line, for example, the Oriental biogeographic region is separated from the Australasian biogeographic region by the deep-water channel Wallace described.

Not all biogeographic regions are bounded by obvious barriers, however, and some of them span several continents.

FIGURE 42.14 Wallace’s Line Wallace’s line corresponds to a deep-water channel that runs between the islands of Bali and Lombok. This channel would have blocked the movement of terrestrial organisms even during the Pleistocene glaciations, when sea level was 100 m lower than it is today.

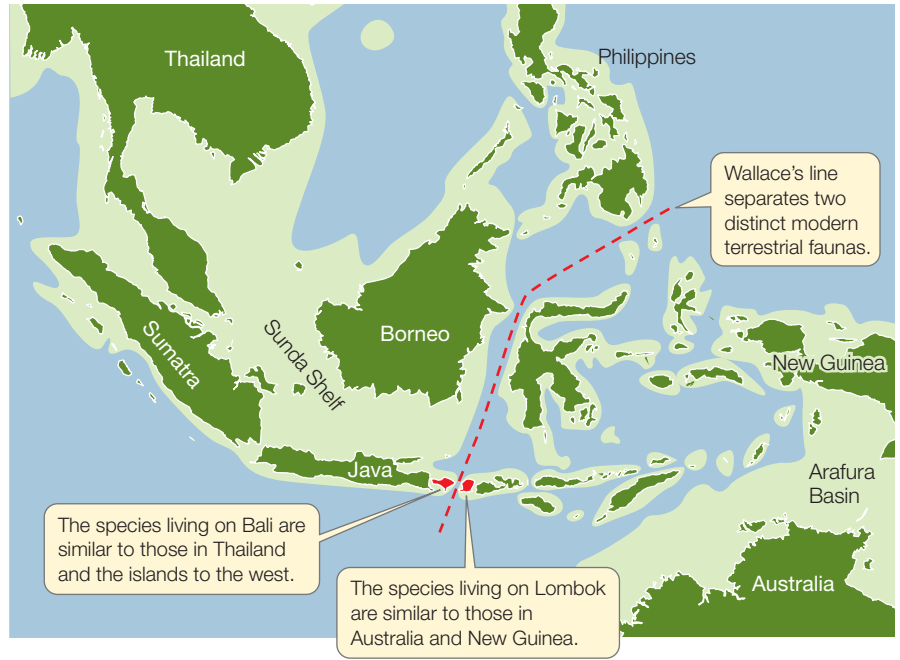

FIGURE 42.15 Movement of the Continents Shaped Earth’s Biogeographic Regions The biogeographic regions we recognize today are essentially the six regions Wallace proposed based on their distinctive assemblages of animals; modern biogeographers add an Antarctic region. Today we know that the boundaries delineating these regions are largely the result of continental drift. On this map, red arrows show the time (in millions of years) since land masses came together. Black arrows show the time since land masses separated.

yourBioPortal.com
 Go to **WEB ACTIVITY 42.1**
Major Biogeographic Regions

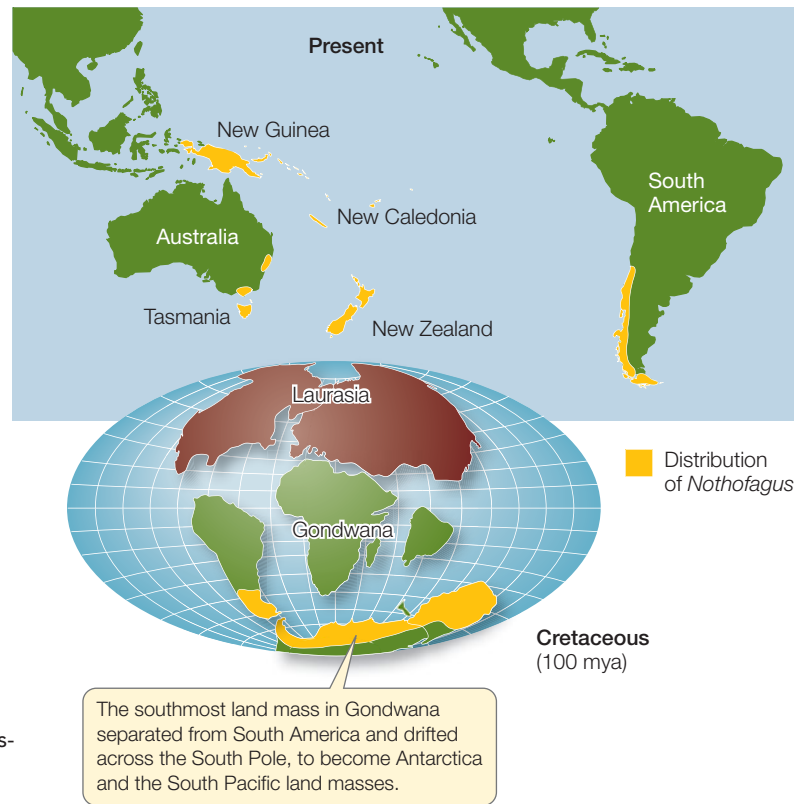

Nothofagus sp.

FIGURE 42.16 Distribution of *Nothofagus* The modern distribution of southern beeches is best explained by their origin on Gondwana during the Cretaceous period. The breakup of Gondwana and subsequent continental drift resulted in the modern distribution of *Nothofagus* in South America, Australia, New Zealand, and some islands of the South Pacific.

Why, for example, are some groups of organisms found at the southern tips of South America and Africa and in New Zealand? Conversely, why are there major biogeographic boundaries in Mexico, northern Africa, and Asia?

These aspects of biogeographic patterns remained a mystery until the second half of the twentieth century, when the theory of continental drift became widely accepted. Until then, biogeographers could only propose arbitrary explanations for the distributions of many organisms, such as rare cross-ocean colonization events or the transient appearances of land bridges. Once the movements of the continents over time were understood, however, it became clear that they have shaped the distributions of organisms by creating and disrupting dispersal routes.

One distribution that was puzzling to early biogeographers was that of southern beeches—trees of the genus *Nothofagus*. These trees are found in South America, New Zealand, Australia, and on certain islands of the southern Pacific Ocean (FIGURE 42.16). Their distribution was once thought to be the product of several separate transoceanic dispersal events. A more parsimonious explanation is that the genus originated on the southern supercontinent Gondwana during the Cretaceous period and was carried along when Gondwana broke apart and its fragments drifted to their present locations. Paleontologists have found fossilized *Nothofagus* pollen dated at over 80 mya in Australia, New Zealand, Antarctica, and South America. This fossil evidence comes from before the breakup of these portions of Gondwana, suggesting that *Nothofagus* was once widely distributed across that supercontinent.

Our understanding of continental drift makes clear that the major biogeographic regions occupy land masses that have been isolated from one another for most of the Cenozoic era—long enough to allow the organisms present at the time of isolation to undergo independent evolutionary radiations. The northern biogeographic regions (Nearctic and Palearctic) became isolated from the southern regions (Neotropical, Ethiopian, Oriental, Australasian, and Antarctic) during the Jurassic period, about 200 mya, when Pangaea broke into two great land masses, Laurasia to the north and Gondwana to the south (see Figure 18.12). The southern biogeographic regions subsequently became isolated from one another when Gondwana began to break apart during the Cretaceous period. The Neotropical, Ethiopian, Oriental, and Australasian regions were separated approximately 100 mya, and Antarctica became isolated from Australia around 45 mya. About 49 mya, the Nearctic and Palearctic regions became isolated by the opening of the Atlantic Ocean, except for a periodic connection via the Bering land bridge between Asia and North America. Thus the biotas of the seven biogeographic regions developed largely in isolation throughout the Tertiary period (about 65 to 1.8 mya), when extensive evolutionary radiations of flowering plants and vertebrates took place (see Table 18.1).

LINK The movements of the continents over geological history are depicted in Figure 18.12

Continued movements of continents have more recently eliminated some barriers to dispersal and have caused mixing of species, referred to as **biotic interchange**. The Oriental

biogeographic region was formed when India collided with Asia approximately 45 mya, allowing mixing of organisms that had previously been isolated. Interchange between Oriental and Palearctic regions was prevented by formation of the Himalayas when the Indian and Asian plates collided. Exchanges of organisms between the Ethiopian and the Palearctic regions became possible when Africa collided with Eurasia about 17 mya, but the Sahara and Arabian deserts present a climatic barrier to extensive exchange. Similarly, biotic interchange between the Neotropical and the Nearctic regions began when a land bridge formed between South America and North America about 6 mya. During this Great American Interchange, many North American species displaced South American lineages and drove them to extinction. Currently the Mexican Plateau provides a barrier to the northward dispersal of tropical species.

Phylogenetic methods contribute to our understanding of biogeography

As we saw in Chapter 16, taxonomists have developed powerful methods of reconstructing phylogenetic relationships among organisms. Biogeographers use phylogenetic information, in conjunction with the fossil record and geological history, to address questions about how the modern distributions of organisms came about. They do so by superimposing on the phylogenetic tree the geographic area that is or has been occupied by a taxon. By comparing the sequence and timing of splits in the phylogenetic tree with the sequence of separation or connection of geographic areas, biogeographers can determine where a lineage originated and reconstruct the history of its diversification and dispersal. For example, if a phylogenetic split coincides in time with the appearance of a barrier to

APPLY THE CONCEPT

Geological history has shaped the distributions of organisms

Below is a phylogenetic tree of mammals based on molecular data. This tree provides estimated dates for major nodes as well as the animals' original and current continental distributions. Refer to Figures 42.15 and 42.16 for estimated times of the separation and reunion of land masses. Use these data to answer the following questions.

1. Which one node in the tree below most clearly corresponds to an event of continental drift?
2. Are there groups of mammals that appear to have dispersed to new areas following removal of a barrier to dispersal?

dispersal, it is reasonable to conclude that the barrier caused the split by subdividing the original range of the ancestral species. If the phylogenetic split comes before or after a barrier arises, then it is likely that a portion of the ancestral population dispersed to a new location and evolved there in isolation from its ancestors.

LINK Review the effects of barriers to dispersal on speciation in Concept 16.1

Do You Understand Concept 42.4?

- What is Wallace's line?
- What kinds of barriers might limit the dispersal of terrestrial species? Of aquatic species?
- Biomes and biogeographic regions relate to two different fundamental factors that mold the distribution of organisms. Explain.

As we have seen, the makeup of ecological systems on Earth is enormously variable in time and space. Recently, however, the change has accelerated because of the activities of one species—*Homo sapiens*. How are our activities affecting the complexity and heterogeneity of ecological systems? We will address this question in the next concept.

concept 42.5 Human Activities Affect Ecological Systems on a Global Scale

Some have said that we are entering a new geological period, dubbed the “Anthropocene,” or Age of Humans, because human activities are altering ecological systems on a global scale. Humans are changing many of the factors that determine the distributions of organisms. We are spreading organisms across the globe without regard to natural barriers to dispersal; we are changing vegetation and topography; and, as Concept 46.4 will describe, we are changing Earth's climates. Others say the new age should be called the “Homogocene,” or Homogeneous Age, because by our activities we are making ecological systems less complex and more homogeneous.

Human-dominated ecosystems are more uniform than the natural ones they replace

Humans have converted almost half of Earth's land area into human-dominated ecosystems, such as croplands, pastures, and urban settlements. Agriculture is the largest human land use. Cities occupy only about 1 percent of the land, whereas an area roughly the size of South America (about 18 million km²) is cultivated, and another roughly the size of Africa (about 35 million km²) is managed as pasture or used as rangeland for cattle. As the human population continues to

FIGURE 42.17 Human Agricultural Practices Produce a Uniform Landscape The cultivation of crop plants for food and other uses diminishes the diversity of ecosystems. This monoculture is a recently harvested field of lavender (*Lavandula angustifolia*) in Provence, France.

grow, the land area devoted to agricultural and urban uses continues to increase as well.

Human-dominated ecosystems contain fewer interacting species than natural ecosystems and therefore are less complex. When an area is converted to agriculture, monocultures (plantings of single crops) often replace species-rich natural plant communities (FIGURE 42.17). Pastures or degraded rangelands often contain fewer species than natural grasslands or forests, as discussed at the start of this chapter. Furthermore, agricultural systems worldwide are dominated by relatively few plant species. Some 19 crops comprise 95 percent of total global food production. Even the highest estimate of crop diversity is a tiny fraction of the approximately 350,000 named plant species on Earth.

Agricultural systems are also more spatially and physically uniform than are natural ecological systems. Because humans provide ideal conditions for their crops by adding fertilizer or water, by planting seeds in prepared soil, and by removing enemies, cultivated species can grow in environments they would not be able to occupy on their own. Hence agricultural systems show much less spatial heterogeneity in species makeup along climatic or soil gradients than do natural ecological systems. Furthermore, because many agricultural systems are monocultures, there is little diversity in the physical structure of the habitat.

Human activities are simplifying remaining natural ecosystems

In addition to replacing natural ecological systems with human-dominated ones, human activities are reducing the complexity of the natural ecological systems that remain.

Converting land to human uses affects not only the converted land itself but also the remaining natural systems nearby. For example, when rivers are channelized or dammed to control flooding, or dewatered by irrigation diversions, species-rich natural riparian (streamside) ecosystems disappear. Similarly, land conversion reduces the area of natural systems that remain and fragments them. Human inputs, such as pollutants, alter the abiotic components of natural systems. All of these changes—habitat loss and fragmentation, pollution, water diversion or impoundment—can degrade natural ecological systems and cause species extinctions. Overexploitation of wild species for food, pharmaceuticals, or building materials can cause extinction of those species as well as others that interact with them. Even introducing new species to natural ecosystems often results in losses of native species, as we'll see in Concept 44.4.

Human-assisted dispersal of species blurs biogeographic boundaries

Humans are moving organisms around on a global scale, sometimes deliberately—as in the case of domesticated plants and animals—and sometimes inadvertently. Only about 1 percent of inadvertent introductions result in self-sustaining populations in the new locality, but the cumulative effect on geographic distributions is large nonetheless. Of the insects found both in Europe and in North America, for example, an estimated half have been transported between the two continents by humans. Similarly, more than half of the plant species on many oceanic islands are not native, and even in many continental areas the figure is 20 percent or more. The pace of introductions is astonishing: in California's San Francisco Bay, for example, an average of one new species became established every 12 weeks during the 1990s.

This human-assisted biotic interchange is homogenizing the biota of the planet, blurring the spatial heterogeneity in species composition that evolved during long periods of continental isolation. One wonders how Alfred Wallace would draw the boundaries of biogeographic regions if he were using present-day data!

Do You Understand Concept 42.5?

- Identify two human activities that alter ecosystems.
- In what ways do agricultural ecosystems differ from the natural ecosystems they replace?
- How does extinction simplify ecosystems?
- In what ways are humans making ecosystems more homogeneous?

We have seen that ecological systems are heterogeneous and complex, and that humans are altering this complexity. In order to understand and protect our planet, ecologists need new ways to make sense of ecological heterogeneity and complexity.

concept 42.6

Ecological Investigation Depends on Natural History Knowledge and Modeling

Ecologists deploy the same tools of scientific inquiry that other scientists use—observation, questioning, inductive and deductive logic, comparison, and experimentation (see Concept 1.5). However, the idiosyncrasy and complexity of ecological systems present special challenges that make certain tools particularly important. These tools include natural history and mathematical modeling.

Surprising as it may seem, **natural history**—the observation of nature outside of a formal, hypothesis-testing investigation—provides important knowledge about the many components of an ecological system, their interactions, and the environmental context of those interactions. Natural history is fundamental to virtually all stages of ecological inquiry. Often natural history observations provide the source of new questions and are critical for the formulation of hypotheses as well as for the design of ecological experiments or comparisons to test them. Laboratory studies can give misleading results if conditions are too different from those in nature, so knowledge of the natural context is essential. Similarly, the design of effective field studies rests on knowing what variable factors other than the ones of interest should be controlled, or how to impose a realistic experimental treatment that achieves the desired effect.

Our lack of natural history knowledge often limits our ability to answer important questions. For example, we cannot answer the question “Has the introduction of honey bees caused declines in native bee species?” without knowing which species were present before honey bees were introduced and how abundant they were. It turns out that this information is available for only a handful of places on Earth.

FRONTIERS To overcome our limited knowledge of Earth's diverse ecological systems, scientists are devising ways to expand our ability to observe nature and assimilate the resulting natural history data. New sensor technologies that allow real-time monitoring of physical and biological variables are giving us “new eyes on the world.” Citizen-science programs are giving us “more eyes on the world.” And computer and internet “informatics” technologies are improving our ability to compile natural history information and make it broadly available.

Models are often needed to deduce testable predictions with complex systems

As we saw in Chapter 1, hypotheses are tested by deducing what predictions follow if the hypotheses are true, and testing those predictions. Sometimes we can use simple rules of logic to develop predictions, but often we need a computer model. What is critical is that we use knowledge about the

system—natural history—to begin building the model. In the case of rangeland systems, for example, the grasses that are eaten by cattle are also affected by interactions with other plants and other herbivores, by soil fertility, by climate, and by wildfire. To predict whether removing cattle will bring back palatable grasses, we need to develop a model of the major interactions in the system that allows us to trace the various paths by which removal of cattle will affect the palatable grasses.

Now that we have explored some of the properties of ecological systems, we are ready to take a closer look, beginning with the smallest scales in the ecological hierarchy: individual organisms and populations.

Why did the rangeland restoration method that worked in Europe fail to work in the Borderlands?

ANSWER As we have seen in this chapter, the physical environment provides a template for the biological communities that inhabit a location. We have also seen that communities are molded by their evolutionary history of geographic isolation from or connection with other locations. Land managers who understand these principles realize that grasslands around the world might look similar but actually behave very differently.

The world's grasslands differ in a number of ways. Some, including many of the pastures of Europe and eastern North America, once were forests that were cleared to make way for grasses; here “resting the range” and managing the size of grazing herds can restore much of the ecosystem (**FIGURE**

FIGURE 42.18 Harmonious Grazers In Switzerland, controlled grazing and managed herd size have led to the maintenance of species-rich grasslands.

42.18). Some, such as the temperate grasslands of midwestern North America, Eurasia, and South America and the tropical savannas of Africa, have long histories of evolution with grazing mammals. Grasslands occupy a range of climatic conditions, from relatively moist to very arid.

As yet, ecologists do not completely understand why removal of cattle has not restored grasslands in the U.S.–Mexico Borderlands. They are actively researching the interacting effects of climate, soil loss, fire, and adaptations of grasses to grazing animals.

42

SUMMARY

concept 42.1 Ecological Systems Vary in Space and over Time

- An **ecological system** consists of one or more organisms and the **biotic** and **abiotic** components of the environment with which they interact.
- Ecological systems can be studied at any scale in the biological hierarchy, from an individual organism and its immediate surroundings to populations, communities, landscapes, or the entire biosphere. **Review Figure 42.1**
- Because the components of ecological systems and their interactions are distributed unevenly in space and change over time, each system, at each time, is potentially unique.

concept 42.2 Climate and Topography Shape Earth's Physical Environments

- **Weather** is the state of atmospheric conditions in a particular place at a particular time, and **climate** is their average state and pattern of variation over longer periods.

- Latitudinal differences in solar energy input are caused by differences in the angle of the sun's incoming rays. **Seasonality** results from the tilt of Earth's axis of rotation relative to its orbit around the sun. **Review Figures 42.3 and 42.4**
- Latitudinal differences in solar energy input drive north–south patterns of atmospheric circulation. These patterns, in turn, influence latitudinal patterns of precipitation. **Review Figure 42.5**
- Prevailing surface winds result from the interaction of the north–south atmospheric circulation cells with Earth's eastward rotation. **Review Figure 42.6**
- Surface **currents** in the oceans are driven by prevailing winds and deflected by continents. **Review Figure 42.7**
- **Climate diagrams** summarize climate at a particular location in an ecologically relevant way. **Review Figure 42.8**
- Variation in the elevation of Earth's surface, known as **topography**, affects the physical environment. **Review Figure 42.9 and ANIMATED TUTORIAL 42.1**

concept 42.3 Physical Geography Provides the Template for Biogeography

- A **biome** is a distinct physical environment that is inhabited by ecologically similar organisms with similar adaptations. The species that occupy the same biome in geographically separate regions may not be closely related phylogenetically but often show convergent adaptations. **See ANIMATED TUTORIAL 42.2**
- The distribution of terrestrial biomes is broadly determined by annual patterns of temperature and precipitation. **Review Figures 42.10 and 42.11**
- Other features of the physical environment—particularly soil characteristics—interact with climate to influence the character of vegetation.
- Climate is less important in distinguishing aquatic biomes than are water depth and flow, temperature, pressure, salinity, and characteristics of the substrate. **Review Figure 42.13 and Table 42.1**

concept 42.4 Geological History Has Shaped the Distributions of Organisms

- Alfred Russel Wallace first noticed a boundary, now known as Wallace's line, between two distinct assemblages of species that was not explained by climate or soil. **Review Figure 42.14**
- The world can be divided into **biogeographic regions**, each of which contains distinct assemblages of species. The boundaries of biogeographic regions generally correspond to present or past

barriers to dispersal and can be explained by continental drift. **Review Figures 42.15, 42.16, and WEB ACTIVITY 42.1**

- Biogeographers use phylogenetic information, in conjunction with the fossil record and geological history, to determine how the modern distributions of organisms came about.

concept 42.5 Human Activities Affect Ecological Systems on a Global Scale

- Humans have converted almost half of Earth's land area into human-dominated ecosystems, which are much more homogeneous and less complex than natural ecosystems, and human activities are reducing the complexity of the natural ecological systems that remain.
- Humans move species around the globe without regard to natural barriers to dispersal. These movements are homogenizing the biota of the planet.

concept 42.6 Ecological Investigation Depends on Natural History Knowledge and Modeling

- Accurate and reliable knowledge of **natural history**—that is, information about the components of ecological systems, their interactions, and the environmental context of those interactions—is crucial to the study of ecology.
- Developing computer models of the major components of an ecological system and their interactions is often needed to generate testable predictions about these complex systems.

Populations

43

Ecologist Rick Ostfeld was studying white-footed mice (*Peromyscus leucopus*) and eastern chipmunks (*Tamias striatus*) at the Cary Institute of Ecosystem Studies in Millbrook, New York, when an unexpected event took his work in a new direction. Ostfeld and his colleague Clive Jones were working on these rodents in order to understand what triggers the dramatic once-in-a-decade outbreaks of the introduced gypsy moth (*Lymantria dispar*) that defoliate oak forests in North America. They suspected that outbreaks start when the moths escape control by mice and chipmunks, which eat moth pupae.

Soon after the study began in 1991, one of the field assistants discovered that half his face was paralyzed and he could not close one eyelid. (He devised a protective eye patch so he would be allowed to continue his fieldwork.) The eventual diagnosis was Lyme disease. Scientists at the time were only beginning to understand this disease, which was not described until 1975 and whose cause—infection by spirochete bacteria of the genus *Borrelia*—was not discovered until 1982. By 1991, epidemiologists had found out that Lyme disease is transmitted by black-legged ticks (*Ixodes scapularis*), which become infected with *Borrelia* when they bite infected hosts, and that Lyme disease risk increases with the abundance of infected ticks. Tick hosts include white-tailed deer, birds, lizards, and rodents as well as humans.

Millbrook turned out to be at the epicenter of the emerging Lyme disease epidemic, and Ostfeld focused his attention on black-legged ticks, recognizing that they are vectors that transmit the bacterial disease. He was already counting ticks on live-trapped mice and chipmunks. Now he began to study how the abundance of rodents and other vertebrate hosts affects

A field worker sweeps for ticks in the forests near Millbrook, New York.

tick abundance and infection rate. He discovered that rodents are the primary reservoir for *Borrelia*. Ticks are not infected when they hatch from eggs as larvae; they become infected when they bite an infected host as a larva or nymph. It turns out that birds and lizards do not harbor *Borrelia*, and that most ticks are already infected by the time they are adults able to climb high into the vegetation, where they encounter large hosts such as deer.

From his previous work, Ostfeld already knew that rodent abundance soars when oaks produce a big acorn crop. Now he found that the number of tick larvae that survive to become nymphs, and of nymphs that survive to become adults, increases with rodent numbers.

How does understanding the population ecology of disease vectors help us combat infectious diseases?

KEY CONCEPTS

- 43.1** Populations Are Patchy in Space and Dynamic over Time
- 43.2** Births Increase and Deaths Decrease Population Size
- 43.3** Life Histories Determine Population Growth Rates
- 43.4** Populations Grow Multiplicatively, but Not for Long
- 43.5** Extinction and Recolonization Affect Population Dynamics
- 43.6** Ecology Provides Tools for Managing Populations

FIGURE 43.2 Population Densities Are Dynamic and Interconnected Densities of acorns, rodents, and nymphal *Ixodes scapularis* (black-legged tick) populations vary over time in the oak forests near Millbrook, New York. Note that rodent density tends to follow acorn density with a 1-year lag, and tick density tracks rodent density with the same time lag.

of rodents, black-legged ticks, and oak acorns vary greatly from year to year (FIGURE 43.2).

FRONTIERS Population studies are often thwarted because individual organisms cannot be marked and followed. Wild bumble bees, for example, are critical pollinators for many plants, including crops. Ecologists and crop scientists want to understand their movements in order to take best advantage of their free pollination services. But how to follow a bumble bee that weighs only as much as a few postage stamps? Ingenious new technologies such as harmonic radar and microchip transponders now allow ecologists to glue tiny tags to bumble bees and follow them as they move through real landscapes.

Do You Understand Concept 43.1?

- For what practical reasons do humans wish to influence the abundance of some species?
- What aspects of abundance do population density and population size measure, respectively?
- Barriers to dispersal and environmental tolerance both influence where a species is found. Which of these factors is more important in determining the geographic range of a species, and which is more important in determining which habitats it occupies within the geographic range?

Why do species abundances vary in time and space? To answer this question, we need to understand the processes that add individuals to or subtract them from populations. The study of these processes is known as *demography* (Greek *demos*, “population”; *-graphia*, “description”).

concept 43.2 Births Increase and Deaths Decrease Population Size

The size of anything, whether a bank account or a population, changes over time through additions and subtractions. Consider the size of something in the future—for example the size of your bank account. It is equal to the size now plus what is added, minus what is taken away. What differs between bank balances and populations are the processes that add or subtract. In the case of your bank account, deposits and interest add to your balance, while withdrawals and bank fees subtract. In the case of populations, births (or the production of seeds in the case of plants) add individuals and deaths remove individuals. To spell this out,

The number of individuals in a population at some time in the future =

the number now + the number that are born – the number that die

If we turn this word equation into symbols, we have the most basic mathematical model of population growth:

$$N_{t+1} = N_t + B - D \quad \text{Equation 43.1}$$

where N is the population size, B is the number of births in the time interval from time t to time $t + 1$, and D is the number of deaths in that same interval. Ecologists call this the “birth–death” or **BD model** of population change.

We can use Equation 43.1 to calculate population size into the future. Most often, the population size will change over time—it will either grow or shrink. How much it changes in a period of time indicates how fast it is changing. Ecologists call this rate of change the *growth rate* of the population (a somewhat confusing term until we realize that when a population shrinks, its growth rate is negative). The population growth rate can be obtained from Equation 43.1 by subtracting N_t (the present population size) from both sides of the equation:

$$N_{t+1} - N_t = \Delta N = B - D$$

The term ΔN means change in population size (using the convention that the Greek letter delta means “change in”). To make more explicit that this is a rate—a change through time—we can divide both sides by ΔT , the time interval from t to $t + 1$:

$$\frac{\Delta N}{\Delta T} = \frac{B - D}{(t + 1) - t} = \frac{B - D}{1} = B - D \quad \text{Equation 43.2}$$

This shows, logically enough, that the change in size over one time interval is the number of births minus the number of deaths during that interval.

Change in size of the total population can be measured directly only for very small, discrete populations, such as a zoo population. Ecologists can get around this difficulty by keeping track of a sample of individuals (a *cohort*) over time. From this sample, they can estimate the number of offspring that an average individual produces, called the *per capita birth rate* (b),

APPLY THE CONCEPT

Births increase and deaths decrease population size

Rancher Jane is thinking of shifting her operation from cattle to American bison (*Bison bison*), but she needs to know how well bison will do on her ranch. She buys 50 female bison that are already inseminated and places 10 of them, picked at random, into their own pasture. These 10 females serve as a sample from which Rancher Jane collects demographic data over one year. Use her data to answer the questions below.

1. What is the total number of births and deaths among this sample population?
2. What are the estimated average per capita birth and death rates (b and d) for the entire bison herd, based on this sample?
3. What is estimated per capita growth rate r ?
4. Based on these estimates, what is the size of Rancher Jane's entire bison herd at the end of the year? (Hint: Use Equation 43.3.)

FEMALE #	ALIVE AT END OF YEAR?	NUMBER OF OFFSPRING
1	Yes	1
2	Yes	0
3	Yes	1
4	Yes	0
5	No	0
6	Yes	1
7	Yes	1
8	No	0
9	Yes	1
10	Yes	0

and the average individual's chance of dying, called the *per capita death rate* (d), in some interval of time. *Per capita* (literally "per head") means "per individual." Total birth and death rates in the population can then be estimated by multiplying per capita birth and death rates by population size, so that $B = bN_t$ and $D = dN_t$. Substituting into Equation 43.1, we have

$$N_{t+1} = N_t + bN_t - dN_t$$

or, equivalently,

$$N_{t+1} = N_t + (b - d)N_t$$

The value $(b - d)$ is the difference between per capita birth rate and per capita death rate and represents the average individual's contribution to total population growth rate. This value is the **per capita growth rate**, which ecologists symbolize as r . Substituting r for $(b - d)$, we have

$$N_{t+1} = N_t + rN_t \quad \text{Equation 43.3}$$

Converting this into an equation of growth rate analogous to equation 43.2, we get

$$\frac{\Delta N}{\Delta T} = rN \quad \text{Equation 43.4}$$

What happens if per capita birth rate is greater than per capita death rate, or death rate greater than birth rate, or they are equal? If $b > d$, then $r > 0$, and the population grows. If $b < d$, then $r < 0$, and the population shrinks. If $b = d$, then $r = 0$, and the population size does not change.

We are now in a better position to understand why population sizes or densities change over time: they *have to* unless the number of births exactly equals the number of deaths. We are also in a better position to understand why population densities vary in space. We saw in Chapter 42 that barriers

to dispersal can cause species to be absent from some places. Another possible reason for a species' absence from a region is a negative population growth rate. A species will not persist in a given location if its per capita growth rate, r , is negative there. Any population that decreases steadily in size over time eventually reaches a density of zero—that is, it goes extinct.

Do You Understand Concept 43.2?

- What is the relationship between per capita birth rate and total births in a population during a time period?
- What do we need in addition to estimates of per capita birth and death rates in order to predict population size at some future time?
- What two strategies could rancher Jane (see "Apply the Concept") use to expand her bison herd faster?

We can understand the dynamics of whole populations, and even some aspects of species' distributions, if we know about the average birth and death rates of the individuals that constitute those populations. What determines these demographic variables?

concept 43.3 Life Histories Determine Population Growth Rates

The demographic processes that influence birth, death, and population growth rates can best be understood in the context of a species' **life history**—the time course of growth and

development, reproduction, and death during an average individual's life.

Life histories are quantitative descriptions of life cycles

Life histories are, in essence, quantitative descriptions of life cycles. To describe the life cycle of the black-legged tick, for example, we can begin with one of the thousands of eggs laid by an adult female in spring (FIGURE 43.3). The egg hatches into a larva in mid-summer. If the larva can obtain a blood meal from a rodent, bird, or lizard, it molts into a nymph and goes dormant for the winter. If it survives the winter, the nymph becomes active again the following summer and seeks another blood meal from a vertebrate host. If it is successful, it molts into the adult stage and seeks a large mammal host (often a deer; hence these are sometimes called deer ticks) in the fall. It mates on this final host and if it is a female it goes dormant for another winter, lays eggs in the spring, and then dies.

A quantitative description of a black-legged tick's life cycle would indicate at what age individuals make life-cycle transitions and how many do so successfully: the fraction of eggs that hatch successfully, of larvae that find a host and molt successfully into nymphs, of nymphs that live through the winter, find a host, and molt into adults; and the number of eggs that the average adult female lays. This information can be summarized in a **life table**.

TABLE 43.1 shows a life table for a cohort of 210 cactus ground finches (*Geospiza scandens*) on Isla Daphne in the Galápagos. Life tables contain two types of information: the fraction of individuals that survive from birth to different life stages or ages, called **survivorship**, and the average number of offspring each individual produces at those life stages or ages if they do survive, called **fecundity**. Survivorship can also be expressed as its opposite, *mortality*, which is the fraction of individuals that do not survive from birth to a given stage or age (mortality = 1 – survivorship). Life tables thus can be used to calculate per capita growth rates (r). Although the calculations involved are complex, in general it is not hard to see how survivorship and fecundity affect r . All else being equal, the higher the fecundity and the higher the survivorship, the higher r will be. If reproduction shifts to earlier ages, r will increase as well.

Life histories are diverse

Species vary considerably in how many and what types of developmental stages they go through, how old they are when they begin to reproduce, how often they reproduce, how many offspring they produce, and how long they live. Black-legged ticks spin out their lives over 2 years, whereas the life cycle of a periodic cicada takes nearly 2 decades. Other arthropods have life spans of days or weeks. Some species, like the tick, go through a discrete series of life stages of variable duration,

FIGURE 43.3 Life History of the Black-Legged Tick The seasonality of the ticks' environment and the difficulty in obtaining the blood meal necessary for metamorphosis have produced a 2-year life cycle that includes two long periods of winter dormancy.

TABLE 43.1

Life Table for the 1978 Cohort of Cactus Ground Finch on Isla Daphne

CALENDAR YEAR	AGE OF BIRD (YEARS)	SURVIVORSHIP ^a	FECUNDITY ^b
1978	0 (hatchlings)	1.00	0.00
1979	1	0.43	0.05
1980	2	0.37	0.67
1981	3	0.33	1.50
1982	4	0.31	0.66
1983 Increased rain	5	0.30	5.50
1984	6	0.20	0.69
1985 Drought	7	0.11	0.00
1986	8	0.07	0.00
1987	9	0.07	2.20
1988	10	0.05	0.00
1989	11	0.05	0.00

^aSurvivorship = the proportion of the original cohort (here, 210 birds) surviving from fledging to age x .

^bFecundity = average number of young fledged per female of age x .

each separated by a molt. Other species, such as humans, develop continuously as they age. Some plants germinate, grow, flower, produce seeds, and die all in one growing season—they are annuals (see Concept 27.2). Other plants live for centuries. Some species spend long periods in a dormant state, whereas others are continuously active. Some organisms, including the tick, reproduce only once and then die, whereas others, such as humans, can reproduce multiple times.

Life histories vary not only among species but within species as well, including among human populations. *Life expectancy* (the age to which an average person survives) among the short-statured, nomadic Aeta people of the Philippines, for example, is 16.5 years, and girls reach puberty at age 12. The taller-statured, pastoralist Turkana of East Africa experience food shortages as frequently as the Aeta but have a life expectancy of 47.5 years, and Turkana women reach sexual maturity at age 15. In well-nourished United States populations, life expectancy is almost 79 years—much greater than for either the Aeta or the Turkana—yet girls in the U.S. reach puberty at age 12 years on average.

Resources and physical conditions shape life histories

Individual organisms must acquire materials and energy to maintain homeostasis and to fuel metabolism, growth, activity, defense, and reproduction. Materials and energy—and the time available to acquire them—constitute **resources**. Organisms also need *physical conditions* that they are able to tolerate.

The primary distinction between resources and conditions is that resources can be used up (e.g., mineral nutrients, photons of light, time, space, or food items), whereas conditions are experienced but not consumed.

The rate at which an organism can acquire resources increases with the availability of resources in the environment. A plant's net photosynthetic rate, for example, increases with sunlight intensity (FIGURE 43.4A). Similarly, an animal's rate of food intake increases with the density of food (FIGURE 43.4B).

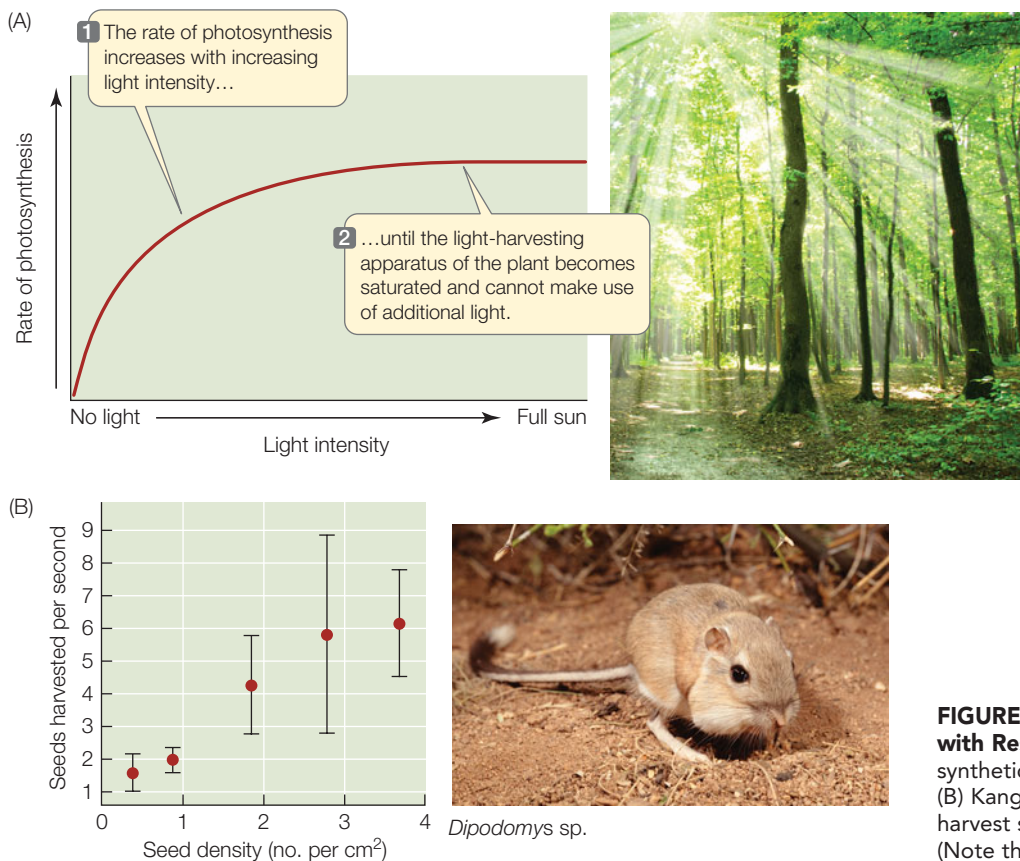

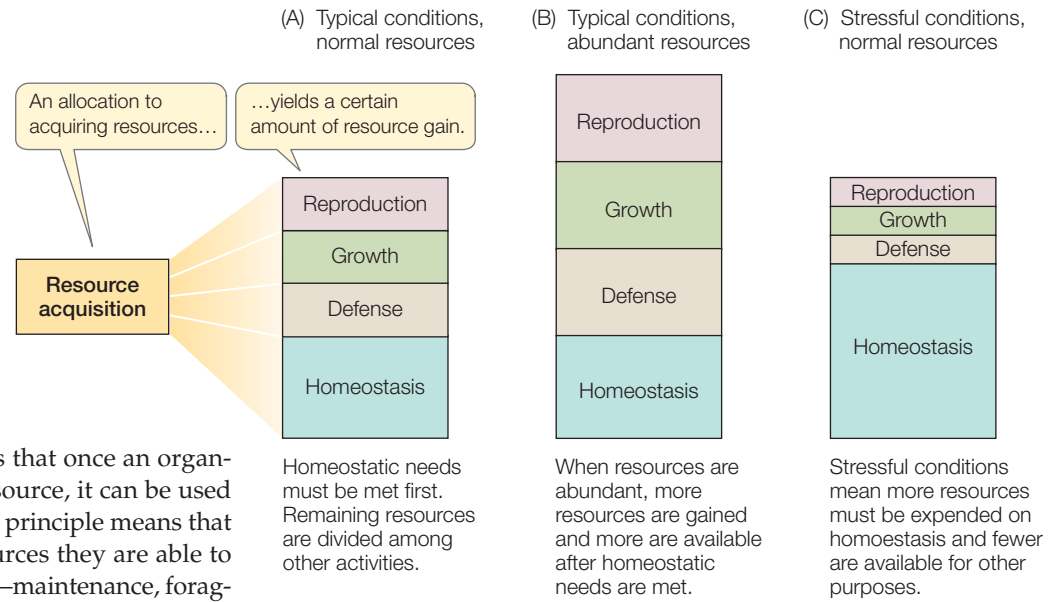

FIGURE 43.4 Resource Acquisition Increases with Resource Availability (A) Plant photosynthetic rate increases with light intensity. (B) Kangaroo rats (*Dipodomys* spp.) are able to harvest seeds faster as seed density increases. (Note the cheek pouch bulging with seeds.)

FIGURE 43.5 The Principle of Allocation Organisms use energy to acquire resources, including foraging for food. The organism then must allocate those resources among competing life functions. In general, an organism's first priority is to maintain the integrity of its body. This figure shows the same amount of energy being allocated to resource acquisition in all three cases.

The **principle of allocation** states that once an organism has acquired a unit of some resource, it can be used for only one function at a time. This principle means that organisms have to divide the resources they are able to obtain among competing functions—maintenance, foraging, growth, defense, and reproduction (FIGURE 43.5). In general, an organism's first priority is to maintain the integrity of its body. Because maintaining homeostasis is more difficult under stressful physical conditions (as was illustrated for temperature in Chapter 29), investment in maintenance is greater in stressful than in benign environments. For example, the hotter their desert environment, the more time day-active lizards must spend in a cool retreat to keep body temperature below a lethal level, and thus the less time they have to look for food (see Figure 29.12). Once an organism obtains more resources than it needs for maintenance, it can allocate the excess to other functions. In general, as the average individual in a population acquires more resources, the average fecundity, survivorship, and per capita growth rate increase.

Life history variation among species and populations often reflects the principle of allocation. A species that invests heavily in growth early in life, for example, cannot simultaneously invest heavily in defense—for example, in protective structures or chemical defenses. As a consequence it reaches adult size quickly, but at the cost of lower survivorship than a species that invests more in defense. A species that starts investing in reproduction early in development grows more slowly and matures at a smaller adult size than a species that waits to reproduce. Species that invest heavily in reproduction often do so at the expense of adult survivorship. They have high fecundity, but short life spans. Such negative relationships among growth, reproduction, and survival are called *life-history tradeoffs*.

The environment shapes much of this life history variation because, together with a species' way of life, it determines the relative costs and benefits, in terms of survivorship and fecundity, of any particular allocation pattern. The Aeta people mentioned earlier, for example, live in an environment that imposes much higher mortality than the Turkana experience. High mortality means that the benefit of early reproduction (more individuals survive to reproduce at least once) outweighs the fecundity benefit of growing to a larger adult size (in general, human females produce 0.24 more offspring per additional centimeter of height). Most Aeta women reach puberty and stop growing at about 12 years of age, at an adult height of 140 cm. For the

Turkana, the lower mortality rate shifts the balance—the advantage of early reproduction is outweighed by the fecundity advantage of larger adult size. Turkana women mature at age 15 and an average height of 166 cm. In the United States, plentiful food and modern medicine reduce the cost of maturing early—girls grow fast and mature early at an adult size equivalent to the Turkana.

Similarly, the short summers in New York State make it advantageous for black-legged tick nymphs to invest in overwinter survival, even though it means they do not reproduce until their second year (see Figure 43.3). Ticks find their host by waiting: they climb up on vegetation, extend their forelegs, and climb aboard when a host bumps into them. Finding a host is such a rare event that a tick can expect at most one meal during the short growing season. As a result, nymphs do not allocate resources to further host-seeking behavior during their first season of life, but instead allocate resources to overwinter survival. The fact that ticks take 2 years to complete their life cycle is thus a consequence of the difficulty in obtaining a host and the seasonality of the environment.

Species' distributions reflect the effects of environment on per capita growth rates

Because a population cannot persist in an environment where its per capita growth rate is negative, we should be able to predict species' distributions from knowledge of how survivorship and fecundity are affected by resource availability and physical conditions. But obtaining complete knowledge of life histories is often impossible for species in the wild. Even incomplete knowledge, however, can help us understand aspects of species' distributions. FIGURE 43.6 illustrates this point for the lizard *Sceloporus serrifer*. By combining measurements of conditions in the animal's natural environment with knowledge of its physiology and behavior, researchers were able to draw conclusions about how climate change can affect survivorship, fecundity, and distribution of these lizards.

INVESTIGATION

FIGURE 43.6 Climate Warming Stresses Spiny Lizards

Barry Sinervo and colleagues investigated whether higher daytime temperatures can reduce the number of hours that Mexican blue spiny lizards (*Sceloporus serrifer*) can remain outside their burrows

without overheating. The researchers knew that climate warming was taking place in Mexico, and that the lizards cannot feed while inside their burrows.

HYPOTHESIS

Spiny lizards are able to forage for fewer hours on hotter days.

METHOD

1. Construct model "lizards" that have the same thermal properties as actual lizards.

2. At 4 sites in the Yucatán, place model lizards in various sunny and shady perches known to be used by real lizards in 1975. In 2008, monitor body temperature of the models and record maximum daily air temperatures throughout the breeding season (March and April).
3. For each day, calculate the number of daylight hours when the body temperature T_b of the thermal models exceeded 31°C —the temperature at which *S. serrifer* are known to retreat to their burrows and become inactive.
4. Determine whether the number of inactive hours increased with maximum air temperature.

RESULTS

The number of hours during which lizards were inactive—and hence could not forage—increased by 0.74 hours for each $^\circ\text{C}$ of increase in daily maximum air temperature ($P < 0.001$).

CONCLUSION

Climate warming can decrease the number of hours per day when *S. serrifer* can forage without overheating.

ANALYZE THE DATA

Between 1975 and 2008, the *S. serrifer* populations went extinct at two of the four sites surveyed. Examine the graph at right and answer the questions below.

- A. How did the hours available for foraging differ between sites where the lizards had gone extinct versus where they persisted?
- B. How might that difference in foraging time influence lizard fecundity, survivorship, and per capita growth rates?
- C. Could global warming have caused the extinctions of the lizard populations? Explain your answer.

Sometimes it is possible to explore the links between environmental conditions, life histories, and species distributions with the help of experiments carried out in the laboratory. Charles Birch used this approach to understand why two species of beetles that infest stored grain are serious pests in some parts of Australia but not in others. In his laboratory, Birch reared populations of the rice weevil (*Sitophilus oryzae*, known in Birch's time as *Calandra oryzae*) and the lesser grain borer

(*Rhyzopertha dominica*) under various conditions of temperature and humidity. He constructed life tables for each set of conditions and used the tables to calculate per capita growth rates for each species. The results, summarized in **FIGURE 43.7**, explain the more tropical distribution of *R. dominica*. In addition, both species had negative per capita growth rates in cool, dry environments, suggesting a strategy for minimizing grain losses: keep the grain cool and dry.

*Sitophilus oryzae* (rice weevil)*Rhyzopertha dominica* (lesser grain borer)

FIGURE 43.7 Environmental Conditions Affect Per Capita Growth Rates and Species Distributions Charles Birch's laboratory research revealed that *R. dominica* populations perform better under warmer conditions than did *S. oryzae* populations, thus explaining why *R. dominica* has a more tropical distribution. The lines marked $r = 0$ indicate the limit of the conditions under which populations of each species can grow; within the hatched areas, per capita growth rates are positive for the species.

concept 43.4 Populations Grow Multiplicatively, but Not for Long

We saw in Concept 43.2 that a population will grow as long as the per capita growth rate, r , is greater than zero. Recall also that r refers to a specific period of time (it might be a day, a week, or a year, depending on the species) over which we have estimated per capita rates of birth and death. During this period, the population will add a number of individuals that is precisely r times its initial size. We actually saw this in equation 43.3, which states that $N_{t+1} = N_t + rN_t$. What may not be obvious at first is that this continues in the next period—the population will again add a multiple r of its numbers, since $N_{t+2} = N_{t+1} + rN_{t+1}$. Because N_{t+1} was already larger than the initial population N_t , this means that an ever-larger number of individuals is added in each successive period of time. Thus the growth is **multiplicative**. Multiplicative growth differs dramatically in its form from **additive growth**, in which a constant *number* (rather than a constant *multiple*) is added in each time period:

Populations Grow Multiplicatively, but Not for Long

Do You Understand Concept 43.3?

- An organism can allocate a unit of resource to which five functions?
- What is the relationship between a life history and a life table?
- Female hummingbirds abandon their young in the nest when food supply declines. What does this imply about their allocation priorities?
- Ecologists added predatory fish to some streams, leaving other streams as controls. How do you expect size and age of first reproduction of prey fish to evolve in the presence of predators? (Hint: consider the example of the Aeta and Turkana)

Knowing whether population growth rates are negative or positive in particular environments tells us why species are absent or present. But this knowledge does not help us to understand why population densities vary among locations where population growth rates are positive. To do so, we must take a closer look at the dynamics of population growth.

Multiplicative growth generates large numbers very quickly

We naturally tend to think in terms of additive growth, and multiplicative growth astonishes us with the phenomenal numbers it can generate in a short amount of time. For example, in 1911, L. O. Howard, then chief entomologist of the U. S. Department of Agriculture, estimated that a pair of flies reproducing for the first time on April 15 would produce a population of 5,598,720,000 adults by September 10 if all the offspring survived and reproduced. Other entomologists disagreed with Howard's calculation—they pegged the number much *higher*!

Charles Darwin was well aware of the power of multiplicative growth:

[E]very organic being naturally increases at so high a rate, that, if not destroyed, the earth would soon be covered by the progeny of a single pair. ...[A]s more individuals are produced than can possibly survive, there must in every case be a struggle for existence.

This ecological struggle for existence, fueled by multiplicative growth, is what drives natural selection and adaptation.

LINK Darwin's theory of natural selection is described in Concepts 15.1 and 15.2.

Multiplicatively growing populations have a constant doubling time

Multiplicative growth characterizes many phenomena other than population growth that affect our everyday lives. These include interest-bearing bank accounts, fossil-fuel consumption, and radioactive decay (see Figure 18.1). Our tendency to think in additive terms impedes our ability to comprehend these phenomena and to understand their practical implications. For example, how much more money will we have in 5 years if we invest \$1,000 in a bank account that earns 2% per year as opposed to 1% per year? How does the drop in per capita rate of growth of the human population, from 0.022 in 1963 to the current 0.013 per year, change our estimates of future population size? Answering these questions requires an understanding of multiplicative growth.

Multiplicative growth has a very striking property: a constant **doubling time**. Because a population growing multiplicatively adds a constant multiple of itself each time period, the amount added increases over time. At some specific time period, the amount added exactly equals the initial population, and the population has doubled. As long as r does not change, the time the population takes to double will also remain constant. The time to double can be calculated if we know r . It is easy to see the implications of multiplicative growth if we

think in terms of doubling times. By doing so, municipalities, for example, would realize that even a seemingly small growth rate of 3% per year would mean that the population would double every 23 years, and that its sewage treatment capacity and other such municipal services would need to do the same.

Density dependence prevents populations from growing indefinitely

If populations grow multiplicatively, why isn't Earth covered with flies, or any other organism? It turns out that populations do not show the J-shaped growth pattern of multiplicative growth (red line in the graph below) for very long. Instead of continuing to increase, population growth slows and usually reaches a more or less steady size. The simplest example is so-called *logistic growth*:

yourBioPortal.com

Go to WEB ACTIVITY 43.1
Population Growth

APPLY THE CONCEPT

Multiplicatively growing populations have a constant doubling time

Yellow star-thistle (*Centaurea solstitialis*) is a spiny annual plant native to the Mediterranean region. The species is a noxious weed that has invaded several regions of the United States. It is unpalatable to livestock (including American bison). Rancher Jane discovers that 1 hectare of the 128-hectare pasture into which she placed her sample cohort of 10 female bison has been invaded by star-thistle. A year later she finds the weed population has grown to cover 2 hectares.

1. Based on the information above, how many hectares do you predict the star-thistle population will cover in 1, 2, and 3 more years if the population is growing additively? How many hectares if the population is growing multiplicatively?
2. Imagine that Rancher Jane only discovers the star-thistle population after it has already covered 32 hectares of her pasture. How many years does she have until the weed completely covers the pasture if its population is growing additively? Multiplicatively?

The invasive yellow star-thistle is noxious to grazing livestock.

Go to ANIMATED TUTORIALS 43.1 and 43.2
 Multiplicative Population Growth
 Logistic Population Growth

Why do populations stop growing? Upon examination, we see that population growth slows because r decreases as the population becomes more crowded—that is, r is **density dependent**. At low population densities, per capita growth rates are at their highest. As the population grows and becomes more crowded, birth rates tend to decrease and death rates tend to increase. As a result, r decreases as population density increases

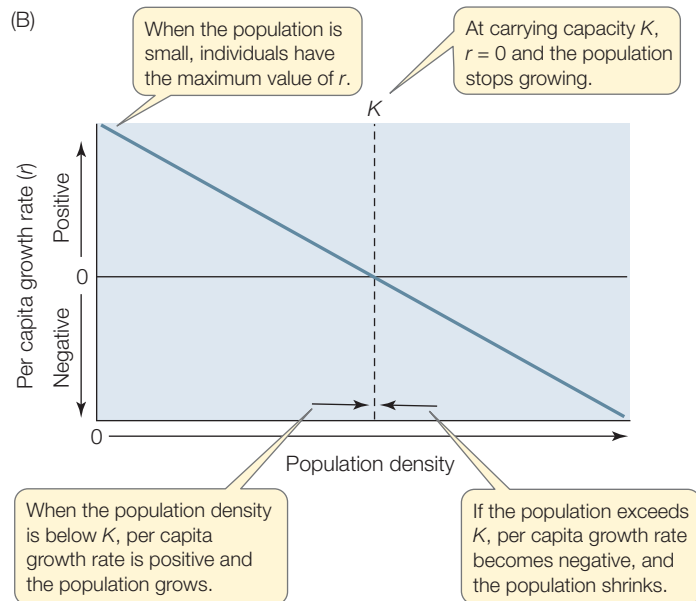

FIGURE 43.8 Per Capita Growth Rate Decreases with Population Density (A) The decline in r as population density increases for in a population of a small crustacean, *Daphnia pulex*. (B) Schematic representation of logistic growth, the simplest form of density dependence, in which r declines linearly with population density.

(FIGURE 43.8A), and eventually reaches zero. When $r = 0$, the population stops changing in size—it reaches an **equilibrium** size that is called the carrying capacity, or K (FIGURE 43.8B). K can be thought of as the number of individuals the environment can support indefinitely. If individuals are added to the population so that it exceeds the carrying capacity, per capita growth rate becomes negative, and the population shrinks. If the population falls below K , per capita growth rate becomes positive, and the population grows.

Why does r decrease with crowding? When an organism uses a resource, it makes it unavailable to other organisms. Therefore, as population density increases, each individual gets a smaller piece of the resource “pie” and has fewer resources to allocate to its life functions (see Figure 43.5). Birth rate decreases, death rate increases, and r decreases with population density. Once again it is useful to spell this out:

Per capita growth rate =
 the maximum possible value in uncrowded conditions –
 an amount that is a function of density

When population density reaches K , the carrying capacity, each individual has just the amount of resources it needs in order to produce enough offspring to exactly replace itself when it dies. When density is less than K , each individual can more than replace itself; when density is greater than K , each individual has less than it needs to replace itself.

Now we are prepared to return to the question posed at the end of Concept 43.3: What causes temporal and spatial variation in population density?

Variable environmental conditions cause the carrying capacity to change

We have learned that resource availability in the environment affects an individual’s success in acquiring resources (see Figure 43.4), and that physical conditions affect the costs of maintaining homeostasis (see Figure 43.5). If these factors vary over space, then the carrying capacity will vary over space as well.

Similarly, if resources or environmental conditions are good in one year but bad in another, the population will find itself alternately above and below the current carrying capacity. As a result, populations will fluctuate around an average K over time. Figure 43.2 illustrates this dynamic for rodents and ticks in Millbrook, New York. Rodent densities increase following years of high acorn production because the rodents have enough food to produce many offspring, and they decrease following poor acorn years. Similarly, nymphal tick densities go up and down following high and low rodent years, respectively, because rodent abundance determines the success of larval ticks in obtaining a blood meal.

A look back at Table 43.1 shows how temporal changes in the environment affected the fecundity of a group (cohort) of 210 cactus ground finches born on one of the Galápagos Islands in 1978. Notice that females in the cohort produced no surviving young when they were 7 and 8 years old, and that survival dropped precipitously in those years. These were years of low

food availability following a severe drought in 1985. Conversely, finch fecundity was unusually high the year they turned 5. This was 1983, an unusually wet year in the Galápagos due to an El Niño event, and the finches had abundant food.

Technology has increased Earth's carrying capacity for humans

The human population is unique among populations of large animals. Not only has it continued to grow, it has grown at an ever-faster per capita rate, as is indicated by steadily decreasing doubling times (**FIGURE 43.9A**). The current growth rate (r) is approximately 1.3 percent per year—lower than the high of 2.2 percent reached in 1963—because birth rates have declined faster than have death rates. Even if this trend continues, however, the human population is projected to reach 8 billion by 2025.

The human population growth rate has jumped with every technological advance that has raised carrying capacity by increasing food production or improving health. The first jump occurred with the rise of agriculture that enabled humans to build civilizations during the Neolithic (about 10,000 years ago). In the nineteenth and twentieth centuries, advances in sanitation and the development of vaccines and antibiotics decreased death rates to a level undreamed of by our ancestors (**FIGURE 43.9B**). Finally, the “Green Revolution” in agriculture more than doubled world grain production between 1950 and 1984.

Human ingenuity has repeatedly stymied attempts to predict the future of the human population. The most famous attempt was that of Thomas Robert Malthus, whose *Essay on the Principle of Population*, first published in 1798, provided Charles Darwin with a mechanism for natural selection. Malthus pointed out that the human population was growing multiplicatively, whereas its food supply was growing additively. He predicted that food shortages would limit human population growth, which he estimated would peak by the end

of the nineteenth century. Malthus could not, of course, have anticipated the effects of medical discoveries and the Green Revolution.

Many believe that the human population has now overshoot its carrying capacity. They give two reasons. First, most twentieth-century technological advances relied on abundant fossil fuels, and these resources are finite. Maintaining current levels of agricultural production depends heavily on fertilizers derived from natural gas, pesticides derived from oil, and petroleum-fueled engines that pump irrigation water, till the soil, and process and transport food. Similarly, the manufacture and distribution of medicines and diagnostic machinery depends on fossil fuels. World production of crude oil appears to have peaked in 2008 and is expected to decline steadily into the future. Although coal reserves are still abundant, they, too, are finite and will eventually be gone.

A second reason many believe we have exceeded our carrying capacity is the climate change and degradation of Earth's ecosystems that have been a consequence of our twentieth-century population expansion. We will consider these topics further in Chapter 46.

Population ecology tells us that any change in the size of the global human population must result from changes in birth and death rates. If the human population has indeed exceeded its carrying capacity, ultimately it will decrease. We can bring this about voluntarily if we continue to reduce per capita birth rate. Alternatively, we can allow the Four Horsemen of the Apocalypse—famine, pestilence, war, and death—to achieve a sustainable human population size by increasing mortality.

LINK Voluntary reduction of birth rates can be achieved by the use of the contraceptive methods described in Table 32.1

Do You Understand Concept 43.4?

- Why don't populations grow indefinitely?
- Explain the fundamental difference between multiplicative and additive growth.
- Why do limits to population growth lead to natural selection? (Hint: Consider that individuals in a population vary in b and d due to inherited traits.)

So far we have considered effects of two demographic processes—birth and death—on populations. But there is another way—immigration—to join a population, and another way—emigration—to leave it. These among-population movements are also important for population dynamics.

concept 43.5 Extinction and Recolonization Affect Population Dynamics

Most organisms live in habitat patches that are separated from other patches by unsuitable environments (FIGURE 43.10; see also Figure 43.1). The population within a region consequently consists of a cluster of distinct *subpopulations* that are linked together by the dispersal of individuals among patches. This larger, regional population is known as a **metapopulation**.

Each subpopulation of a metapopulation changes as all populations do—through births and deaths—but with the added input of individuals that move into the population

FIGURE 43.10 A Metapopulation Has Many Subpopulations
The coast of Scandinavia is characterized by a many natural freshwater rockpools containing populations of small crustaceans of the genus *Daphnia* (sometimes called “water fleas”), which feed by filtering algae from the water. Each rockpool houses a subpopulation; the surrounding habitat is inhospitable to *Daphnia*, but may be crossed by enough individuals to recolonize or reinvigorate other subpopulations.

(immigrants) and loss of individuals that move away (emigrants). Adding the number of immigrants (I) and emigrants (E) to the BD growth model, we get the **BIDE model**:

$$\begin{aligned} &\text{The number of individuals in a population} \\ &\text{at some time in the future} = \\ &\text{the number now} + \text{the number that are born} + \\ &\text{the number that immigrate} - \\ &\text{the number that die} - \\ &\text{the number that emigrate} \end{aligned}$$

The important difference between the BD and BIDE models is that the latter includes dispersal of individuals into and out of the subpopulation. In the BD model, a subpopulation that goes extinct forever stays extinct. Once the subpopulation reaches zero there are no individuals left to reproduce. With the BIDE model, however, immigration can bring an extinct population back to life.

In fact, extinction in small habitat patches is fairly common even when the environment of the patch is favorable. When subpopulations are small there is a reasonable chance that no female gives birth or that all individuals die of natural causes during a time period. Small populations are also at greater risk than large ones if there is an environmental disturbance.

Once a subpopulation goes extinct, it will remain at zero density—unless individuals disperse in and thus recolonize. Thus, if there is no dispersal among patches, the subpopulations will “wink out” one by one, and the metapopulation as a whole will eventually go extinct. The time to extinction is longer the larger each subpopulation is and the more subpopulations there are in the metapopulation, but extinction will occur nonetheless. If subpopulations are connected by dispersal, however, the metapopulation as a whole will persist much, much longer because empty patches can be repopulated and declining subpopulations can be “rescued” from extinction by immigration. The repopulated patches, in turn, can colonize others, causing them to “wink on.”

We can see the recolonization process at work in the Santa Clara County, California metapopulation of Edith’s checkerspot butterfly. Many subpopulations of this endangered butterfly went extinct during a severe drought that gripped California between 1975 and 1977. The only subpopulation that did not go extinct at that time was the largest one, on Morgan Hill (see Figure 43.1). The extinct subpopulations remained at zero density until 1986, when 9 suitable habitat patches were recolonized from the Morgan Hill source population. Patches closest to Morgan Hill were most likely to be recolonized because adult butterflies do not fly very far.

Do You Understand Concept 43.5?

- What is the fundamental difference between BD (see Concept 43.2) and BIDE models of population growth?
- Human-caused changes in land use often break up the original habitat of a species into spatially separated fragments. Why does this increase risk of extinction?

APPLY THE CONCEPT

Extinction risk decreases as population size increases

In a study of subpopulations of *Daphnia* in Swedish rockpools (see Figure 43.10), ecologist Jan Bengtsson established a number of artificial rockpools that held either 12, 50, or 300 liters of water. He introduced *Daphnia* and then covered the pools with mesh, which prevented immigration or emigration. Over the subsequent 4 years, Bengtsson returned repeatedly to census numbers of *Daphnia*, thereby obtaining the average population size in each pool. If a population went extinct, he included only the non-zero values for population sizes before extinction in calculating the average. We can calculate the grand average of these time-based averages for pools in which the populations went extinct, and for those in which they persisted, to explore how extinction risk changes with pool and population size.

1. Graph the relationship between pool size and probability of extinction, using size as the x -axis. What does your graph show you?

POOL SIZE (L)	NUMBER OF REPLICATE POOLS	PERCENTAGE OF POPULATIONS GOING EXTINCT	GRAND AVERAGE SIZE OF PERSISTENT POPULATIONS	GRAND AVERAGE SIZE OF EXTINCT POPULATIONS
12	27	18.5	1,500	65
50	25	16	2,705	530
300	11	9.1	9,690	1,800

2. Within each pool size, which populations were at greatest risk of extinction?
3. How are these two results related to each other?
4. What might have happened if Bengtsson had removed the mesh from the pools after some amount of time?

In Chapter 42 we saw that ecological knowledge has many important applications in our everyday lives—in medicine, agriculture, and so on. An ability to predict the dynamics of populations and metapopulations contributes to these applications by allowing us to influence the fates of natural populations, as several examples will illustrate.

concept 43.6 Ecology Provides Tools for Managing Populations

For millennia, humans have tried to reduce populations of species they consider undesirable and maintain or increase populations of desirable or useful species. Such efforts to manage populations are most likely to be successful if they are based on knowledge of how those populations grow and what determines their densities.

Knowledge of life histories helps us to manage populations

Knowing the life history of a species helps us to identify those life stages that are most important for reproduction and survival, and hence for population growth rate. Let's look at a few examples of how this knowledge can be applied.

MANAGING FISHERIES The black rockfish (*Sebastes melanops*) is an important game fish that lives off the Pacific coast of North America. Rockfish exhibit indeterminate growth—that is, they grow continually throughout their lives. As in many other animals, the number of eggs a female produces is proportional to her size, so larger females produce more eggs than smaller females. Larger females are also better able to provision their eggs with oil droplets, which provide energy to the newly hatched larvae, allowing them to grow faster and survive better than larvae from eggs with smaller oil droplets.

These life history characteristics have important implications for the management of rockfish populations. Because fishermen prefer to catch big fish, intensive fishing off the Oregon coast from 1996 to 1999 reduced the average age of female rockfish from 9.5 to 6.5 years. Thus, in 1999, females were, on average, smaller than in 1996. This change decreased the average number of eggs produced by females in the population and reduced the average growth rate of larvae by about 50 percent, causing a rapid decline in rockfish population density. Because a relatively small number of large females can produce enough eggs to maintain the population, one strategy for maintaining productive rockfish populations without shutting fishing down completely is to set aside a few no-fishing areas where some females are protected and can grow to large sizes.

LINK Strategies for maintaining the viability of a habitat for all its interacting species are discussed in Concept 45.6

REDUCING DISEASE RISK Because adult black-legged ticks feed and mate primarily on large mammals—white-tailed deer in particular—it seems logical that controlling deer densities would reduce the abundance of tick nymphs, which present the greatest risk of transmitting Lyme disease to humans. Surprisingly, experimental reductions in deer density have had very weak effects on subsequent nymph abundance. Studies of the tick's life history (see Figure 43.3) indicate that the success of larval ticks in obtaining a blood meal, not the number of them that hatch from eggs, has the greatest effect on the subsequent abundance of nymphs. As is true of rockfish, a very few adult female ticks can produce enough eggs to maintain populations. Hence, controlling the abundance of hosts for larvae (rodents) is a more effective strategy for reducing tick populations than controlling the abundance of deer.

CONSERVING ENDANGERED SPECIES The larval life stage is critical to the dynamics of Edith's checkerspot butterfly populations. Temporal and spatial variation in butterfly density are closely tied to the availability of two larval food plants: California plantain (*Plantago erecta*) and purple owl's clover (*Orthocarpus densiflorus*). Maintaining healthy populations of these plants is critical for conservation of these endangered butterflies. The two food plants are only found on serpentine soils, which have an unusual chemical makeup, but serpentine grasslands are being invaded by tall non-native grasses that suppress the low-growing *Plantago* and *Orthocarpus*. Grazing by cattle—another introduced species—can control the invasive grasses, and grazing is an important strategy for conserving *Euphydryas editha*. This shows that conservation goals often can be achieved without preventing other human uses.

Knowledge of metapopulation dynamics helps us conserve species

One goal of conservation efforts is to avoid the extinction of species. From studies of factors that affect extinction rates in individual populations, we know that risk to metapopulations is affected by the number and average size of subpopulations and rates of dispersal among them. This knowledge helps us to shape conservation strategies. Conservation plans therefore begin with an inventory of remaining areas of natural habitat and evaluation of the risks to those habitat patches. They then attempt to devise ways to protect as many habitat patches as possible.

FRONTIERS The National Aeronautics and Space Administration (NASA) and the United States Geological Survey (USGS) have teamed up to compile vast numbers of Landsat images (collected by "land-sensing" satellites in orbit around Earth) into computerized Geographic Information Systems (GIS) databases. With this information, conservation biologists can overlay maps of protected areas onto maps of endangered-species habitats, thus identifying gaps in the protection of critical habitats. This Gap Analysis Program allows them to efficiently plan for conservation of endangered species.

Priority is given to patches with the largest area because these can potentially host the largest populations. Another step is to evaluate the quality of the patches, as measured by their carrying capacity for the species, and to develop ways to restore or maintain quality. Finally, opportunities for dispersal among subpopulations must

INVESTIGATION

FIGURE 43.11 Corridors Can Rescue Some Populations Data from the experiments summarized here suggest that corridors between patches of habitat increase the chances of recolonization, and thus of subpopulation persistence.

HYPOTHESIS

Subpopulations of a fragmented metapopulation are more likely to persist if there is no barrier to recolonization.

METHOD

1. On replicate moss-covered boulders, scrape off the continuous cover of moss to create a "landscape" of moss "mainland" with patches surrounded by bare rock. A central 50-cm² moss "mainland" (M) is surrounded by 12 circular patches of moss 10 cm in diameter (subpopulations). In the "insular" treatment (I), the patches are surrounded by bare rock (which is inhospitable to moss-dwelling small arthropods, and thus a barrier to recolonization). In the "corridor" treatment (C), the patches are connected to the mainland by a 7 × 2 cm strip of live moss. In the "broken-corridor" treatment (B), the configuration is the same as the "corridor" treatment, except that the moss strip is cut by a 2-cm strip of bare rock.

2. After 6 months, determine the number of small arthropod species present in each of the mainlands and small patches.

RESULTS

Patches connected to the mainland by corridors retained as many species as did the mainland to which they were connected. Fewer species remained in the broken-corridor and insular treatments.

CONCLUSION

Barriers to recolonization reduce the number of subpopulations that persist in a metapopulation.

ANALYZE THE DATA

- A. What percentage of the species present in the mainlands was lost, on average, in the corridor patches?
- B. What percentage of the species present in the mainlands was lost, on average, in the insular and broken-corridor patches? What does this percentage tell you about the average risk of extinction for the subpopulation of each arthropod species in each patch?
- C. The broken-corridor treatment controls for another factor that can affect extinction risk. What is this factor?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

yourBioPortal.com

Go to ANIMATED TUTORIAL 43.3
Habitat Corridors

be evaluated. For some species (such as Edith's checkerspot butterfly, which can fly through unsuitable habitat to reach a new serpentine outcrop), simple proximity of patches determines rates of recolonization. For those species, patches that are distant from one another can be connected by a series of intervening subpopulations that serve as "stepping stones." For other species, however, a continuous **corridor** of habitat through which the species can disperse is needed to connect subpopulations (FIGURE 43.11). Dispersal corridors can sometimes be created by maintaining vegetation along roadsides, fence lines, or streams, and by creating bridges or underpasses that allow individuals to circumvent roads or other barriers to movement (FIGURE 43.12).

Do You Understand Concept 43.6?

- What similarities do you see between the rockfish and black-legged tick examples summarized above?
- Name three elements of a conservation plan for a species that has a metapopulation structure.
- Conservation plans for aquatic species such as rockfish often lack a corridor component. Why?

You may have noticed that although this chapter has focused on single-species populations, it has also mentioned many interactions among species—rodents interacting with acorns and

ticks, ticks with hosts and bacteria, butterflies with food plants and invasive plants. These ubiquitous between-species interactions, which play important roles in the population dynamics of all the interacting species, are the subject of the next two chapters.

How does understanding the population ecology of disease vectors help us combat infectious diseases?

ANSWER How frequently people come into contact with a dangerous pathogen depends on its abundance and distribution and those of any vectors that may transmit it to humans. Population ecology helps us understand what determines the abundance and distribution of pathogens and their vectors, and hence allows us to devise ways of controlling their abundance or avoiding contact with them.

By studying the survivorship and fecundity of the black-legged tick through its life history (Concept 43.3), Rick Ostfeld learned that it is the abundance of hosts for larvae, rather than weather or the abundance of deer, that determines tick abundance. Furthermore, Ostfeld ascertained that ticks become infected with *Borrelia* when they feed on infected hosts, and that rodents are the most effective reservoirs for *Borrelia*. Long-term studies of rodent population dynamics had shown that their abundance is determined by acorn availability (Concept 43.4).

This knowledge suggests an immediate way to reduce the probability of contracting Lyme disease (Concept 43.6). Acorn production can be used to predict areas that are likely to become infested with disease-carrying ticks, and various measures can be taken to reduce the risk of human contact with those ticks. These measures include boosting public education efforts for several years after a big acorn crop, posting warning signs in high-risk areas, and alerting health-care specialists whose patients live or work in high-risk areas. A longer-term possibility that has yet to be assessed is to reduce the fraction of ticks that carry *Borrelia* by augmenting populations of lizards and birds—which do not harbor *Borrelia*—in the host community.

FIGURE 43.12 A Corridor for Large Mammals
An overpass above the Trans Canada Highway in Banff National Park, Alberta. Bears, elk, deer and other large mammals use such overpasses, limiting the number of encounters with speeding vehicles that can have devastating effects for all involved.

43

SUMMARY

concept 43.1 Populations Are Patchy in Space and Dynamic over Time

- **Population density** is the number of individuals in a population per unit of area (or volume). **Population size** is the total number of individuals in a population.
- The region within which a species occurs is called the species' **geographic range**. Within that range, the species may be restricted to particular suitable **habitats**; these may occur in **habitat patches** separated by areas of unsuitable habitat. **Review Figure 43.1**
- Population densities vary over time as well as over space. **Review Figure 43.2**

concept 43.2 Births Increase and Deaths Decrease Population Size

- According to the **BD model**, the population size at some future time is the current size plus the total number of births minus the number of deaths that occur until that time. Equations based on the BD model can be used to calculate a population's growth rate.
- Ecologists can estimate the **per capita growth rate** (r) of a population by tracking births and deaths in a sample of individuals.
- If a population's per capita growth rate does not equal zero, then its size must be changing. If r is positive, the population is growing. If r is negative, the population is shrinking.

concept 43.3 Life Histories Determine Population Growth Rates

- A species' **life history**, which is a quantitative description of its life cycle, can be summarized in a **life table**. **Review Figure 43.3 and Table 43.1**
- The fraction of individuals that survive to particular life stages or ages is **survivorship**, and the average number of offspring they produce at those life stages or ages is **fecundity**. Survivorship and fecundity determine the per capita growth rate, r . **Review Table 43.1**
- To survive and reproduce, organisms need materials and energy and the time to acquire them—all of which constitute **resources**. Organisms also need physical **conditions** they are able to tolerate.
- The rate at which an organism can acquire resources increases with the availability of resources in its environment. **Review Figure 43.4**
- The **principle of allocation** states that once an organism has acquired a unit of some resource, it can be used for only one function at a time. **Review Figure 43.5**
- The environment shapes life histories because it determines the relative costs and benefits of any particular pattern of allocation to different functions.

- Species can persist only in environments in which their per capita growth rate is positive. **Review Figures 43.6 and 43.7**

concept 43.4 Populations Grow Multiplicatively, but Not for Long

- Populations grow **multiplicatively**, increasing or decreasing by a constant multiple of their current size in each interval of time. As a result, populations that are increasing in size have a constant **doubling time**. **Review WEB ACTIVITY 43.1 and ANIMATED TUTORIALS 43.1 and 43.2**
- As a population becomes denser and resources become scarcer, birth rates decline and death rates increase. Thus the per capita growth rate is said to be **density dependent**.
- When $r = 0$, the population reaches an **equilibrium** size. That size, called the **carrying capacity**, or K , is the number of individuals the environment can support indefinitely. **Review Figure 43.8**
- Changes in resource availability or physical conditions cause the carrying capacity to change.
- Technology has increased Earth's carrying capacity for humans, and the human population has responded by growing rapidly. **Review Figure 43.9**

concept 43.5 Extinction and Recolonization Affect Population Dynamics

- The regional distribution of a species often takes the form of a **metapopulation**, a cluster of distinct subpopulations in separate habitat patches linked together by the dispersal of individuals among them.
- The **BIDE model** adds immigration and emigration to the BD model. Immigration can rescue an extinct subpopulation.

concept 43.6 Ecology Provides Tools for Managing Populations

- Knowing the life history of a species makes it possible to identify those life stages that are most important for its population growth rate. That knowledge can be applied by managers to reduce populations of species considered undesirable and maintain or increase populations of desirable or useful species.
- Conservation efforts give priority to protecting the largest remaining habitat patches because these patches can host the largest populations. Providing continuous **corridors** of habitat through which individuals can disperse among patches reduces extinction risk. **Review Figure 43.11, WORKING WITH DATA 43.1, and ANIMATED TUTORIAL 43.3**

Ecological and Evolutionary Consequences of Species Interactions

44

On a morning walk in the Arizona desert, it's hard to resist the temptation to stop and watch the parades of colorful flower and leaf fragments that march across your path. The fragments aren't moving on their own, of course—they're being carried by *Acromyrmex versicolor*, one species of leaf-cutter ant. Leaf-cutter ants are tropical insects whose geographic range barely extends into North America. If you travel south through Mexico and into the New World tropics, however, you will see more and more ant highways and more and more different leaf-cutter species. Leaf-cutter ants originated in South America about 10 million years ago, crossing into North America only after the Panamanian land bridge connected the two continents.

Leaf-cutter ants are major herbivores in the Neotropics. A single colony can contain 8 million workers, occupy 20 cubic meters of soil, and consume more than 2 kilograms of plant material per day—enough to strip a large area of vegetation.

Leaf-cutters are no ordinary herbivores, however: they're fungus farmers! They use the leaves they harvest to grow a fungus that occurs in their nests and nowhere else on Earth. The interaction between fungus and ant is an obligate one—neither species can live without the other—that involves a remarkable array of specialized adaptations on the part of both partners.

New queens carry a pellet of fungus with them when they leave the nest where they were born and use it to start their own fungus garden, which they fertilize with their feces. They lay eggs in the developing fungal mass, and the resulting larvae feed on the fungus. Once the larvae

develop into worker ants, they collect leaf material to feed the growing fungus garden, avoiding plant species toxic to their fungal crop. As the colony expands, its workers take on additional tasks as scouts, nest excavators, gardeners, nurses, and garbage collectors—even bodyguards of leaf harvesters.

Leaf-cutters also associate with other species that benefit their interaction with the fungus. A bacterium in the genus *Pseudonocardia*, carried in special organs in the ants' exoskeletons, manufactures antibiotics that suppress the crop-killing green mold *Escovopsis* but do not harm the cultivated fungus. And just recently, researchers discovered a nitrogen-fixing bacterium, *Klebsiella*, in the fungus gardens. Who knows how many more leaf-cutter associates remain to be discovered?

Leaf-cutter ants of the tropical species *Atta cephalotes* carry coca leaves through the rainforest. The ants riding on the leaves are thought to be "bodyguards," warding off parasitic flies that would otherwise lay their eggs on the larger worker ants.

How could the intricate ecological relationship between leaf-cutter ants and fungi have evolved?

KEY CONCEPTS

- 44.1 Interactions between Species May Be Positive, Negative, or Neutral
- 44.2 Interspecific Interactions Affect Population Dynamics and Species Distributions
- 44.3 Interactions Affect Individual Fitness and Can Result in Evolution
- 44.4 Introduced Species Alter Interspecific Interactions

concept 44.1 Interactions between Species May Be Positive, Negative, or Neutral

The interactions between leaf-cutter ants and their nest associates represent but a small fraction of the ants' interactions with other species. When they harvest leaves, the ants interact with many plant species. The ants themselves are consumed by parasitic flies, beetles, and pathogenic fungi, and the ant corpses that are hauled to the colony's refuse dump are consumed by many species of microbes. The leaf-cutter example illustrates one of life's certainties: at some point between birth and death, every organism will encounter and interact with individuals of other species. These **interspecific interactions** have consequences that can affect the individual's fitness. Thus they can influence the densities of populations, alter the distributions of species, and lead to evolutionary change in one or both of the interacting species.

Interspecific interactions are classified by their effect on per capita growth rates

The details of interspecific interactions are bewilderingly diverse. Nonetheless, we can make considerable progress in understanding their ecological and evolutionary consequences by simply asking whether an interaction is beneficial or detrimental to individuals of the participating species—that is, whether an interaction increases, decreases, or does not affect each species' per capita growth rate.

If we consider all the possible pairwise combinations of negative (–), positive (+), and neutral (0) effects, we come up with five broad categories of interspecific interactions (**FIGURE 44.1A**): competition (–/–), consumer–resource (+/–), mutualism (+/+), commensalism (+/0), and amensalism (–/0).

Interspecific competition refers to –/– interactions in which members of two or more different species use the same resource. Recall from Concept 43.4 that when an organism consumes a resource, it makes that resource unavailable to other individuals of the same or different species, potentially reducing their resource intake and their per capita growth rate. We say “potentially” because not all resources are in short enough supply to limit per capita growth rate. However, at any one time there generally is one **limiting resource** that is in the shortest supply relative to demand. The limiting resource need not be food; it may be water, space, or—in the case of plants—sunlight (**FIGURE 44.1B**), inorganic nutrients, or pollinators. Competition can occur among predators that depend on the same prey species, among herbivores that depend on the same host plant, among pathogenic microbes that attack the same host, among neighboring plants, and even among plants vying for the attention of pollinating animals.

Consumer–resource interactions are those in which organisms gain their nutrition by eating other living organisms or are eaten themselves. It's obvious why these are +/- interactions: the consumer benefits while the consumed organism—the resource—loses. Consumer–resource interactions include

predation, in which an individual of one species (the **predator**) kills and consumes individuals of another species (the **prey**); **herbivory**, in which an animal consumes part or all of a plant (**FIGURE 44.1C**); and **parasitism**, in which a parasitic organism consumes part of a host individual but usually does not kill it. Parasites are generally smaller than their hosts. Some parasites are considered pathogens because they make their host ill by damaging tissue or producing toxins in the host's body.

A **mutualism** is an interaction that benefits both species (+/+). The interaction between leaf-cutter ants and fungi described at the start of this chapter is mutualistic: the ants feed, cultivate, and disperse the fungi; the fungi, in turn, convert inedible plant material into food the ants can eat. The interactions between plants and pollinating or seed-dispersing animals (**FIGURE 44.1D**), or between humans and the bifidobacteria in our guts (see Figure 42.2), are similarly beneficial to both partners. Mutualisms take many forms and involve many kinds of organisms. They also vary in how essential the interaction is to the partners. We have seen several examples of mutualism in this book, including interactions between mycorrhizal fungi and plants (see Concepts 22.2 and 25.2); between fungi, algae, and cyanobacteria in lichens (see Concept 22.2); and between corals and dinoflagellates (see Concept 20.4).

Competition, consumer–resource interactions, and mutualism all affect the fitness of both participants. The other two defined types of interactions affect only one of the participants.

Commensalism is an interaction in which one participant benefits while the other is unaffected (+/0). Most examples of commensalism (Latin, “eating together”) involve one species whose feeding behavior makes food more accessible for another. For example, the brown-headed cowbird (*Molothrus ater*) owes its common name to its habit of following herds of grazing cattle, foraging on insects flushed from the vegetation by their hooves and teeth. (*M. ater* has been called the buffalo bird because it followed the American bison herds that were once abundant across North America; see Figure 44.1C). The ungulate–cowbird interaction is a commensal one because the cowbirds have no effect on the fitness of the ungulates.

In other cases, the feeding behavior of one species enhances the availability of food for another species by converting food that is unusable to a second consumer into a usable form. Cattle, for example, convert plants into dung, which dung beetles can use. Dung beetles, in turn, are on the giving end of another commensalism: dung-living organisms that cannot fly, such as mites, nematodes, and even fungi, attach themselves to the bodies of the beetles, which not only can fly but are very good at locating fresh dung. The hitchhikers have no apparent effect on the dung beetles' fitness.

Amensalism refers to interactions in which one participant is harmed while the other is unaffected (–/0). A herd of elephants moving through a forest or a herd of bison grazing the plains crush insects and plants with each step (see Figure 44.1C), but the large mammals are unaffected by this carnage. Amensal interactions tend to have a more accidental relationship to the biology of the participants than do other interactions.

(A)

Major Types of Species Interactions

TYPE OF INTERACTION	EFFECT ON SPECIES 1	EFFECT ON SPECIES 2
Competition	-	-
Consumer–resource: Predation, herbivory, parasitism	+	-
Mutualism	+	+
Commensalism	+	0
Amensalism	-	0

(C)

Consumer–resource
The American bison feeds on the grasses of the Great Plains.

Amensalism, Commensalism
The large mammal unwittingly destroys insects and their nests. The buffalo birds feed on insects disturbed by the bison's passage.

(B)

Competition

Green plants compete for light. The leaves of tall trees have reduced the light available to the plants growing on the forest floor.

(D) *Tegeticula yuccasella*

Mutualism

The female yucca moth collects and carries pollen grains in specialized mouthparts...

...and deposits the pollen on the stigma of another flower.

Female moths subsequently lay eggs in the plant's ovary. The resulting larvae eat some of the developing seeds.

Because commensalism and amensalism are not reciprocal (that is, only one species is affected by the abundance of the other), they do not show the same ecological or evolutionary dynamics as reciprocal interactions do. For this reason, we will not focus on commensalism or amensalism in the remainder of the chapter.

Many interactions have both positive and negative aspects

Although ecologists find it useful to group interspecific interactions into the five categories we have described, the boundaries separating these categories are not always clear. Most interactions have both beneficial and harmful aspects, and the net effect of one species on another can be positive or negative, depending on the relative strengths of these beneficial and harmful aspects. These relative strengths in turn may be contingent on environmental conditions.

Sea anemones, for example, sting and eat small fish, but a select few fish species (mostly anemonefish; genus *Amphiprion*) are protected by a special mucus coat and thus can live among the anemones' stinging tentacles (FIGURE 44.2). Although the

FIGURE 44.1 Types of Interspecific Interactions (A) Interactions between species can be grouped into categories based on whether their influence on the per capita growth rate of each species is positive (+), negative (-), or neutral (0). (B) The composition of canopy (treetop) and understory (low-growing) vegetation in a forest is largely a product of competition for light. (C) Commensalisms between large, grazing ungulates and insect-eating birds are found in grassland environments around the world. (D) The mutualisms between desert *Yucca* plants and their moth pollinators are highly specialized. In the case seen here, *Yucca filamentosa* has an obligate mutualism with its sole pollinator, the moth *Tegeticula yuccasella*.

Ecological Interactions

benefit of this association to the anemonefish is clear—they escape their own predators by hiding behind the anemones' nematocysts and can scavenge food caught by the anemones—the consequences for the anemones are less clear. Do they benefit because the fish defecate nitrogen-rich feces whose nutrients they can use? Do they suffer because the fish steal some

APPLY THE CONCEPT

Interactions between species may be positive, negative, or neutral

In many animals that face uncertain food availability, a tendency to collect and store more food than they can eat immediately has evolved. Desert seed-eating rodents such as Merriam's kangaroo rat (*Dipodomys merriami*; see Figure 43.4B), for example, will harvest as many seeds as you put in front of them and bury the seeds in shallow depots scattered around their territory. In some years seed production is low, and the rodents eat all the seeds they manage to store. In other years they store more seeds than they are able to eat, and the uneaten stored seeds are likely to germinate as grass seedlings.

In a classic long-term study done in the 1930s and 1940s, researchers at the Santa Rita Experimental Range in southern Arizona monitored the effect of kangaroo rats on native grasses. They established replicate enclosures, removed kangaroo rats from half of them, then monitored the abundance of grasses in the two types of enclosures over a period of 10 years. From 1931 to 1935 the region experienced a severe drought and grass populations declined. Rains returned in 1935. The year 1941 saw particularly high (for the desert) rainfall. Use the graph to answer the following questions.

1. During the drought, did kangaroo rats have a positive, negative, or neutral effect on the per capita growth rate of grasses? Explain your reasoning.
2. Did the effect of kangaroo rats on grasses change after rains returned? Explain your reasoning.
3. What aspects of kangaroo rat behavior are detrimental to grasses? What aspects might help grasses?
4. How might year-to-year variation in rainfall influence the relative strengths of the positive and negative effects kangaroo rats have on grass growth rates?

of their prey? The net effect of the interaction on the anemones may well depend on the availability of nitrogen-rich food in their environment.

Amphiprion ocellaris

FIGURE 44.2 Interactions between Species Are Not Always Clear-Cut Ecologists long believed that the relationship between sea anemones and anemonefish was a commensalism: that the fish, by living among the anemones' stinging tentacles, gained protection from predators. But could it also be considered a mutualism—if the fishes' feces provide the anemones with beneficial nutrients—or competition—if the fish occasionally steal the anemones' prey?

Do You Understand Concept 44.1?

- What is the criterion for classifying interspecific interactions?
- What type of interspecific interaction would you consider human cultivation and consumption of crop plants to be?
- Describe an experiment that would allow you to determine whether the effect of anemonefish on sea anemones is positive, negative, or neutral.

Because interspecific interactions affect per capita growth rates, it is clear that they affect the population dynamics of the participant species. How exactly are those dynamics affected?

concept
44.2

Interspecific Interactions Affect Population Dynamics and Species Distributions

As we saw in Concept 43.2, the growth rate of a population equals the average individual's contribution to change in population size (the per capita growth rate, r) multiplied by the number of individuals in the population. If r does not change, population size either follows a J-shaped trajectory to infinity

(if r is positive) or decreases to zero (if r is negative). We also saw in Concept 43.4 that r usually decreases with population density, and that this density dependence dramatically alters the trajectory of growth: instead of growing to infinity, populations stop growing and fluctuate around a carrying capacity (K).

Interspecific interactions can modify per capita growth rates

Density-dependent population growth reflects *intraspecific*, or within-species, interactions among the individuals in a population. These intraspecific interactions are usually detrimental because per capita resource availability decreases as a population's density increases (see Concept 43.4). Density-dependent population growth therefore generally describes **intraspecific competition**.

The word equation on page 852 describes the intraspecific effects of density dependence, but can be extended to include competition between two species:

$$\begin{aligned} \text{per capita growth rate } (r) \text{ of species A} = & \\ \{ \text{maximum possible } r \text{ for species A in uncrowded conditions} - & \\ \text{an amount that is a function of A's own population's density} \} - & \\ \{ \text{an amount that is a function of the population density of} & \\ \text{competing species B} \} & \end{aligned}$$

Notice that we need to write a pair of equations—one each for competing species A and B. Each equation consists of an expression that describes growth of one species in the absence of the other, minus an expression that describes the effect of the other species.

Interspecific interactions other than competition can be described in a similar way. Depending on the type of interaction, we must either subtract or add the effect of the other species (see Figure 44.1A). In consumer–resource interactions, we subtract the effect of the consumer (e.g., the predator) in the equation for the resource species (e.g., the prey), since the consumer increases the mortality of the resource species. Conversely, we add an effect of the resource in the equation for the consumer, since the consumer benefits from the presence of the resource. In mutualistic interactions, we add an effect of each mutualist to the equation for the other. In commensal interactions we add a term in the equation of the species that benefits, and in amensal interactions we subtract a term in the equation of the species that is harmed. (For commensal and amensal interactions, the equations for the partner species contain no reciprocal terms, because by definition the partner is unaffected by the interaction.)

Interspecific interactions can lead to extinction

Because interspecific interactions modify per capita growth rates, populations show different dynamics in the presence and absence of other species. The Russian ecologist G. F. Gause demonstrated the effects of interspecific interactions on the population dynamics of several species of the protist *Paramecium* in a classic laboratory study published in 1934. Gause

grew these unicellular organisms (see Figure 20.6) both in single-species cultures and in cultures containing a competing species of *Paramecium*. In order to better understand the different outcomes he observed, Gause used both word models such as the one we gave earlier, and mathematical expressions of the same interactions. In the many decades since Gause's work, mathematical models have proved to be useful tools for understanding how interspecific interactions affect population dynamics. In the case of competition, all models lead to the following conclusions:

- The presence of a competitor always reduces population growth rate. In **FIGURE 44.3A**, notice that the slope of the curve of population density versus time at any given population density is shallower in the presence of a competitor, because the competitor reduces the per capita growth rate from what it would be with just intraspecific density dependence.
- In addition, when two species coexist as in Figure 44.3A, they achieve lower equilibrium population densities than either would achieve alone.
- In some cases, competition causes one species to go extinct (**FIGURE 44.3B**).

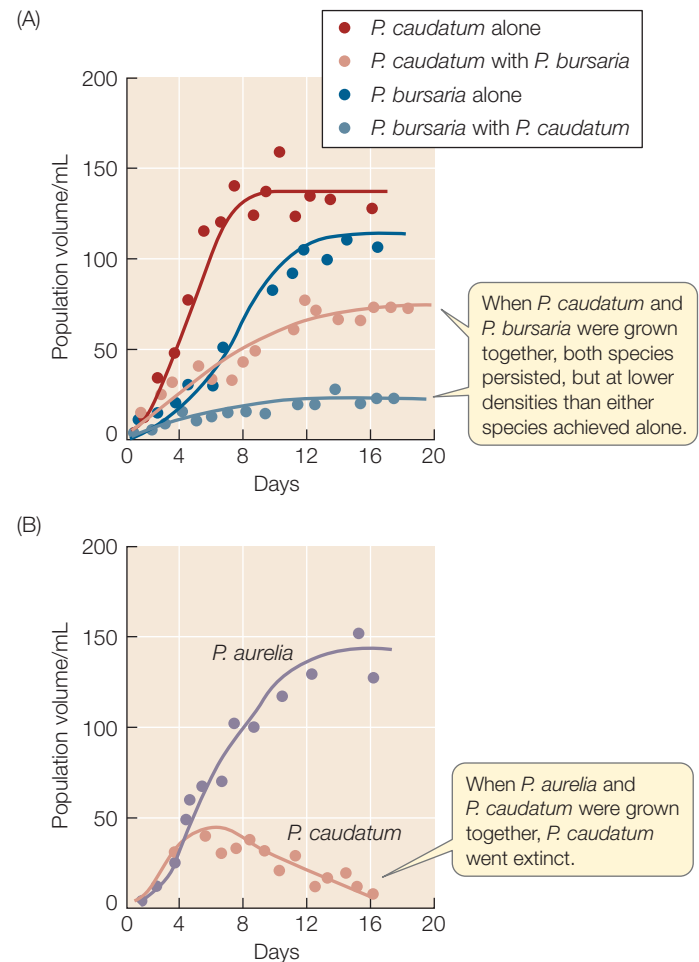

FIGURE 44.3 Interspecific Competition Affects Population Growth (A) Populations of the unicellular protist *Paramecium* grow more slowly and reach lower equilibrium densities when a competing species is present. (B) Competition can result in extinction.

Other types of interspecific interactions have similar consequences:

- In all cases, the per capita growth rate of each interacting species is modified by the presence of the other, sometimes positively and sometimes negatively.
- In all cases, the average population densities of each species differ in the presence and absence of the other species. Population densities are increased in positive interactions and decreased in negative interactions.
- Finally, in interactions that have negative effects—that is, consumer–resource interactions, competition, and amensalism—extinction of one or both of the interacting species is possible.

Interspecific interactions can affect the distributions of species

In Chapters 42 and 43 we saw that a species may be absent from a particular location, either because barriers to dispersal have prevented the species from colonizing it or because the environment is unfavorable for the species' population growth. We can now see that even if a species reaches a site, interactions with other species may affect its distribution. A site can be unfavorable because it lacks suitable prey or because it harbors a competitor or predator; conversely, an otherwise unfavorable site may be improved by the presence of a mutualist.

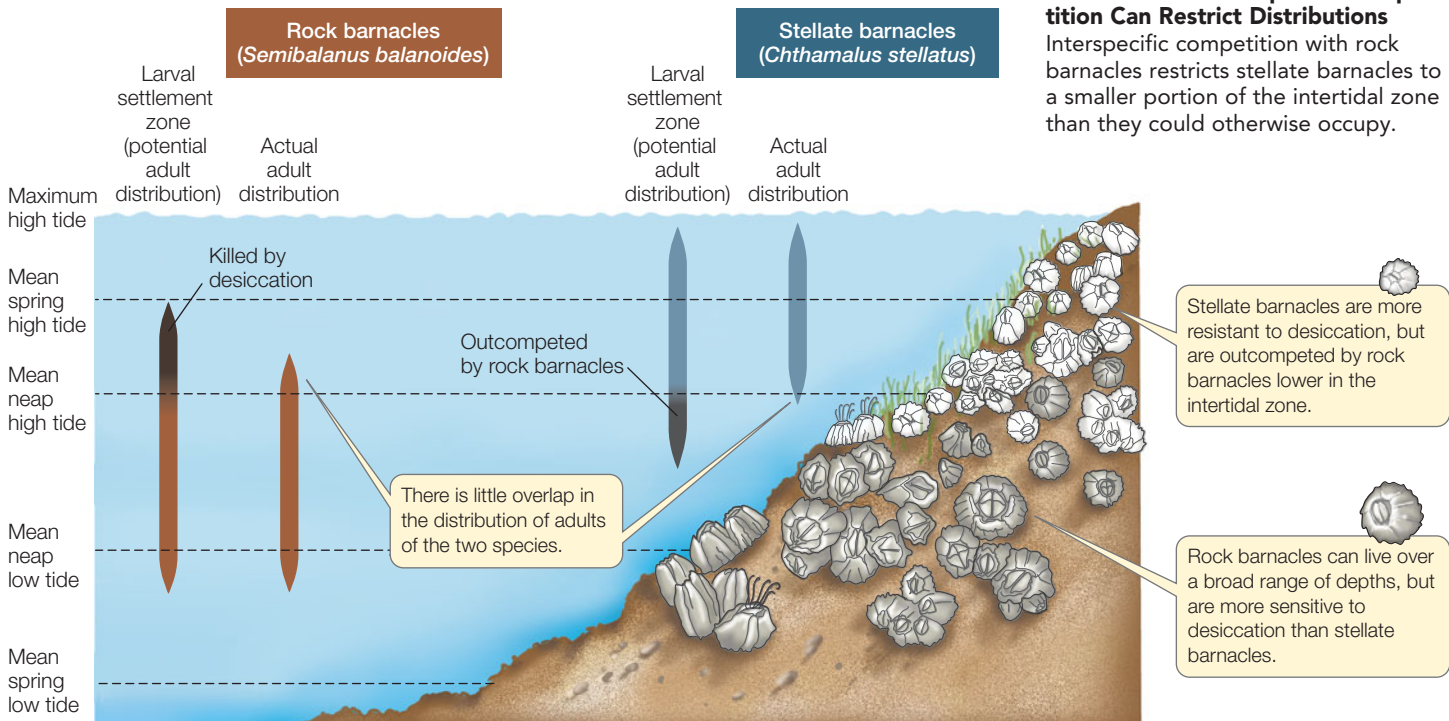

FIGURE 44.4 shows a classic example of how competitive interactions can restrict the habitats in which species occur. The rock barnacle (*Semibalanus balanoides*) and Poll's stellate barnacle (*Chthamalus stellatus*) compete for space on the rocky shorelines of the North Atlantic Ocean. In these organisms, occupying a space on a rock amounts to having the opportunity

to feed because adult barnacles attach permanently to rocks, filtering food particles from the water that flows past them. The planktonic (swimming) larvae of both *S. balanoides* and *C. stellatus* settle in the intertidal zone and metamorphose into sessile adults. There is little overlap between the areas occupied by adults; the smaller stellate barnacles generally live higher in the intertidal, where they face longer periods of exposure and desiccation, than do the rock barnacles.

In a famous experiment conducted almost 50 years ago, Joseph Connell removed each of the species from its characteristic zone and observed the response of the other species. Stellate barnacle larvae settled in large numbers throughout much of the intertidal zone, including the lower levels where rock barnacles are normally found, but they thrived at those levels only when rock barnacles were not present. The rock barnacles grew so fast that they smothered, crushed, or undercut the stellate barnacle larvae. In other words, by outcompeting them for space, rock barnacles made the lower intertidal zone unsuitable for stellate barnacles. In contrast, removing stellate barnacles from higher in the intertidal zone did not lead to their replacement by rock barnacles; the rock barnacles were less tolerant of desiccation and so failed to thrive there even when stellate barnacles were not present.

Rarity advantage promotes species coexistence

Mathematical models of interspecific interactions have been useful not only in helping us understand how interactions affect population dynamics and species distributions, but also by giving us insights into the conditions that allow interacting species to coexist.

Models of interspecific competition indicate that two competitors will coexist when each species suppresses its own per capita growth rate more than it suppresses the per capita growth rate of its competitor. In other words, intraspecific competition must be stronger than interspecific competition. When this is the case, a species gains a growth advantage when it is at a low density and its competitor is at a high density—that is, when the species is rare—and this *rarity advantage* prevents the species from decreasing to zero. The result is coexistence.

One mechanism that can cause intraspecific competition to be stronger than interspecific competition is **resource partitioning**: differences between competing species in resource use. For example, *Paramecium caudatum* can coexist with *P. bursaria* but not with *P. aurelia* (see Figure 44.3), because *P. bursaria* can feed on bacteria in the low-oxygen sediment layer at the bottom of culture flasks—a habitat that *P. caudatum* cannot tolerate. This partitioning of habitat is possible because *P. bursaria* harbors symbiotic algae that provide it with additional oxygen as a by-product of algal photosynthesis.

FIGURE 44.5 illustrates how, in general, differences between species in their use of resources cause individuals to have a larger effect on the resources available to another individual of their own species than to the typical individual of another species. If differences in resource use are sufficiently large, competing species can coexist, as we will discuss again in Concept 44.3.

In the case of predators and prey, a number of processes can result in a rarity advantage that protects prey from being driven extinct by their predators. For example, prey may become harder to find as they become more rare because they all can hide in the best refuges; or they can invest in better defense when they are at low densities and have more resources available per capita. Predators may also stop looking for rare prey and switch to another prey. Alternatively, some other limiting factor (such as availability of nest sites) may prevent the predators from becoming numerous enough to eat all the prey. The effect of such processes is that per capita growth rates may rebound when prey become rare, thus making prey extinction less likely.

Do You Understand Concept 44.2?

- Describe the components of an equation for the per capita growth rate of a species that interacts with another species.
- What are the possible outcomes for the final population sizes of two species involved in a predator–prey interaction?
- Explain, in terms of resource use, why the equilibrium population size of one species is reduced by the presence of a competing species.

The effects of interspecific and intraspecific interactions on individual members of a population are not fixed, but depend on the individuals' characteristics. For example, the overlap between seed-eating birds in the size of the seeds they are able to eat depends on just how different their beak sizes are. How successful a lynx is at catching a snowshoe hare depends on how

FIGURE 44.5 Resource Partitioning Can Result in Intraspecific Competition Being Greater than Interspecific Competition

When two species differ in resource use, individuals will have a greater effect on resource availability to individuals of the same species than to individuals of the second species.

conspicuous the hare is and how fast or alert the lynx is. If individuals vary in attributes that determine how much a competitor affects their access to resources or their risk of being eaten by a predator, then the interaction will result in natural selection in both interacting species.

concept 44.3

Interactions Affect Individual Fitness and Can Result in Evolution

As we saw in Chapter 43, an individual's contribution to population growth summarizes its success in surviving and in reproducing. We have seen that both intraspecific and interspecific interactions affect per capita growth rates. If individuals involved in an interaction are affected by it to different extents, they will differ in *fitness*: those phenotypes that gain the most from a positive interaction or suffer the least from a negative interaction will increase in frequency in the population, and the population will evolve (see Chapter 15). The mixes of positive and negative effects that distinguish the various types of interactions cause different evolutionary dynamics, as we will now see. We will begin with intraspecific competition.

Intraspecific competition can increase carrying capacity

Equations of density-dependent growth assume that all the individuals in a population are equally affected by its density. However, individuals often vary in traits that affect how well they can use available resources. Suppose, for example, that in a particular population of seed-eating birds, individuals with small beaks can feed on both large and small seeds, whereas birds with larger beaks cannot feed efficiently on the small seeds. In this situation, more resources are available to the small-beaked individuals, their per capita growth rate—their *fitness*—exceeds that of the larger-beaked individuals, and the frequency of small-beaked individuals in the population will increase.

As small-beaked individuals come to dominate the population, the average beak size in the population will get smaller,

INVESTIGATION

FIGURE 44.6 Resource Partitioning Allows Competitors to Coexist In the Galápagos archipelago, seed-eating finches (*Geospiza* spp.; see Figure 17.7) use their beaks to crack open seeds, which are often in short supply. Individuals with big beaks can crack large, hard seeds that individuals with small beaks cannot eat, whereas small-beaked birds are more efficient at eating small, soft seeds. Dolph Schluter and Peter Grant documented how 15 of the islands differed in both their seed resources and in which *Geospiza* species were present.

HYPOTHESIS

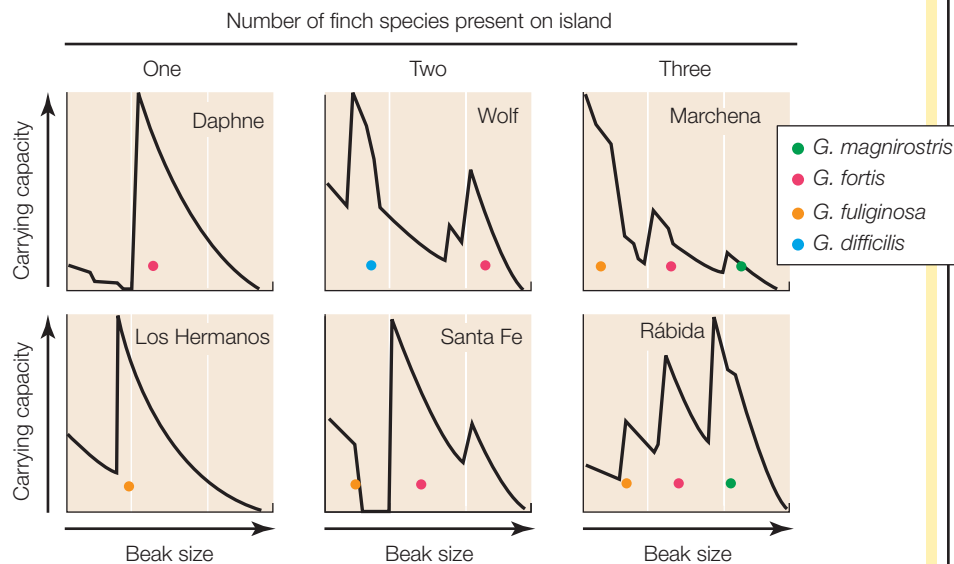

Multiple species of *Geospiza* coexist only where they can partition seed resources.

METHOD

1. Determine which species of seed can be eaten efficiently by *Geospiza* with different beak sizes.
2. Measure the abundances of seeds of different sizes on 15 islands.
3. Characterize the availability of food for finches with different beak sizes, expressing availability as the population density that can be supported on each island (a measure of carrying capacity).
4. Determine the average beak sizes of finch species present on each island.

RESULTS

Islands supported between 1 and 3 finch species (shown here for 6 of the 15 islands). The number of species present (indicated by colored dots) increased with the number of seed sizes available (reflected in the number of distinct peaks in carrying capacity).

CONCLUSION

Coexisting *Geospiza* species differ in beak sizes and thus in resource use.

ANALYZE THE DATA

- A. The average beak sizes of finch species present on an island (indicated by the locations of the colored dots) closely match the peaks in carrying capacity. Why might this be so?
- B. Why do peaks in seed availability have no more than one associated finch species?
- C. Why might some peaks in seed availability lack an associated finch species? (Hint: See Concept 45.1.)

LINK The three patterns of selection—directional, stabilizing, and disruptive—are described in Concept 15.4

Interspecific competition can lead to resource partitioning and coexistence

Just as individuals can vary in traits that affect their sensitivity to intraspecific competition, they can vary in traits that affect their sensitivity to interspecific competition. Studies from the Galápagos Islands show that beak sizes of a given finch species can vary from island to island, that beak sizes appear to match the sizes of available seeds, and that no island supports more than one finch species with a given beak size (FIGURE 44.6). These results are interpreted as another example of resource partitioning, in this case as an evolutionary response to interspecific competition. To see how this might occur, consider another example from the Galápagos, this time between a finch and an insect.

The small ground finch (*Geospiza fuliginosa*) consumes flower nectar as well as seeds. Smaller-size birds are better at obtaining nectar than are larger birds, whereas larger birds are better at cracking seeds. Carpenter bees (*Xylocopa darwini*) compete with *G. fuliginosa* for nectar on some islands but are absent from others. Small finches are affected more strongly by competition from these bees than are larger individuals because they are less adept at eating foods other than nectar. As a consequence, the finches are larger in size and drink less nectar on islands where carpenter bees are present (FIGURE 44.7). This evolutionary shift to larger size and greater use of seeds means *G. fuliginosa* resource use has diverged from that of their bee competitors on islands where the two species coexist.

and the population will grow larger because the abundance of small seeds makes the carrying capacity greater for populations with a smaller average beak size. The population will stop growing when it reaches the higher carrying capacity for smaller-beaked birds. This change in average beak size, and the associated change in carrying capacity, are the results of directional selection.

Consumer–resource interactions can lead to an evolutionary arms race

Predators, parasites, and herbivores benefit if they can acquire lots of nutritious food quickly and inexpensively, whereas resource species benefit if they can deter these natural enemies at little cost. The interests of consumer and resource species are obviously at odds. These opposing interests can lead to an

Geospiza fuliginosaNectar Use and Size of *G. fuliginosa*

Xylocopa darwini

“evolutionary arms race,” in which prey continually evolve better defenses and predators continually evolve better offenses, and neither gains any lasting advantage over the other. The Red Queen summed up such a dynamic in Lewis Carroll’s *Through the Looking-Glass* with the words “it takes all the running you can do, to keep in the same place.”

Resource species have various defensive strategies available to them. Some mobile animals use speed, size, or weapons to thwart predators. Others hide or use camouflage to avoid being detected, or they mimic unpalatable species (FIGURE 44.8A). Immobile organisms have other tricks up their sleeves; for example, they may have evolved thick armor, or they may be non-nutritive or poisonous. In response to these strategies, natural selection in populations of consumers favors greater speed, size, or strength; keen senses; armor-piercing

FIGURE 44.7 Finch Morphology Evolves in Response to Competition with Carpenter Bees On those Galápagos islands where small ground finches are the sole pollinators of small flowers, the birds are small (as measured by their short wingspans). Small size lowers their energy requirements and may increase their ability to negotiate the flowers. On islands where carpenter bees compete with these finches for nectar, the birds are larger and have stronger beaks (which allows them to include seeds in their diet).

or crushing tools (FIGURE 44.8B); or means of detoxifying poisons.

Plants produce a great variety of chemicals that are toxic to herbivores or pathogens, as we saw in Chapter 28. Used in small quantities, some of these chemicals spice up our lives—the caffeine of coffee and tea, the mustard oils of cabbages, the capsaicins of chilis, and the piperine of black pepper are examples of plant defensive chemicals. Ways around these defenses have evolved in some herbivores. *Heliconius* butterflies store or detoxify the cyanide-containing defensive compounds of passionflower (*Passiflora*) vines they feed on as larvae, and even use these poisons as defenses against their own predators. In turn, in some *Passiflora* species, modified leaf structures have evolved that resemble butterfly eggs (FIGURE 44.9).

(A)

*Episyrphus balteatus**Vespa vulgaris*(B) *Anodorhynchus hyacinthinus***FIGURE 44.8 Defense Mechanisms and “Arms Races”**

(A) The harmless hoverfly (above) gains protection by mimicking a dangerous stinging wasp species (below) that predators have come to avoid. (B) Brazil nuts (the seeds of *Bertholletia excelsa*) are protected by extremely hard shells that most birds cannot penetrate. The evolution of beak strength in the hyacinth macaw, however, has kept pace with the nut’s hardness.

FIGURE 44.9 Using Mimicry to Avoid Being Eaten The raised yellow bumps on these passionflower leaves resemble the eggs of the plant's principal herbivores, zebra butterflies (*Heliconius* spp.). Because female butterflies will not lay their eggs on leaves that already contain eggs, these "false eggs" protect the plant from being eaten by caterpillars.

Since female butterflies will not lay eggs on plants that already contain eggs, the egg-mimicking structures reduce the plant's probability of being eaten by *Heliconius* caterpillars.

FRONTIERS Molecular genetic methods are allowing ecologists to better understand how coevolution—the reciprocal evolution of traits in interacting species—occurs at the level of genes. Scientists can alter the expression of single genes affecting traits that are important in interspecific interactions, and study the ecological consequences for the organisms involved. For example, ecologists have used molecular methods to "turn off" plant genes that control the production of defensive chemicals. This allows researchers to determine precisely how those chemicals influence insect herbivory, and thereby plant fitness. Besides improving our understanding of coevolution, such research has potential applications in agriculture.

Mutualisms can involve exploitation and cheating

Mutualisms are often misunderstood. How often do we hear that "bees visit flowers to pollinate them" or that "flowers provide food for their pollinators"? The problem with such statements is they imply an impossible evolutionary process in

APPLY THE CONCEPT

Interactions affect individual fitness and can result in evolution

Crabs feed on mussels, and individual mussels can respond to the presence of crabs in their environment by thickening their shells—if they can perceive the threat. On the east coast of North America, blue mussels (*Mytilus edulis*) face two non-native crab predators. The European green crab (*Carcinus maenas*) was introduced to the United States almost 200 years ago, and the Asian shore crab (*Hemigrapsus sanguineus*) arrived only 20 years ago. *C. maenas* has spread all along the Atlantic coast of North America, whereas *H. sanguineus* has not yet reached northern Maine. Have mussels evolved the ability to detect this new enemy and respond to it?

Researchers collected very young *M. edulis* from northern populations that have experienced *C. maenas* but not *H. sanguineus* and from southern populations that have experienced both predator species. They grew mussels from each population on floating docks under three different conditions: no crab nearby (controls); a hungry *C. maenas* caged nearby; and a hungry *H. sanguineus* caged nearby. After 3 months, researchers measured mussel shell thickness.

Use the graph at right to answer the following questions. Error bars indicate 95% confidence intervals; bars with different letters are statistically different from one another ($P < 0.05$).

1. Have mussel populations exposed to predation by non-native crabs evolved the ability to detect and respond to them by thickening their shells?
2. Which comparison is critical to your conclusion?

3. Do mussels in southern populations have thinner shells than in northern populations? Would a difference in average shell thickness between the two populations invalidate your conclusion?
4. What do these data suggest about how quickly evolution can take place?

which species display traits that evolved solely for the benefit of another species. As Charles Darwin said,

If it could be proved that any part of the structure of any one species had been formed for the exclusive good of another species, it would annihilate my theory, for such could not have been produced through natural selection.

In truth, most pollinators visit flowers to get food and happen to pollinate the flowers in the process; flowers provide food (usually as little as possible) to lure the animals, not to fatten them up; birds and bees “like” any conspicuous color that signals the presence of food; and most flowers are visited by any animal that gains economically by doing so, whether it pollinates the plant or not. In the rough-and-tumble world of ecological interactions, species benefit other species not because they are altruistic, but because acting in their own self-interest happens to benefit others.

LINK The coevolution of plants and pollinators is discussed in Concept 21.5

All mutualisms involve “biological barter”: the exchange of resources and services. Plants and pollinators exchange food (nectar or pollen) for pollen transport. Plants and frugivores exchange food (fruit) for seed dispersal. Some mutualists (such as leaf-cutter ants and fungi) exchange food for care and dispersal. Others (such as ants and plants) exchange food or shelter for defense or parasite control. Still others (such as plants and mycorrhizae, or mammals and gut bacteria) exchange one kind of nutrient for another. In such “barter” systems, the fitness effect of the mutualism can vary depending on environmental conditions that determine the value and cost of the goods and services that are exchanged. Mycorrhizae, for example, benefit plants in nutrient-poor soils, but they can be a liability to plants in nutrient-rich soils, where the cost of feeding the mycorrhizae outweighs their value in nutrient uptake.

Go to **ANIMATED TUTORIAL 44.1**
An Ant-Plant Mutualism

“Cheating” is common in mutualisms. Some flowers mimic the form and smell of female insects and are pollinated when males attempt to copulate with them (see Figure 17.9). Others cheat pollinators by providing no nectar. And most provide less food than their visitors would like. Pollinators cheat too when it is cost-effective to do so. Some bees “rob” flowers by extracting nectar through holes they bite in the base of the flower, consuming the nectar without pollinating the flower. Other pollinators become “secondary robbers” by reusing these holes. And some yucca moth species (see Figure 44.1D) cheat by laying eggs in *Yucca* flowers without depositing a pollen mass, or by laying so many eggs that the larvae consume all the flower’s seeds.

Because mutualisms are diverse and often complex, their evolutionary consequences are difficult to predict. Some mutualisms evolve into obligate, one-on-one relationships with ever-

tighter reciprocal adaptation. Others evolve into diffuse, many-species relationships with generalized adaptations. Some are unstable and dissolve into consumer–resource relationships. Understanding the conditions under which mutualisms follow different evolutionary trajectories is an active area of current research.

FRONTIERS Ecologists are collaborating with sensory physiologists and neurobiologists to learn how different animals perceive the world and how perception influences their ecological interactions. This new field of cognitive ecology is exploring how pollinating insects distinguish flowers from other objects. For example, although it has long been known that bees have color vision, one surprising new discovery is that they cannot distinguish colored objects such as flowers until those objects are close enough to simultaneously stimulate dozens of adjacent ommatidia (see Figure 35.15). The results of such studies will improve our understanding of plant–pollinator interactions.

Do You Understand Concept 44.3?

- What are the two components of fitness?
- How are these two components related to r ? (Hint: Recall from p. 845 in Chapter 43 the ten female bison that rancher Jane followed for a year.)
- Why might individual plants in populations within the geographic range of an insect herbivore contain high levels of defensive chemicals while individuals in populations outside of the insect’s range produce no defensive chemicals?

We have now discussed how interspecific interactions influence the population growth rates and the adaptations of the interacting partners. What happens when the partners are suddenly forced to interact with new species?

concept 44.4 Introduced Species Alter Interspecific Interactions

As we saw in Concept 42.5, humans are introducing many species to new places, both intentionally and unintentionally. These introductions not only blur biogeographic boundaries but have the potential to alter interactions among native species.

Introduced species can become invasive

Species that are introduced into a region where their natural enemies are absent may reach very high population densities. Such introduced species may become **invasive**—that is, reproduce rapidly and spread widely. They are likely to have negative effects on native species that lack adaptations to compete

with or defend themselves against the newcomers. However, introduced species may benefit some native species, if they provide a resource that was not available previously.

Invasive species are spread in several ways. Marine organisms, for example, have been spread throughout the oceans by ballast water from ships, taken on at the port of departure and discharged at the destination port along with its content of surviving animals and plants. Similarly, many terrestrial plants and animals have “hitchhiked,” unbeknownst to their carriers, as humans have moved themselves and their belongings to new locations. All such movements can be thought of as accidental. In addition, there are deliberate introductions by humans, who wish to reconstruct their familiar surroundings in a new location, or who believe that an introduction improves a native ecological system. For example, Europeans colonizing new continents deliberately brought a wide range of plants and animals to their new homes. This transport is still ongoing in the form of ornamental plants, exotic pets, and so on. Some species deliberately introduced to control other invasive species have themselves become invasive and caused further problems.

Introduced species alter ecological relationships of native species

The ways in which invasive species may harm native species are diverse. For example, introduced flowering plants can alter relationships between native plants and their pollinators. Purple loosestrife (*Lythrum salicaria*), introduced into North America in the early 1800s, has expanded its range dramatically and now dominates many wetlands in the United States (FIGURE 44.10). This species competes for pollination with the native species *Lythrum alatum*, which receives fewer visits from pollinators and produces fewer seeds when purple loosestrife is present.

Some invaders alter ecological interactions by causing extinction of native species. Concept 22.3 described the case of an introduced sac fungus and cause of a blight that drove the once-dominant

American chestnut (*Castanea dentata*) to extinction. The chestnut has been replaced by oaks throughout the forests of the northeastern United States. Because acorn production varies greatly from year to year, whereas chestnuts produced consistent nut crops every year, the loss of chestnuts has contributed to the year-to-year fluctuations in rodents, ticks, and Lyme disease (see the opening story in Chapter 43).

Organisms that are deliberately introduced to control pests can alter interactions among native species if they do not confine their attention to the pest species. *Rhinocyllus conicus*, for example, is a Eurasian weevil whose larvae eat developing seeds. It was introduced into North America in 1968 to control the invasive musk thistle (*Carduus nutans*). When the abundance of musk thistle declined, the weevil moved over to the native Platte thistle (*Cirsium canescens*), and then to wavyleaf thistle (*C. undulatum*). By entering into consumer–resource interactions with native thistles, the introduced weevil has also become a competitor of the native insects that eat thistles.

Do You Understand Concept 44.4?

- What are two ways in which species are introduced into new areas by human activities?
- Why do some introduced species become invasive?

The effects of invasive species on interspecific interactions highlight the fact that these interactions occur within a larger web of multispecies interactions. As we have seen, these interactions determine which species can coexist in an area, and they affect the abundances of those species. The number of species present and their relative abundances determine the structure of communities—the topic of the next chapter.

FIGURE 44.10 An Invasive Species Purple loosestrife (*Lythrum salicaria*) was introduced into North America and now dominates many wetlands, especially in the northeastern United States. Thriving in the absence of its natural herbivores, the invasive plant has crowded out native species such as cattails, affecting the life cycles of wetland organisms such as waterfowl and amphibians.

How could the intricate ecological relationship between leaf-cutter ants and fungi have evolved?

ANSWER We have seen that interactions between species can be mutually beneficial, positive for one species and negative or neutral for the other, negative for one species and neutral for the other, or mutually detrimental (Concept 44.1). These interspecific interactions affect the per capita growth rates of the respective populations, and hence the fitness of the individuals involved in the interaction (Concept 44.2). Any traits that increase the benefit of a positive interaction, or decrease the fitness loss of a negative interaction, will give individuals with those traits a fitness advantage. Such favored phenotypes will increase in frequency in the population (Concept 44.3). In the case of the mutually beneficial interaction between leaf-cutter ants and their farmed fungus, both ants and fungus gain nutrition from their interaction. In addition, the ants disperse the fungus and protect it from pathogens.

Fungus cultivation presumably originated when fungus-eating ancestors of the leaf-cutters stabilized their food supply by eating fungi growing on the refuse in their nests. Ants that provided better growing conditions for these fungi had more fungus to eat (FIGURE 44.11), and fungi that provided better ant food benefited from faster ant colony growth and queen production. Ants that chose the best fungus cultivars benefited from more productive crops, and fungi that provided ants with nutrient-rich and easy-to-harvest structures were more likely to be propagated by ants. Leaf-cutter ants expanded their food base by feeding fresh leaf material (which ants cannot digest) to their fungus; the fungus then converted

leaf matter into food the ants could consume. The fungi benefited by having access to food that they would not be able to use if ants did not chop it up for them. The ants' behavior contributed to the great ecological success of leaf-cutter ants and their fungus; leaf-cutter ants are not only major herbivores in the Neotropics, they have expanded into dry environments, such as the Arizona desert, that are normally hostile to fungi.

FIGURE 44.11 A Fungal Garden Cutaway view of the nest chamber of the leaf-cutter ant *Acromyrmex octospinosus*. The ants cultivate and feed on the white fungus.

44

SUMMARY

concept 44.1 Interactions between Species May Be Positive, Negative, or Neutral

- **Interspecific interactions** have consequences that affect the fitness of individuals and thus the growth rates and densities of populations and the distributions of species.
- Interspecific interactions can be divided into five broad categories depending on whether their effects on the interacting species are positive, negative, or neutral. **Review Figure 44.1 and WEB ACTIVITY 44.1**
- **Interspecific competition** refers to interactions in which members of two or more species use the same resource. There generally is one **limiting resource** that is in the shortest supply relative to demand.
- In **consumer–resource interactions**, the consumer gains nutrition and the resource species is killed or harmed. Consumer–resource interactions include **predation**, **herbivory**, and **parasitism**.
- A **mutualism** is an interspecific interaction that benefits both participants.

- **Commensalism**, in which one participant benefits while the other is unaffected, and **amensalism**, in which one participant is harmed while the other is unaffected, are not reciprocal and thus do not show the same ecological or evolutionary dynamics as other types of interspecific interactions.
- Many interspecific interactions have both beneficial and harmful aspects, and their effects may be contingent on environmental conditions. **Review Figure 44.2**

concept 44.2 Interspecific Interactions Affect Population Dynamics and Species Distributions

- The equation for density-dependent population growth, which describes **intraspecific competition**, can be extended to include the effects of interspecific competitors on per capita growth rates. Consumer–resource interactions and mutualisms can be described in a similar way by equations.

- The per capita growth rate and the average population size of each interacting species are modified by the presence of the other in a way that depends on the type of interaction.
- In interactions with negative effects on one species (consumer–resource interactions, competition, and amensalism), extinction of one or both of the interacting species is possible. **Review Figure 44.3**
- The presence or absence of other species can make an environment favorable or unfavorable for a species and so affect its distribution. **Review Figure 44.4**
- Coexistence of species competing for resources, and of prey species with their predators, is possible if the populations of such species can increase even at low densities. Differences between competing species in their use of resources, known as **resource partitioning**, often are great enough to generate such a rarity advantage. **Review Figure 44.4**

concept 44.3 Interactions Affect Individual Fitness and Can Result in Evolution

- If intraspecific competition results in directional selection for traits that allow individuals to use new resources, or to use resources more efficiently, it can increase the carrying capacity of the population.
- If interspecific competition results in directional selection for traits that allow individuals of one species to use resources different

from those a competitor species uses, resource partitioning and coexistence may result. **Review Figures 44.6 and 44.7**

- The opposing interests of consumer species and resource species can lead to an “evolutionary arms race” in which resource species continually evolve better defenses and consumer species continually evolve better offenses.
- Mutualisms involve mutual exploitation and the exchange of goods and services. The fitness effects of mutualisms may vary with environmental conditions that determine the value and cost of the goods and services that are exchanged. Mutualisms often involve cheating. **See ANIMATED TUTORIAL 44.1**

concept 44.4 Introduced Species Alter Interspecific Interactions

- Species introduced into a new region by humans, whether accidentally or intentionally, can alter interactions among the native species of that region.
- Species introduced into a region where their natural enemies are absent may become **invasive**, reproducing rapidly and spreading widely.
- Invasive species are likely to have negative effects on native species that lack adaptations to compete with or defend themselves against the invaders. Invasive species may even drive native species extinct.

Ecological Communities

45

We have *Coffea arabica* to thank for 70 percent of our morning cup of coffee. This understory shrub or small tree of tropical forests originated in the southwestern Ethiopian highlands as a natural hybrid between *C. canephora* (“robusta” coffee, from which we get the other 30 percent) and *C. eugenioides*, both of which hail from west and central Africa.

Coffea arabica has probably been cultivated in Ethiopia for 1,500 years, although the earliest written description of the plant dates to a tenth-century set of physician’s notes. Molecular genetic evidence indicates that cultivation spread to Yemen about A.D. 575. Coffee was widely traded within the Muslim world, in spite of controversy there about use of a stimulant (see the opening of Chapter 5), and the first coffeehouses were in Arabia. The beverage reached Italy in the 1600s and later spread through Europe. Arabs tried to keep a corner on the coffee market by banning export of plants and fertile seeds, but the Dutch managed to smuggle some live plants out of Yemen and introduced the crop into their colonies.

By the 1700s, coffee cultivation had spread from Africa to Southeast Asia and the Americas. Coffee is now one of the most valuable export commodities of the developing world, second only to oil. As demand has grown, worldwide production has risen from about 5 million metric tons per year in the 1970s to about 7 million metric tons today, and coffee production employs some 25 million people in developing countries.

Most coffee is grown in tropical regions using a variety of cultivation methods. The least intensive, traditional method is to plant coffee in the shade of undisturbed

forests. This practice embeds coffee in natural forest communities, with minimal loss of their original plant and animal species. Medium-intensity shade cultivation replaces the forest with a low-diversity plantation of trees, under which the coffee is grown. High-intensity sun cultivation uses no shade trees; modern genetic cultivars are planted at high densities, heavily pruned, and subsidized with fertilizer, herbicides, and pesticides. Thus the more intense methods increasingly replace natural communities with human-constructed communities that contain far fewer species. High-intensity methods increase coffee yields, but they sacrifice the greater biological diversity that traditional methods maintain, cause greater pollution, and require costly chemicals.

This coffee plantation uses high-intensity sun cultivation techniques that increase crop yield at the expense of species diversity.

Can we use principles of community ecology to improve methods of coffee cultivation?

concept 45.1 Communities Contain Species That Colonize and Persist

The interactions between pairs of species that we explored in the last chapter are only a part of the much broader web of interactions taking place in ecological communities. A **community** is a group of species that coexist and interact with one another within a defined geographic area. Ecologists sometimes specify the boundaries of a community in terms of discontinuities in habitat; the edge of a pond, for example, defines a community of aquatic species that interact much more with one another than with terrestrial species outside the pond. Alternatively, ecologists may define a community somewhat arbitrarily by designating the boundaries of an area they wish to study.

Because it is impossible or impractical to study all the species within a defined area, ecologists often restrict their attention to particular subsets of species. Those subsets may be defined taxonomically or by types of interactions. Hence biologists may speak of the bird community of an island, the *Daphnia* community of rock pools (see Figure 43.10), the community of beetles that live in dung, or the pollinator community of a forest.

We characterize communities in terms of their **species composition**: the particular mix of species they contain and the relative abundances of those species. The mix of species in a community is determined by the same factors that explain the distributions of species—as we saw in Chapter 43, a species can occur in a location only if it is able to colonize that location and to persist there. A community thus contains those species that have colonized minus those that have gone extinct locally. Extinction can occur for several reasons. Individuals may be unable to tolerate environmental conditions, or a resource may be lacking. Populations may be excluded by competitors, predators, or pathogens. Finally, some species may go locally extinct because their populations are so small that, by chance, all individuals die during a time interval without reproducing (see Concept 43.5). Abundances of the species that remain in the community are determined by population-level processes that were discussed in Chapters 43 and 44.

We can therefore think of communities as being *assembled* through the gain and loss of individual species. This process is

well illustrated by Krakatau, a small (17 km²) volcanic island in the Sunda Strait of Indonesia (**FIGURE 45.1A**). The volcano exploded in 1883, sterilizing what was left of the island and covering it with a thick layer of ash. Scientists quickly mounted expeditions to observe the return of life to the island and have re-surveyed it periodically ever since. By 1886, seeds of 10 plant species that grow on nearby tropical beaches had floated to the island (**FIGURE 45.1B**), and the wind had brought seeds or spores of 14 additional species of grasses and ferns. By the 1920s, the wind had carried tree seeds to the island. As the forest canopy closed in, some pioneering plant species that require high levels of light disappeared from the island's now-shady interior.

Once forests developed, fruit-eating birds and bats began to be attracted to the island, bringing new animal-dispersed seeds with them. In the many years since Krakatau exploded, the types of communities found there have stabilized. Nonetheless, the species composition of those communities continues to change as new species colonize, earlier colonists go extinct, and species abundances shift.

Do You Understand Concept 45.1?

- Describe at least two ways in which ecologists define which species to include in the study of a community.
- Describe the processes that are involved in community assembly.
- Why would abundances of the species on Krakatau shift as new species arrive? (Hint: See Concept 44.2.)

Krakatau provides a dramatic illustration of a general feature of communities: their species composition changes over time. Communities also change in space. Are there general rules that govern which species we find where and when?

FIGURE 45.1 Vegetation Recolonized Krakatau (A) Almost 125 years after a massive eruption left the island an ash-covered shell, vegetation has once again covered much of the island. (B) Beach vegetation such as *Ipomoea pes-caprae* (beach morning glory) was among the first to take hold on the denuded island.

concept 45.2 Communities Change over Space and Time

Ecologists have noted repeated patterns to spatial and temporal changes in species composition, indicating that the species we find in one place and time are not a random subset of those that potentially could be there. Let's take a closer look at these patterns and what they mean.

Species composition varies along environmental gradients

Even a small island like Krakatau contains gradients in physical conditions, ranging from shoreline habitat that is buffeted by wind and waves to inland habitat that varies in elevation (from 0 m at sea level to 800 m at the highest point) and from gentle ash-covered slopes to steep rocky escarpments. When we look at plant species composition, we find that it is similar in locations on the island with similar physical conditions, and different in locations with different conditions. In other words, species composition changes along environmental gradients. Sandy beaches all around the island are dominated by low-growing herbs and vines, bordered inland by a fringe of short trees and shrubs. Gentle inland slopes are dominated by taller trees with an understory of vines and ferns. The summit, which often is in the clouds, is covered in a thick growth of short, moss-covered trees (see Figure 45.1).

Such spatial variation in environmental conditions is generally associated with predictable changes in species composition. The serpentine outcrops that provide habitat for Edith's checkerspot butterfly (see Figure 43.1), for example, contain soils that are chemically distinct from those of surrounding

areas. Many plants cannot tolerate the high content of heavy metals in serpentine soils, which therefore support very different plant communities than do non-serpentine soils. If we measure off a *transect*—a straight line used for ecological surveys—running from a non-serpentine to a serpentine area and identify the plants that occur along it, we will find different species in each type of soil the transect encounters. As we move along the transect, we will observe *species turnover* through space—that is, some species drop out and new ones appear (FIGURE 45.2).

The early naturalist-explorers who documented associations of climate and vegetation—the *biomes* described in Concept 42.3—likewise documented associations of vegetation with particular animal species. In some cases, such as Edith's checkerspot butterfly, animal species are found in certain plant communities because the plants that they eat grow there. In other cases, animals are associated with particular plant communities because plants modify physical conditions such as temperature and humidity and contribute to *habitat structure*—characteristics of the surfaces and the horizontal and vertical distribution of objects. The vertical distribution of leaves and the density, size, and surface texture of plant stems differ considerably between forest and grassland communities, for example. Animals typically are associated with habitats of particular structure because structure determines the effectiveness of an animal's particular method for obtaining food or escaping predators (FIGURE 45.3).

Several processes cause communities to change over time

As we saw in the case of Krakatau, community composition changes not only over space, but also through time. Krakatau is not unique—all communities, not just those in the early stages of assembly, are dynamic. Over very long periods, of course, the species composition of communities reflects evolutionary changes. But species composition also changes over short periods.

Three major processes contribute to this dynamism—extinction and colonization, disturbance, and climate change.

EXTINCTION AND COLONIZATION Ecological communities are unlikely to remain unchanged even in a constant environment because species may go locally extinct and be replaced by new species that arrive from time to time. As we saw in Concept 45.1, extinction has several causes. As we saw in Chapters 42 and 43, dispersal is an ongoing process that delivers a constant influx of new individuals to all but the most isolated locations. When those individuals arrive at a location that already contains a population of the same species, they add to its size; when those individuals are members of a new species, they can establish a new population. The result of ongoing extinction and colonization is steady turnover in

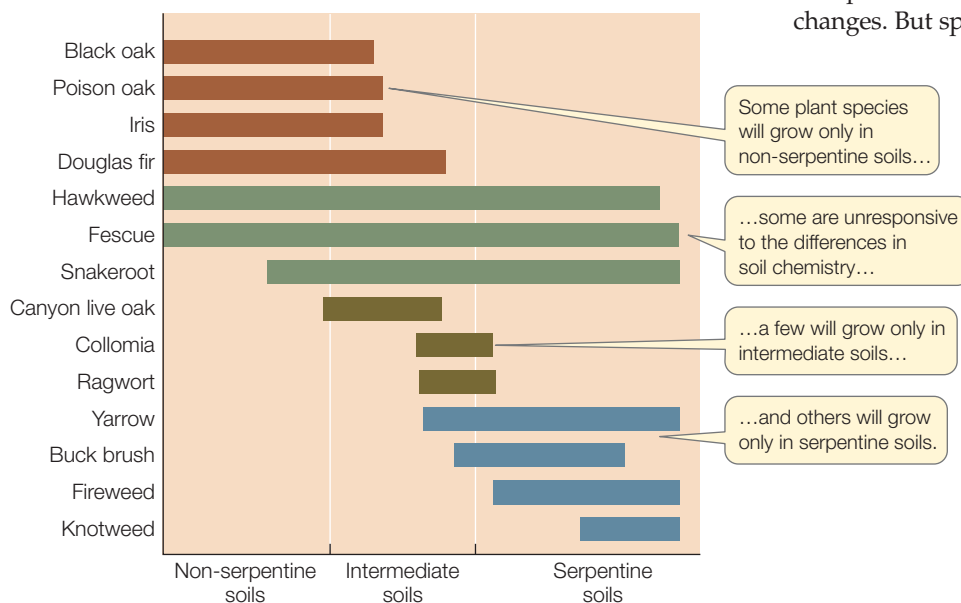

FIGURE 45.2 Species Turnover along an Environmental Gradient As ecologists identified plant species along a transect running from non-serpentine to serpentine soils, they found that some species dropped out and new ones appeared.

FIGURE 45.3 Many Animals Associate with Habitats of a Particular Structure (A) The legs and feet of the red-breasted nuthatch (*Sitta canadensis*) allow it to cling to the trunks, branches, and twigs of trees as it gleans small arthropods and seeds. It prefers conifer forests. (B) Elk (*Cervus canadensis*) prefer open habitats that present no obstacles to escape from wolves.

the species composition of communities, as is occurring on present-day Krakatau.

DISTURBANCE Species turnover can be caused by sudden environmental change. Examples are volcanic eruptions, wildfires, hurricanes, landslides, and human activities. Such disturbances wipe out some or all of the species in communities and alter the physical environment. Sudden environmental change also can occur without the destruction of a resident community. New environments can suddenly appear, for example when an island rises out of the sea, a glacier melts away, a depression fills with rainwater—or a large mammal deposits dung.

After a sudden change in the environment, species often replace one another in a relatively predictable sequence called **succession**. A freshly deposited patch of elephant dung, for example, is colonized by a predictable sequence of species of dung beetles (Scarabidae). These animals eat dung and lay their eggs on it; some species typically arrive early and are replaced by later arrivals (**FIGURE 45.4**).

Several factors are responsible for successional sequences. One is that species vary in their colonizing ability. The first species to arrive are good dispersers. Early-arriving dung beetles tend to be strong fliers with excellent senses of smell, or “hitchhikers” that ride on dung-producers and colonize the dung as it

is produced. Similarly, the first plant species on Krakatau were those with seeds that are readily dispersed by sea or wind.

A second factor in succession is that environmental conditions in the disturbed or new site change over time, and species differ in their environmental tolerances. Early-arriving dung beetles must cope with wet conditions; pioneering species on Krakatau had to tolerate full sun and volcanic ash. Later-arriving species experience an environment that has changed because of physical processes and the presence and activities of early-arriving species. Dung dries out over time, so late-arriving beetle species must cope with a drier environment. Similarly, the seeds of plants that colonized Krakatau after the forest canopy had closed had to be able to germinate in the shade of other plants and to compete successfully for water and nutrients in soils that earlier colonists had modified.

When a disturbance destroys a pre-existing community, succession often leads eventually to reestablishment of a community that resembles the original one. On Krakatau, the tropical forests destroyed by the volcanic eruption eventually came back. After some types of disturbance, however, the original community is not reestablished. Instead, there is an **ecological transition** to a distinctly different community. The conversion of grasslands to shrublands in the U.S.–Mexico Borderlands following intensive cattle grazing (see the opening of Chapter 42) appears to be an example of such a transition.

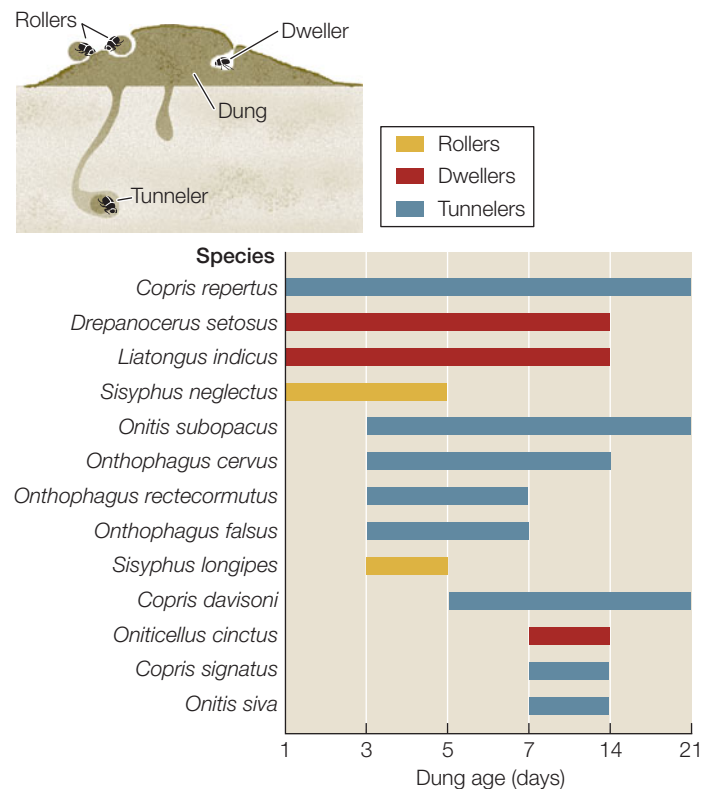

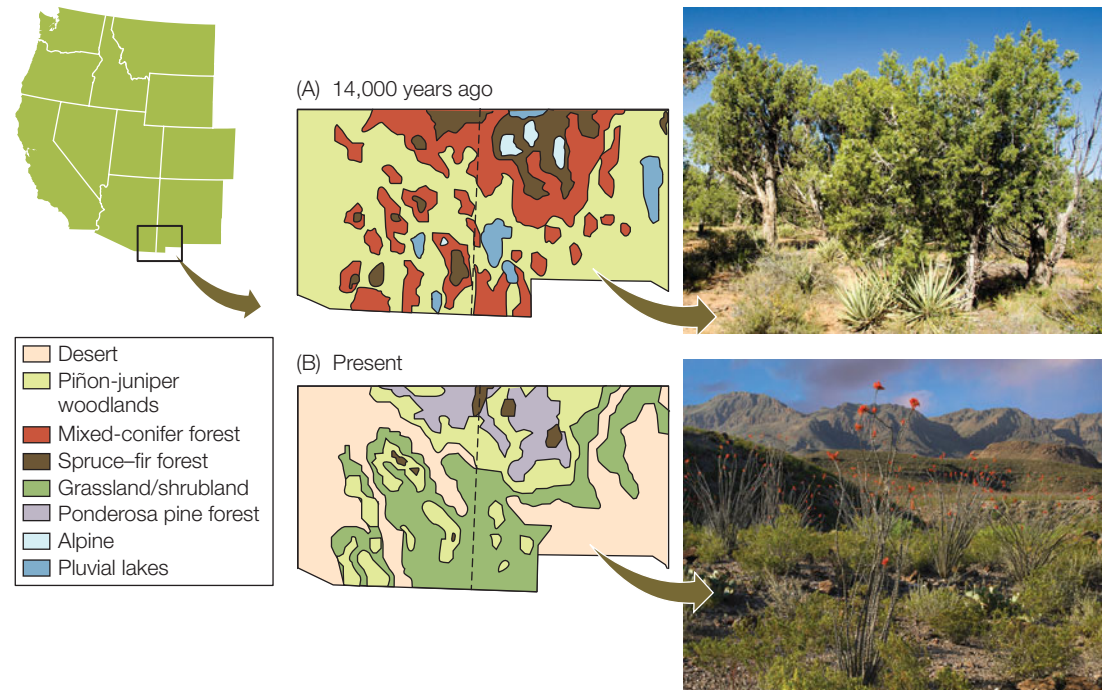

FIGURE 45.4 Dung Beetle Species Composition Changes over Time The Indian dung beetles in this study feed on and lay eggs in piles of elephant dung. Exactly which species are present in a given pile of dung varies over time in a predictable way, dictated by the adaptations of each species for finding and using dung.

FIGURE 45.5 Species Composition Changes with Climate Change (A) Fossilized plant remains extracted from ancient packrat middens indicate that 14,000 years ago, when the climate was moist, valleys in the U.S.–Mexico Borderlands held lakes whose shores were clothed in piñon–juniper woodland. (B) In today’s more arid climate, the lakes have dried up and the woodland has given way to desert grassland and shrubland.

Succession on a Glacial Moraine

CLIMATE CHANGE A final cause of temporal variation in communities is climate change. As physical conditions change, the geographic ranges of species necessarily change with them. One way in which ecologists have been able to reconstruct the history of such changes is by analyzing fossilized remains of plants found in middens—refuse piles—left by packrats (*Neotoma* spp.). These rodents bring plant material into their nests, which, when preserved, provides a record of the vegetation that was present when the packrats were alive. Using carbon-14 (see Figure 18.1) to date packrat midden fossils, biologists have been able to show how plant communities of the Borderlands changed over the last 14,000 years as the climate became drier (**FIGURE 45.5**).

Do You Understand Concept 45.2?

- Why are animal species often associated with particular plant communities?
- How do successional sequences differ from species turnover resulting from ongoing colonization and extinction?
- Give an example of an environmental gradient that you have observed yourself, explaining what factors change along it and what visible changes you see in the species present.

Now that we have seen what factors can affect the species composition of a community, let’s examine how interactions among those species influence the movement of energy and materials through the community.

concept 45.3

Trophic Interactions Determine How Energy and Materials Move through Communities

Each species in a community has a unique **niche**. This central ecological concept refers to the set of environmental tolerances of a species, which define where it can live. It also refers to the way in which a species obtains energy and materials and to its pattern of interaction with other species in the community, both of which affect the dynamics of the species’ population (see Chapters 43 and 44).

Interactions among the members of a community are extensive. For example, most plants are pollinated by more than one pollinator species, and pollinators rarely visit only one plant species. Furthermore, each species in a web of pollination interactions is connected to a much larger set of species that act as its competitors, hosts, parasites, consumers, and so forth. *Prosopis* species (mesquite; see the opening of Chapter 42) in southeastern Arizona are pollinated by many species of native bees and other insects, and their leaves are eaten by dozens of species of herbivorous insects. The seeds are eaten (and dispersed) by various ants, rodents, and beetles as well as by coyotes, foxes, and deer. The roots interact with an entire community of soil fungi and bacteria as well as with roots of other plants. Each of the species that interacts with *Prosopis* in turn interacts with a constellation of other species.

Consumer–resource interactions determine an important property of communities

Although the extensive network of interspecific interactions within a community may seem bewildering, one way to

simplify it is to focus on how these interactions contribute to an important community-level property: the flow of energy and materials through the community. Most interspecific interactions directly or indirectly involve the exchange of energy and materials. In predator–prey and host–parasite interactions, one species (the prey or host) is a resource—a source of energy and materials—to a consumer (the predator or parasite). Most competition occurs between consumers that use some of the same sources of energy and materials—for example, sunlight, chemical nutrients, or food. Even mutualisms usually involve consumers and resources. In most plant–pollinator interactions, the service of pollination is a by-product of the consumption of a resource (nectar or pollen) by a consumer (the pollinator). Protists that live inside corals photosynthesize, producing carbohydrates that the corals consume (see Figure 20.19).

Consumer–resource, or **trophic** interactions (Greek *trophes*, “nourishment”) cause energy and materials to flow through a community. Most biologically available energy enters communities via photosynthetic organisms, which use solar energy to manufacture the carbohydrates that fuel their metabolism. Because these organisms convert solar energy into a form that can be used by the rest of the community, they are called **primary producers**. They are also called **autotrophs** (“self-feeders”) because they create their own “food” from inorganic sources.

Species that obtain energy by breaking apart organic compounds that have been assembled by other organisms are called **heterotrophs** (“other-feeders”). Heterotrophs that dine on primary producers are called **primary consumers**, or herbivores. Those that consume herbivores are called **secondary consumers**, or primary carnivores; those that consume primary carnivores are called **tertiary consumers**, or secondary carnivores, and so on. These feeding positions—primary producers and primary, secondary, and tertiary consumers—are called **trophic levels**. Some organisms, called **omnivores**, feed from multiple trophic levels. **Decomposers**, also called **detritivores**, feed on

waste products or dead bodies of organisms. Decomposers are largely responsible for the recycling of materials within ecosystems—they break down organic matter into inorganic components that primary producers can absorb (TABLE 45.1).

Trophic interactions can be described in diagrams that show linkages between interacting species as arrows that indicate the direction of the flow of energy and materials—that is, who eats whom—and to organize those linkages vertically according to trophic level. An interaction diagram organized in this way is called a **food web** (FIGURE 45.6).

Energy is lost as it moves through a food web

The total amount of energy that primary producers capture and convert to chemical energy during some period of time is called **gross primary productivity (GPP)**. The energy that is contained in the tissues that primary producers have produced during that time is called **net primary productivity (NPP)**, and it is what is available for consumption. GPP and NPP can be measured from the rate of uptake of carbon dioxide during photosynthesis and its release during respiration. Although new technologies allow us to measure such gas exchange in nature, it is often more convenient to use change in *biomass* of primary producers (the dry mass of their tissues) during a period of time as an approximation for NPP.

The flow of energy through trophic levels is shown in simplified form in FIGURE 45.7. Only about 10 percent of the energy

FIGURE 45.6 A Food Web in the Yellowstone Grasslands

The arrows show who eats whom. Even as highly simplified here, the web is complex. Species whose sole source of food is plants (green arrows) are primary consumers. Secondary and tertiary consumers are carnivores who kill and eat live animals (red arrows). Omnivores such as grizzly bears, coyotes, and ravens eat plant and animal tissues; ravens and grizzlies also eat carrion (dashed red arrows), so these species are also decomposers.

TABLE 45.1 The Major Trophic Levels

TROPHIC LEVEL	SOURCE OF ENERGY	EXAMPLES
Primary producers (photosynthesizers)	Solar energy	Green plants, photosynthetic bacteria and protists
Primary consumers (herbivores)	Tissues of primary producers	Elk, grasshoppers, gypsy moth larvae, pollinating bees, geese
Secondary consumers (carnivores)	Tissues of herbivores	Spiders, great tits, cheetahs, parasites
Tertiary consumers (carnivores)	Tissues of carnivores	Tuna, killer whales, parasites
Omnivores	Several trophic levels	Coyotes, opossums, crabs, robins, white-footed mice
Decomposers (detritivores)	Dead bodies and waste products of other organisms	Fungi, many bacteria, vultures, earthworms, dung beetles

incorporated in primary producer biomass is incorporated in primary consumer biomass. Similarly, only about 10 percent of the energy in primary consumer biomass becomes secondary consumer biomass. This **ecological efficiency** of roughly 10 percent means that, on average, the total biomass of each trophic level is about one-tenth that of the level it feeds on. This loss of available energy at successive levels limits the number

of trophic levels a community can support; few communities support more than four.

There are several reasons for the incomplete transfer of energy between trophic levels. First, not all the biomass at one trophic level is ingested by the next one—for example, herbivores routinely miss hard-to-get plant parts or avoid eating plants that are well defended chemically. Second, some ingested matter is indigestible and is excreted as waste. Tree bark, for example, contains lignin and cellulose, which most herbivores cannot digest. Finally, and most importantly, consumers as well as primary producers use much of the energy they assimilate (the digested portion of what they ingest) to fuel their own metabolism rather than to add biomass through growth or reproduction.

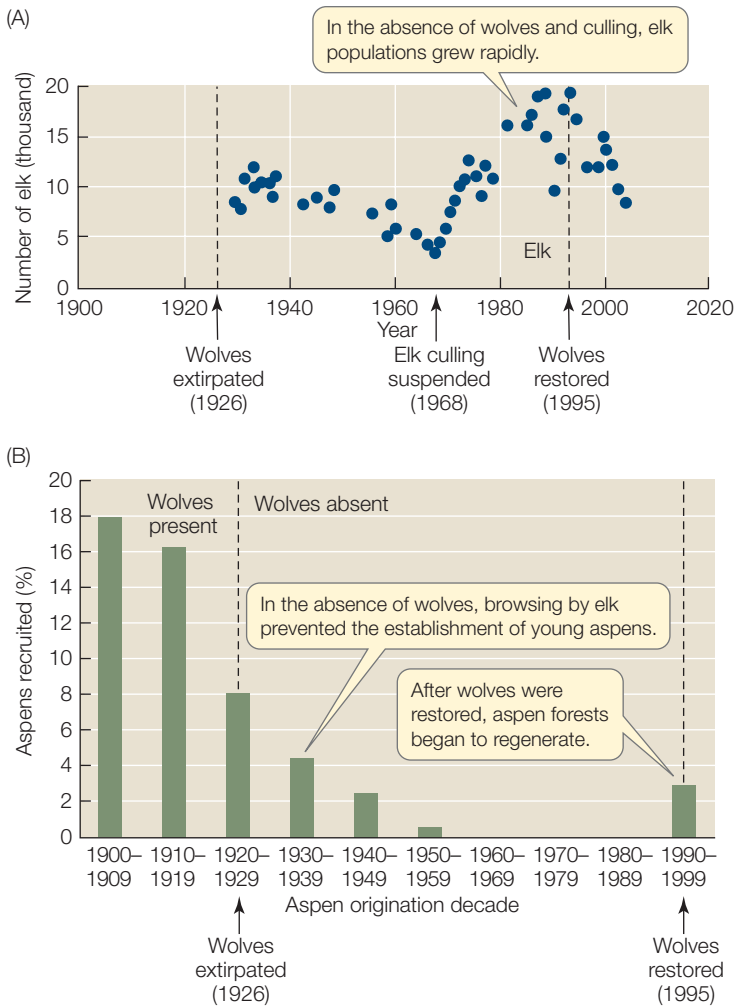

Trophic interactions can change the species composition of communities

As we saw in Chapter 44, interspecific interactions affect the per capita growth rates, and densities, of the participating species—positively in the case of mutualisms, negatively in the case of competition, and positively for one species and negatively for the other in consumer–resource interactions. The per capita growth rate of a species is a function of the sum of the positive and negative contributions across all of the species with which it interacts. The extensive web of interaction among species in a community means that a change in the density of any one species (or the addition of a new species) can precipitate changes in density that ripple through the community. Succession can be driven by such interactions when, for example, later-colonizing species of dung beetles inhibit early colonizers by competing for dung nutrients, or late-arriving plants

Go to **WEB ACTIVITIES 45.1 and 45.2**
The Major Trophic Levels
Energy Flow through an Ecological Community

FIGURE 45.7 Energy Flow through Ecological Communities On average, the total energy incorporated into the biomass of a trophic level per unit time is about one-tenth that of the level above it (i.e., the level that it feeds on). Of the 90 percent of energy not available to the next trophic level, some is waste or dead material used by decomposers, and some is used up in the cellular respiration that supports metabolism.

(C) *Populus tremuloides***FIGURE 45.8 Removing Wolves Initiated a Trophic Cascade**

(A) The elk population in Yellowstone National Park increased rapidly once wolves were removed (extirpated) and the park stopped culling the elk herd. (B) Young aspens did not become established when wolves were absent and the abundant elk browsed the trees. (C) Researchers constructed an “elk exclusion” fence to demonstrate that aspen regenerated only inside the fence, where elk were absent.

aspen groves and willow thickets, where they are especially vulnerable to wolf predation (see Figure 45.3B). The consequence is that young aspen now survive, willows regrow, and species associated with them, such as beavers, have increased. Thus by eliminating and then restoring one predator species, humans caused trophic cascades that affected species at two lower trophic levels.

shade out pioneering species. Consumer–resource interactions are so prevalent in communities that ripple effects often cross trophic levels, resulting in a pattern called a **trophic cascade**.

An example of an anthropogenic (human-caused) trophic cascade comes from Wyoming’s Yellowstone National Park. Wolves in the park feed on a variety of large mammals, including elk (see Figure 45.6). Wolves exert particularly strong effects on the park community’s structure and dynamics, as demonstrated by the effects of their absence during most of the twentieth century. For much of the twentieth century, there were no restrictions on wolf hunting, and by 1926 wolves had been eliminated from the park. Their removal had several effects on species at other trophic levels.

Park managers initiated annual censuses of elk in 1920. Concerned by the rapid increase in elk numbers after wolves disappeared, the park deliberately reduced elk densities (that is, culled some members of the herd) until public pressure caused them to stop in 1968. Elk densities subsequently increased (FIGURE 45.8A). The elk browsed aspen trees so heavily that no young trees were added to the population after 1960 (FIGURE 45.8B). The elk also browsed streamside willows, with the result that beavers, which depend on willows for food, nearly went extinct locally.

In 1995 park managers reintroduced wolves to Yellowstone. Not only did elk populations decrease, but elk began to avoid

FRONTIERS The complexity of ecological interactions makes mathematical modeling an essential tool for studying community properties and dynamics. Ecologists are studying webs of ecological interactions with the same mathematical theory that is used to understand human social interaction networks (Facebook, for example) and communication networks (the Internet, for example). Studies of ecological interaction webs are providing insights into such issues as whether losses of species from a community will lead to further species extinctions.

Do You Understand Concept 45.3?

- What is the major source of energy for communities, and how does it enter them?
- At what trophic level would you place humans?
- What is the general rule of “10 percent ecological efficiency,” what explains it, and how does it influence the number of trophic levels we see in communities and the total biomass at each level?
- What would a terrestrial landscape look like if its communities contained no decomposers?

Ecologists view trophic interactions and the resulting flow of energy and materials as manifestations of *community function*. In the next concept we will see what community function is and how it is affected by another community-level property, *species diversity*.

concept 45.4 Species Diversity Affects Community Function

Communities differ in their biological variety, often to a striking degree. Most people who visit a tropical rainforest, for example, are struck by the impression that each plant or animal they encounter differs from the last one, whereas other types of communities are more monotonous. It is these differences among communities that we wish to capture in a measure of their species diversity. Such measures are important because species diversity influences many functional properties of a community, including ones that affect humans.

The number of species and their relative abundances contribute to species diversity

Ecologists recognize two primary components of species diversity, which are illustrated in **FIGURE 45.9**. One is simply the number of species in the community, called **species richness**. A community that contains more species is more diverse, all else being equal. A less intuitive component of diversity has to do with the distribution of species' abundances, a property called **species evenness**. A community that has four equally abundant species is more diverse than one in which 75 percent of individuals are one species and the remaining 25 percent are spread among three other species. The former community has a more even distribution of species abundances.

Ecologists can use species richness as a simple measure of diversity, but they often prefer to use a mathematical diversity index that incorporates both richness and evenness. This is because both aspects of diversity affect *community function*. A species' influence in a community depends not only on its pattern of interaction, but also on its abundance. Properties

of a community with a few very abundant species are largely defined by them, rather than by the many rare ones.

Species diversity affects community processes and outputs

As we saw in Chapter 42, an ecological community can be thought of as a system, analogous in some ways to a man-made machine that has inputs, "internal workings," and outputs. Communities function by taking in, transforming, and putting out energy and materials. The function of a community can be measured in terms of these inputs and outputs. Important measures of overall function are the total flow of energy into the community, which is GPP, and the net energy that is made available for consumption by heterotrophs, which is NPP. We also can measure function for parts of the community. Wolves convert elk into new wolves, for example—a conversion of primary consumer biomass (an input) into secondary consumer biomass (an output). The output of seeds and fruits by most flowering plants is a function of an input by insect pollinators. Retention of nutrients within an ecosystem is a function of the output of the community's decomposers—the recyclers. Many of these outputs affect not only species in the community but also humans and other ecosystems—they represent "goods" and "services," as we will see in Concept 45.6.

Ecologists have discovered that community outputs vary with species diversity. Within a community type, NPP generally is greater and more stable over time as species diversity increases. Control of agricultural pests by natural predators and parasites is enhanced when multiple crops are planted together or when a diverse natural plant community borders agricultural fields. Diverse plant communities use inputs of soil nutrients more efficiently. These are just a few examples.

David Tilman and his colleagues at the University of Minnesota have undertaken a long-term study of prairie plant communities. They cleared several outdoor plots into which they seeded

FIGURE 45.9 Species Richness and Species Evenness Contribute to Diversity These hypothetical communities of fungi (mushrooms) are all the same size (12 individuals) but differ in species richness (3 versus 4 species) and the species' relative abundances, both of which affect diversity.

between 1 and 32 native prairie species. After the plots had grown for 3 years, they harvested the plants and measured their above-ground biomass. They found that this measure of NPP increased as the species diversity of a plot increased (FIGURE 45.10A).

Ecologists are still discovering why species diversity affects community function, and this is an active area of research. Two basic possibilities exist. First, the relationship may be an effect of *sampling*: communities that contain more species are more likely, by chance, to contain some that have a strong influence on total community output. These species may be particularly good at pollination or pest control, or particularly productive, or particularly efficient in their resource use. Alternatively, diversity may affect community function because of *niche complementarity*: communities that contain more species may be better able to use all available resources because they are more likely

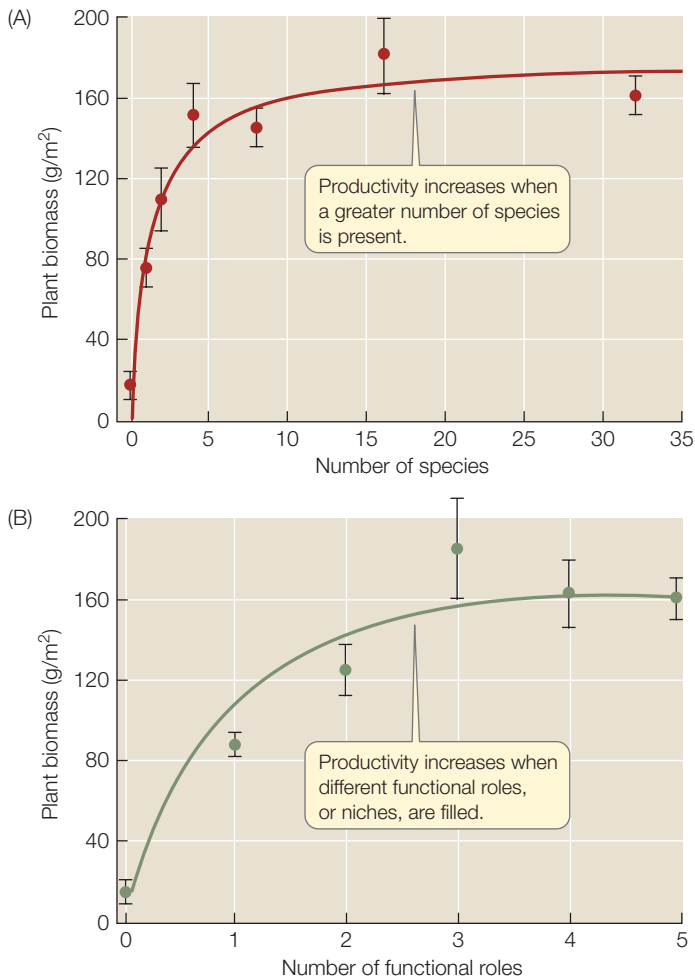

FIGURE 45.10 Species and Functional Group Diversity Affect Grassland Productivity (A) Primary productivity (measured as plant biomass produced over a 3-year period) increased with greater species richness. (B) Tilman and colleagues realized that species-rich plots also contain a greater diversity of plant functional groups (e.g., both C₃ and C₄ grasses, legumes with nitrogen-fixing bacteria, and woody shrubs) that differ in their growth responses to temperature, nutrient availability, and drought. These results suggest that productivity is enhanced by a greater variety of species with complementary functional roles.

to include species that have complementary niches. Indeed, Tilman and colleagues found that their most species-rich prairie plots also contained the largest number of plant *functional groups* (FIGURE 45.10B)—groups that differ in such traits as their ability to grow in warm versus cool seasons, in their associations with nitrogen-fixing bacteria, in their allocation to growth versus reproduction, and so on.

Do You Understand Concept 45.4?

- What are the two elements of species diversity?
- How are these two elements parallel to aspects of cultural and ethnic diversity in human societies?
- What outcome of Tilman and colleagues' experiment would have suggested that the effect of species diversity on community function is due to "sampling"?

We have now seen that species diversity is an important characteristic of communities because it affects how the community functions as an ecological system. But what factors influence species diversity?

concept 45.5 Diversity Patterns Provide Clues to Determinants of Diversity

The explorer–naturalists of the eighteenth and nineteenth centuries provided the first catalogues of how many species occurred in the various places they visited during their travels. Geographic patterns in species richness soon became apparent. These patterns indicate possible factors that affect diversity by modifying the balance between processes that add species to and remove species from communities.

Species richness varies with latitude

About 200 years ago, when the German naturalist Alexander von Humboldt traveled around Central and South America, Europe, and Asia, he remarked in the account of his voyages that "the nearer we approach the tropics, the greater the increase in variety of structure ... of organic life." Humboldt's observation that species richness varies with latitude has been amply confirmed for many taxonomic groups. A tropical forest in Malaysia, for example, may contain 227 tree species within a 2-hectare plot, whereas a comparable area of temperate forest in Michigan may contain 10–15 tree species. There are 56 bird species that breed in Greenland, 105 in New York State, 469 in Guatemala, and 1,395 in Colombia. Many other taxonomic groups (although not all) show similar latitudinal patterns (FIGURE 45.11).

What is it about the tropics that supports such diversity? Ecologists have tackled this fascinating and still-unresolved question by looking for correlations between latitude and environmental factors that can affect diversity. They have identified many possible causes of latitudinal diversity gradients. One possibility is

FIGURE 45.11 Species Richness Increases toward the Equator

Among swallowtail butterflies (Papilionidae), species richness decreases with latitude both north and south of the equator. Similar latitudinal gradients of species richness have been observed in many other taxa.

that climatic conditions have been more stable in the tropics because they were not subjected to the effects of the dramatic glacial cycles that disrupted temperate regions, causing massive shifts in geographic ranges and many extinctions. Tropical communities are certainly dynamic, and they are strongly influenced by disturbance such as the death and fall of individual trees—but the absence of disturbance at large spatial scales may have allowed these communities to retain more of their species, leaving them with higher diversity today.

We also know that climate changes with latitude. The tropics receive abundant solar energy input, which makes them warm and wet (see Concept 42.2). These conditions promote rapid growth of primary producers, so NPP, like diversity, increases toward the equator. Productivity can enhance diversity (as well as be enhanced by diversity; see Concept 45.4) if greater energy input into food webs supports larger population sizes. It can also enhance diversity if greater energy input allows species to maintain viable population sizes even as they become more specialized in their use of resources or habitats. In this way, greater energy flow through communities could facilitate coexistence of a greater number of species with narrow, specialized niches.

LINK Some ways in which differences in resource use evolve and promote coexistence are described in Concepts 44.2 and 44.3

Spatial heterogeneity could interact with greater niche specialization to amplify tropical diversity. In general, diversity is higher in more structurally complex habitats. Bird species diversity, for example, increases with the diversity of foliage height in deciduous forests (FIGURE 45.12). If tropical species have more specialized habitat requirements, and if tropical vegetation is more structurally complex by virtue of greater plant species richness, then environmental heterogeneity and productivity may interact to increase tropical diversity.

Although ecologists still have much to learn about the relative contributions of these various factors to the puzzle of tropical diversity, the research stimulated by that puzzle has demonstrated that disturbance patterns, productivity, and environmental heterogeneity all affect the diversity of at least some taxa in some locations.

**Diversity represents a balance between colonization and extinction**

In addition to documenting latitudinal diversity gradients, the explorer–naturalists noted that oceanic islands contain fewer species than areas of comparable size on nearby mainlands. They also noted that small islands contain fewer species than large islands, and isolated islands contain fewer species than comparable-size islands closer to a mainland. These patterns, shown for birds in FIGURE 45.13, have been documented for a wide variety of taxa, and for islands worldwide.

Island diversity patterns remained mysterious for a long time—they could not be explained by productivity, habitat heterogeneity, or disturbance rate because those factors do not vary consistently with island size or isolation. In 1963, Edward O. Wilson and Robert MacArthur realized that, just as population size reflects the balance between additions (births)

FIGURE 45.12 Structurally Complex Habitats Support Greater Diversity The greater the foliage height diversity is in a deciduous forest, the greater its bird species diversity.

FIGURE 45.13 Area and Isolation Influence Species Richness on Islands Species richness increases with island area and decreases with distance from a source of colonists.

and losses (deaths), species richness on islands might represent a balance between the rate at which new species are added to a community and the rate at which resident species go extinct. Their theory of **island biogeography** accounts for island diversity patterns as follows:

- An offshore island gains species only if they colonize from elsewhere—usually from nearby islands or continents, whose communities make up the pool of potential colonists.
- The rate at which new species arrive on an island must decline as the island fills with species. At first, every immigrant represents a species new to the island, but as the island fills up, more and more of the arriving individuals represent species already resident there. (If all species in the mainland species pool were present, the colonization rate would be zero.)
- The overall rate at which species are lost from the island—the extinction rate—must increase as the island fills with species. In a time period, each species has some chance of going extinct from

FIGURE 45.14 MacArthur and Wilson's Theory of Island Biogeography (A) Species richness reaches a stable equilibrium when the colonization rate equals the extinction rate. (B) Smaller islands have larger per species extinction rates, and hence lower equilibrium species richness. (C) Islands more distant from the mainland have lower colonization rates, and hence lower equilibrium species richness.

various causes, and as the number of species increases, so does the overall number that go extinct per unit of time.

- The number of species on an island—its species richness—stops changing if the colonization rate equals the extinction rate. When we plot colonization and extinction rates on a graph, this equilibrium species richness is represented by the point at which the two curves cross, \hat{S} (FIGURE 45.14A).

This theory predicts that an island's equilibrium species richness will depend on relative rates of colonization and extinction. And those rates, as MacArthur and Wilson pointed out, should vary both with island size and island isolation. Population sizes will decline as island size decreases, and since small populations are more at risk of extinction, the extinction rate for small islands should rise more steeply than that of large islands as a function of total species on the islands. Thus the equilibrium species richness should be lower on small islands (FIGURE 45.14B). Similarly, fewer wind- and waterborne seeds, and fewer dispersing animals, will encounter a distant island than one closer to the mainland species pool. As a result, the colonization rate, and thus equilibrium species richness, should be lower for more isolated islands (FIGURE 45.14C).

The theory of island biogeography has been tested in natural communities and has proved to be one of the most successful explanatory theories in ecology (FIGURE 45.15).

INVESTIGATION

FIGURE 45.15 The Theory of Island Biogeography Can Be Tested By experimentally removing all the arthropods on four small mangrove islands of equal size but different distance from the mainland, Simberloff and Wilson were able to observe the process of recolonization and compare the results with the predictions of island biogeography theory.

HYPOTHESIS

The rate at which experimentally defaunated islands accumulate species initially, and their equilibrium species number, will decrease with distance from a mainland source of colonists.

METHOD

1. Census the terrestrial arthropods on 4 small mangrove islands of equal size (11–12 m diameter) but different distance from a mainland source of colonists.
2. Erect scaffolding and tent the islands. Fumigate with methyl bromide (a chemical that kills arthropods but does not harm plants).

3. Remove tenting. Monitor recolonization for the following 2 years, periodically censusing terrestrial arthropod species.

RESULTS

Recolonization was fastest on the closer islands, slowest on the one farthest from the mainland. Two years after defaunation, each island had about the same number of species it had before the experiment.

CONCLUSION

The data support the theory that species richness on islands represents a dynamic balance between colonization and extinction rates.

Do You Understand Concept 45.5?

- Describe at least two factors that may contribute to the high species diversity of tropical forests.
- Tropical coral reef communities are among the most species-rich of any on Earth. Speculate on factors that might explain their diversity.
- What do Figures 45.14B and C tell you about the predicted rate of change in species composition (species turnover rate) at equilibrium on small versus large islands and on islands distant from versus close to a mainland? (Hint: think of turnover rate as the number of new species that replace previous species in a period of time.)

Quantitative studies of species richness and island biogeography have contributed greatly to our knowledge of the structure and function of ecological communities. We will next turn to some ways in which this knowledge can be applied to conserving these communities and their valuable services.

concept
45.6

Community Ecology Suggests Strategies for Conserving Community Function

Ecological communities provide humans with critical goods and services, and a community's ability to deliver them often depends on its diversity. We have discussed several factors that influence the diversity of communities, including the balance between colonization and extinction and how complex the habitat is in terms of its physical structure. How can we apply this knowledge to maintain the diversity, and therefore the function, of ecological communities?

Ecological communities provide humans with goods and services

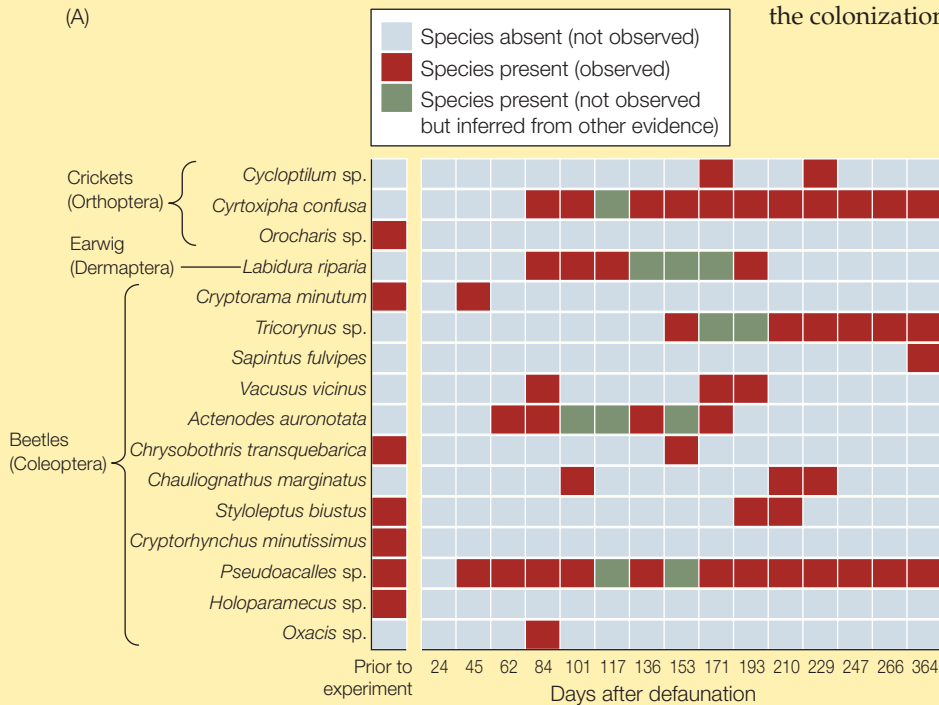

Humans depend on the ecological interactions that occur in communities and the interactions between communities and their physical environment. Although this seems obvious today, explicit recognition of the value of ecological systems is recent. Environmental writers introduced the idea of "natural

APPLY THE CONCEPT

Diversity patterns provide clues to determinants of diversity

An alternative to MacArthur and Wilson's explanation for patterns of species richness has been proposed: that any island has a particular mix of "niches" that support an island-specific community. For Simberloff and Wilson's study (see Figure 45.15), this would mean that each island gradually reassembled its original arthropod community, and the number of species stopped changing when the full complement of species was restored. Review the two additional results from that study shown below and answer the associated questions.

(A)

(B)

1. Figure A is a sample of census results for individual insect species on one island. Do these census results support or refute the alternative hypothesis? Explain your answer.
2. Figure B shows the accumulation of insect species in three functional groups—herbivores, carnivores, and parasites—for the same island. Did the ratio of herbivores : carnivores : parasites change over time? Does your answer suggest that niches may play a role in the colonization sequence? Explain your reasoning.

capital" in the 1940s; it was in 1970 that ecological systems were first said to provide people with "goods and services." The goods include food, clean water, clean air, fiber, building materials, and fuel; services include flood control, soil stabilization, pollination of plants, and climate regulation.

Because many of these goods and services involve exchanges between communities and the physical environment, they are called **ecosystem services**; a short list of them is given in **TABLE 45.2**. We will consider those that involve physical and geological processes in more detail in Chapter 46.

Goods that are of direct biological origin are obvious to us all—everybody knows that we get food from plants and animals, wood from trees, wool from sheep, and aesthetic enjoyment from flowers and birds. The roles of properly functioning communities in providing ecosystem services are less obvious, however, and we often take them for granted—at least until something goes wrong.

European settlers of Australia learned the hard way about the importance of the services provided by decomposers. When the first settlers arrived in 1788, they brought cattle with them. From the beginning, however, the Australian cattle industry

ran into problems: native dung beetles, adapted as they were to the dry, fibrous dung of forest marsupials, shunned the copious amounts of wet manure produced by cattle in open pastures. As a consequence, cattle dung piled up higher and deeper. The accumulated dung reduced pasture productivity (because the nitrogen-rich dung was not being recycled, and because cattle avoid eating fouled plant material) and provided a perfect nursery for native bush flies and introduced blood-sucking buffalo flies, whose populations exploded.

In 1964 Australia's national scientific research organization, CSIRO, finally tackled the problem. Insect biologists traveled the world to find dung beetle species that could process cattle dung in Australian environments without disrupting native beetle communities—an important precaution since many well-intended introductions have ended up having catastrophic impacts (see Concept 44.4). CSIRO introduced the first beetle species in 1968; by 1984, over 50 species had been introduced. The Australian Dung Beetle Project was successful: soil nitrogen content and water retention improved, pasture productivity increased, fly numbers plummeted, cattle became healthier, and native dung beetles were unharmed.

TABLE 45.2 Some Major Ecosystem Goods and Services

GOOD OR SERVICE	COMMUNITY PROCESS	EXAMPLES
Food production	Trophic interactions	Production of wild food, production of crops and livestock
Materials production	Trophic interactions	Production of lumber, fuel, fiber
Pollination and seed dispersal	Plant–pollinator and plant–disperser interactions	Plant reproduction and dispersal
Maintenance of fertile soil	Decomposition; composition of vegetation; plant- and animal-microbe mutualisms	Nitrogen fixation, nutrient recycling, erosion control
Waste treatment	Decomposition	Breakdown of toxins and wastes
Pest control	Predator–prey, host–parasite, and competitive interactions	Removal of pests and pest breeding sites
Water supply	Regulation of water infiltration and runoff by vegetation structure and animal activity	Retention of water in watersheds, reservoirs, and aquifers
Climate regulation	Metabolic gas exchange	Regulation of greenhouse gases and cloud formation
Disturbance control	Composition and biomass of vegetation	Damping of storm winds and wave surges; flood control
Recreational and cultural opportunities	Ecological processes; species diversity	Ecotourism, outdoor recreation; aesthetic, educational, spiritual, scientific values

Ecosystem services have economic value

Ecosystem services have economic value, as the Australian Dung Beetle Project shows. Similarly, in the United States wild native pollinating insects (not including domesticated honey bees) contribute \$3 billion annually to crop production.

Services related to food production are relatively straightforward to value because they are included in commercial markets. Many others—such as greenhouse gas regulation—are more difficult to value, but that does not mean they lack value. Consider the case of New York City’s water, which comes from reservoirs in the Catskill Mountains. For many years, natural ecological systems in the Catskills provided pure water that met U.S. Environmental Protection Agency standards. However, changes in land use began to convert forests to agricultural fields and housing developments. The loss of forest cover decreased water infiltration into the soil, thus increasing discharges of sewage, fertilizers, pesticides, and sediment into streams. Water quality deteriorated to the point that New York was faced with the prospect of a new water treatment facility that would cost \$6–\$8 billion to build and \$300 million annually to run. When the city considered what it would cost to restore the Catskills’ natural water-purifying function, it realized that it could meet EPA water-quality standards by investing \$1.5 billion in land protection and better sewage treatment in the Catskills. This is a lot of money, to be sure, but much less than the technological alternative. New York City’s Long-Term Watershed Protection Plan, completed in 2006, has been a complete success.

The New York City example is not an isolated one. Many types of ecosystems can provide more goods and services, at lower cost, than artificial substitutes. But as we have seen, the community functions that deliver those goods and services depend on community diversity. Therefore, biological

communities can best meet our needs if we do not manage them so intensively, or disturb them so severely, that their ability to provide natural goods and services is compromised.

Island biogeography suggests strategies for maintaining community diversity

As we saw in Chapter 42, humans are rapidly converting natural communities into less diverse, human-managed communities such as croplands, pastures, and urban settlements. The effect of this land conversion is that once-continuous large areas of habitat are reduced to scattered small fragments—habitat “islands” surrounded by “seas” of human-modified habitat (**FIGURE 45.16**). Habitat fragmentation can be expected to cause losses of species from communities for several reasons—the total amount of habitat decreases, the average patch size decreases, and patches become more isolated from one another. Given what you have learned about the theory of island biogeography, you now can predict the results. Populations become smaller as habitat area shrinks, and are therefore more prone to extinction. The matrix of human-dominated habitat surrounding the patches may serve as a barrier to dispersal, decreasing colonization rates. The net consequence of fragmentation is lower species richness in the fragments than in the original habitat.

MacArthur and Wilson’s insight that species richness reflects a balance between colonization and extinction suggests that the detrimental effects of fragmentation can be minimized by enhancing colonization and reducing extinction. Colonization can be increased either by clustering habitat fragments close to one another or to a large “mainland” patch, or by connecting fragments with dispersal corridors, as described in Concept 43.6. Species extinction can similarly be minimized

FIGURE 45.16 Habitat Fragmentation in Tropical Forests Less than half of the tropical forest that existed in Central America in 1950 remained by 1985, most of it in small patches. Although the rate of deforestation slowed somewhat after 1985, an additional 19 percent of the forest had disappeared by 2005.

by retaining large patches of the original habitat and by preserving the capacity of remaining patches to support healthy populations.

Several of these predictions have been tested in a remarkable large-scale experiment. Land owners in Brazil agreed to preserve tropical forest patches of certain sizes and configurations laid out by biologists (**FIGURE 45.17**), and they allowed the biologists to survey the parcels before and after intervening forest was cleared for pasture. Species soon began to disappear from the patches. The first species lost were monkeys that travel over large areas of forest. Army ants and the birds that follow their columns also disappeared rapidly. Species were lost more rapidly in isolated fragments than in ones of equal area that were connected to nearby unfragmented forest, and small isolated fragments lost species more rapidly than larger isolates.

Results of studies such as these now guide land use planning worldwide. They suggest that dispersal corridors and large habitat patches are necessary to maintain healthy, diverse communities.

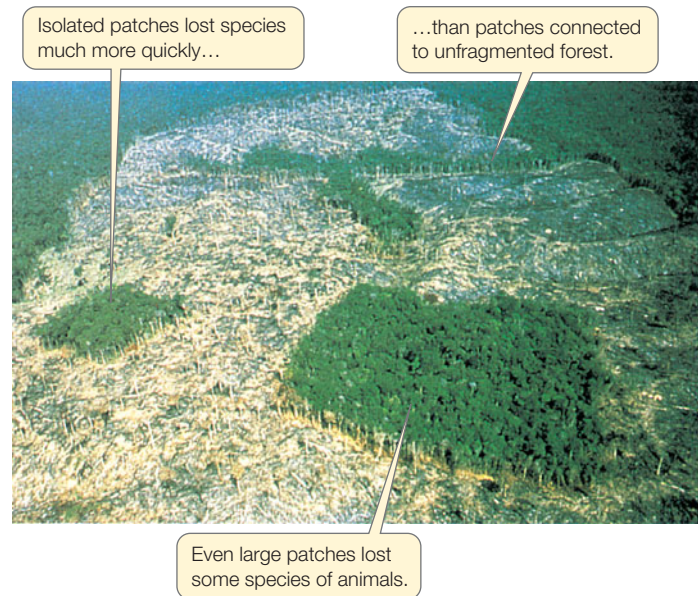

FIGURE 45.17 A Large-Scale Study of Habitat Fragmentation Biologists studied patches of tropical evergreen forest near Manaus, Brazil, before and after the parcels were isolated by forest clearing. The results of the study demonstrated that small, isolated habitat fragments support fewer species than larger or less isolated patches of the same habitat.

Edge Effects

Trophic cascades suggest the importance of conserving critical components of food webs

It is all well and good to plan for dispersal corridors and large patches, but species differ considerably in their habitat area requirements and in the kinds of dispersal corridors they will use. How big should natural areas be? What constitutes an effective corridor? These decisions can often be facilitated if they target species that play particularly important roles in communities.

The wolves of Yellowstone National Park provide an example of a species whose presence has a major effect on community structure and function. Wolves are crucial for maintaining healthy aspen forests and watersheds via trophic cascades that also involve elk, aspen and willow, and beavers. Conservation planning is now targeting such critical species. The Yellowstone to Yukon Conservation Initiative, for example, is a program that has as its goal the maintenance of a continuous corridor of wolf habitat between Yellowstone National Park and areas of similar habitat to the north. It is hoped that the corridors will maintain the Yellowstone wolf population, and hence a healthy Yellowstone ecosystem.

The relationship of diversity to community function suggests strategies for restoring degraded habitats

We have seen that even highly disturbed communities, such as those on Krakatau or on experimentally defaunated mangrove islands, can recover. This insight from community ecology suggests that degraded ecological systems can often be

INVESTIGATION

FIGURE 45.18 Species Richness Can Enhance Wetland Restoration In one large-scale field experiment, ecologists compared different methods for restoring denuded areas of the Tijuana

Estuary, a wetlands environment near San Diego, California. They found that several measures of community function improved more rapidly in species-rich than in species-poor plantings.

HYPOTHESIS

Faster progress toward restoring the community's original condition will be made by planting mixtures of species than by planting single species alone.

METHOD

1. In an area of wetland denuded of vegetation, mark off replicate small experimental plots, all of the same size.
2. Choose 8 native species typical of the region. Plant some plots with each of the 8 species by itself, others with different 3-species subsets, and others with different 6-species subsets. Plant the same total number of seedlings per plot. Leave some plots unplanted as controls.
3. Return over the the next 18 months to measure the vegetation and soil nitrogen levels.

RESULTS

Vegetation covered the bare ground more quickly in those plots with higher species richness. Those same plots developed complex vertical structure more quickly and accumulated more nitrogen in plant roots per m^2 of area.

CONCLUSION

Planting a mixture of species leads to more rapid restoration of wetlands

ANALYZE THE DATA

- The unplanted control plots (above) showed non-zero values of stored nitrogen after 18 months. Is this a surprise? Why or why not?
- One of the 8 species in the study, *Salicornia virginica*, contributed a disproportionate share of the biomass, cover, and nitrogen in mixtures in which it was included. In the two graphs at left, each circle represents the performance of a particular plot; the lines graph the average values. Based on these two graphs, what do you conclude about the mechanism for the higher success of species-rich plantings? Is the dominance of *S. virginica* the likely explanation?

restored—that their function can be improved. Devising ways to do so is the goal of the field of *restoration ecology*. The relationship between diversity and community function suggests that one of the best ways to improve the functioning of a damaged system is to restore the original species diversity. To do so, restoration ecologists draw on their knowledge of the factors that shape diversity (FIGURE 45.18).

As we have also seen, however, disturbance sometimes results in an ecological transition to a community that is very different from the original community. In such cases it may be difficult to find a way to reverse the transition and restore the function of the original community (recall the opening question in Chapter 42). This is a sobering reminder that restoration

can be challenging and requires deep understanding of individual ecological systems.

Do You Understand Concept 45.6?

- Give two examples each of goods and services provided to humans by natural ecological systems, and by ecological systems constructed and managed by humans.
- If you were working as a restoration ecologist to restore a specific system, what measures might you use to assess whether your efforts were successful?

FIGURE 45.19 Traditional Coffee Cultivation and Community Diversity

Low-intensity, high-diversity coffee cultivation (often marketed as “shade-grown organic coffee”) results in lower yields but can net a higher profit by avoiding the costs of fertilizers and other chemicals—with the added benefit of maintaining the services provided by natural forests.

crop production by growing crop plants in complementary functional groups together.

The desired output of coffee plantations is, of course, seeds (coffee “beans”). Although *Coffea arabica* flowers can pollinate themselves, seed production is enhanced when bees move pollen between individual plants. From our knowledge of community ecology, we might predict that diverse bee communities provide the best pollination overall, be-

cause different species may pollinate in complementary ways. Recent research in Indonesia confirms this prediction: seed production was 50 percent higher, and varied less from year to year, in plantations that hosted 20 wild bee species than in those that hosted 3 bee species.

We also know that pollination of flowers is a free ecosystem service (Concept 45.6) provided by wild species of pollinators. This suggests that embedding coffee plants in diverse communities of plants and animals might be an effective way to reap the benefits of better pollination. Research in both Costa Rica and Indonesia confirmed this prediction as well: planting coffee close to intact patches of forest and leaving flowering weeds in place was all it took to attract a diverse bee community and thus increase production (**FIGURE 45.19**). This research is at the forefront of a new movement to enhance pollination and pest-control services for crops by bordering croplands with species-rich and structurally diverse communities.

Traditional low-intensity cultivation methods therefore seem a cost-effective way to increase coffee production by maintaining high diversity of native bees. Although traditional methods may not provide the highest yields per acre, they may nevertheless be very profitable. A study of nine coffee plantations in Mexico reported that high-intensity sun cultivation produced more coffee per hectare, but that low-intensity plantations were the most profitable because they avoided costs of chemicals and labor. That low-intensity cultivation also avoids pollution and helps maintain natural communities and their species are added benefits of taking advantage of natural ecosystem services.

In this chapter we have discussed factors that influence the species composition of communities and the interactions that shape the flow of energy and materials through them. We have seen how species composition affects a community’s function, including its outputs of goods and services. But outputs are limited by inputs, and to understand what determines inputs to communities, we need to consider their abiotic environments. The next chapter applies this ecosystem perspective, and considers how humans are influencing the global ecosystem.

Can we use principles of community ecology to improve methods of coffee cultivation?

ANSWER Croplands are ecological communities that are governed by the same factors that govern natural communities. We can therefore use our understanding of how natural communities function to improve the function of agricultural communities. For example, we know from studying natural communities that species diversity often enhances community function (Concept 45.4)—whether we are talking about pollination, pest control, or primary productivity. We also know that species diversity is increased when there are opportunities for species with diverse niches to coexist and when colonization rates are high and extinction rates are low (Concept 45.5). We can use these ecological principles in many situations to produce more food at less cost and with fewer negative effects on the environment. For example, we can enhance

45

SUMMARY

concept 45.1 Communities Contain Species That Colonize and Persist

- A **community** is a group of species that coexist and interact with one another within a defined geographic area.
- A community is characterized by its **species composition**: the particular mix of species it contains and the abundances of those species.
- A community contains those species that are able to colonize an area and persist there.

concept 45.2 Communities Change over Space and Time

- Variation in space in environmental conditions and habitat structure is associated with predictable turnover in species composition. **Review Figure 45.2**
- Even in a constant environment, ongoing extinction and colonization result in a steady turnover in the species composition of communities through time.
- After a sudden disturbance, species sometimes replace one another in a more or less predictable sequence called **succession**. Succession following a disturbance that removes the original community often results in a community that resembles the original one. **Review Figure 45.4 and ANIMATED TUTORIAL 45.1**
- Some types of disturbance lead to an **ecological transition**, in which an original community is replaced by a different type of community.
- Climate change can cause the species composition of a community to change over time. **Review Figure 45.5**

concept 45.3 Trophic Interactions Determine How Energy and Materials Move through Communities

- Each species has a unique **niche**—a set of environmental tolerances and pattern of interactions with other species.
- The **trophic interactions** by which a species obtains energy are a critical aspect of its niche. These interactions determine how energy and materials flow through communities.
- Energy enters communities through **primary producers**, which use photosynthesis to synthesize organic compounds that can be used by the rest of the community.
- Species that feed on primary producers are called **primary consumers**, or herbivores. Those that consume primary consumers are **secondary consumers** (or primary carnivores), and so on. These feeding positions are called **trophic levels**. **Review Table 45.1 and WEB ACTIVITY 45.1**
- Trophic interactions can be described in a diagram called a **food web**. **Review Figure 45.6**
- The total amount of energy that primary producers capture and convert into chemical energy during some period of time is called **gross primary productivity (GPP)**. The portion of GPP that becomes available to consumers during that time is called **net primary productivity (NPP)**. **Review WEB ACTIVITY 45.2**

- The **ecological efficiency** of energy transfer from one trophic level to the next is only about 10 percent. **Review Figure 45.7**
- Changes in species composition or species densities at any trophic level may cause a **trophic cascade** of changes at other trophic levels. **Review Figure 45.8**

concept 45.4 Species Diversity Affects Community Function

- Species diversity has two primary components: the number of species in the community, called **species richness**, and the distribution of those species' abundances, called **species evenness**. **Review Figure 45.9**
- Ecologists often quantify diversity by using a mathematical diversity index that incorporates both species richness and species evenness.
- The outputs of the interactions between species in a community and between species and their physical environment are measures of community function. Community outputs increase with increasing species diversity of the community. For example, NPP is greater, and more stable over time, in diverse communities. **Review Figure 45.10**

concept 45.5 Diversity Patterns Provide Clues to Determinants of Diversity

- Species richness is greatest in the tropics and decreases with increasing latitude. Possible causes of tropical species diversity include greater tropical climate stability, greater energy input, and greater habitat complexity. **Review Figures 45.11 and 45.12**
- Species richness is greater on large islands than on small islands and greater on islands closer to a source of colonists than on more distant islands. **Review Figure 45.13**
- The theory of **island biogeography** proposes that community diversity on islands represents a balance between the rate at which new species colonize and the rate at which resident species go extinct. **Review Figures 45.14, 45.15, ANIMATED TUTORIAL 45.2, and WORKING WITH DATA 45.1**

concept 45.6 Community Ecology Suggests Strategies for Conserving Community Function

- Ecological systems provide humans with a variety of goods and services. These **ecosystem services** have economic value. **Review Table 45.2**
- Production of ecosystem services is threatened by human activities, including the fragmentation of natural habitats. The detrimental effects of habitat fragmentation can be mitigated by land-use management that minimizes extinction in each habitat "island" and maximizes dispersal among them. **Review Figure 45.17 and ANIMATED TUTORIAL 45.3**
- Ecosystem function often can be preserved or restored by focusing on particular species that play especially important roles in the community, and by maintaining or restoring overall species diversity. **Review Figure 45.18**

The Global Ecosystem

46

The 1800s were a golden age for Earth science. Geologists deduced the astonishing age of the planet and discovered that past climates differed from modern ones—for example, that vast sheets of ice covered parts of the continents only 15,000 years ago.

What could cause such dramatic climate variation? One possibility, proposed in 1861, pointed to atmospheric gases such as CO_2 and water vapor, which had been found to absorb infrared (heat) radiation. Scientists hypothesized that these gases might influence Earth's climate by trapping heat in a manner analogous to the glass of a greenhouse. By the end of the nineteenth century, they had outlined a "carbon dioxide theory" for how fluctuating atmospheric CO_2 could cause fluctuations in this *greenhouse effect* and explain past ice ages.

Scientists pursuing the carbon dioxide theory had an additional insight. They realized that coal and petroleum contained fossilized carbon from dead plants and animals. Since the Industrial Revolution, humans had been burning these *fossil fuels*, releasing carbon as CO_2 . Might this be increasing CO_2 in the atmosphere, and thus the greenhouse effect? Some skeptics felt that any effect of CO_2 must be insignificant because it comprises only about 300 parts per million (ppm) of the molecules in the atmosphere. In the 1930s, however, physicists and chemists demonstrated that changes in atmospheric CO_2 could affect climate. In the 1950s the American scientist Gilbert Plass estimated the rate at which atmospheric CO_2 was increasing and used one of the first electronic computers to forecast that increased CO_2 could significantly raise the average global temperature.

A big problem remained, however: nobody had yet been able to measure atmospheric CO_2 with precision. The challenge was met by a young American chemist, Dave Keeling, who developed sensitive new instruments and set them up atop Mauna Loa in Hawaii, 4,000 meters above sea level and far from most sources of human-generated pollution. Keeling recognized that the challenge was to see if the estimated rise in atmospheric CO_2 could be detected, and he pledged himself to a long-term study. He began in 1957, the International Geophysical Year (IGY), one of the first international scientific collaborations supported by governments. But the IGY money soon dried up. Undaunted by periods of insufficient funding, Keeling continued his research on atmospheric CO_2 and the carbon cycle over the next four decades.

Mauna Loa observatory on the "Big Island" of Hawaii provides scientists with climatological data.

How did Keeling's research contribute to our understanding of the global ecosystem?

concept 46.1 Climate and Nutrients Affect Ecosystem Function

As we saw in Concept 42.1, the term “ecosystem” is generally applied to an ecological community plus the abiotic environment with which it exchanges energy and materials. Most of the interactions among components of ecosystems happen at a local scale. A plant, for example, can only absorb nitrate molecules that are in physical contact with root hairs; an elk in Manitoba cannot fall prey to a wolf living in Wyoming’s Yellowstone National Park; and a raindrop interacts directly only with soil particles it contacts. For this reason, most studies of ecosystems involve relatively small spatial scales, such as a single river drainage, lake, or patch of forest.

Ecosystems are linked, however, by slower exchanges that occur on spatial scales that range from tens of kilometers within regional landscapes to thousands of kilometers within the entire biosphere. These long-distance exchanges occur when organisms disperse or migrate among communities and when materials are moved around the planet by the physical circulation of the atmosphere and the oceans, the movement of flowing water, and by geological processes within Earth’s crust. These large-scale linkages ultimately influence patterns of input or loss of materials to or from local ecosystems, making it impossible to understand a local ecosystem completely without considering it in the context of the larger systems of which it is a part. The present chapter therefore takes both local and global perspectives.

NPP is a measure of ecosystem function

Ecosystems, like other ecological systems, can be characterized by their components and by patterns of interaction among the components. The biological community as a whole is often treated as one component, and distinct portions of the abiotic environment, such as soil, atmosphere, or water, as other components. The dynamic processes by which these components exchange and transform energy and materials are aspects of *ecosystem function*. Ultimately, movements of materials between the abiotic and biotic components of ecosystems are tied to carbon, life’s energy currency. Primary producers convert inorganic carbon into carbohydrates, and energy stored in the chemical bonds of those molecules fuels the synthesis of additional biomass, which ultimately contains all the atomic constituents of the bodies of organisms. Calcium in the bones of a wolf, for example, came from the elk it ingested; the elk obtained calcium from the plants it ate; and the plants absorbed calcium from the soil in a metabolic process fueled by energy released by breakdown of the carbohydrates produced during photosynthesis. The rate per unit of area at which an ecosystem produces primary-producer biomass—its *net primary productivity*, or *NPP* (see Concept 45.3)—is therefore a measure of the influx of materials, as well as energy, into that community. This measure of ecosystem function does not incorporate all exchanges of materials between organisms and the abiotic environment—organisms take in or excrete inorganic water

or salts to maintain homeostasis, for example. Rates of such exchanges, however, are indirectly coupled with primary productivity because they are fueled by the energy that enters the community via primary producers.

Scientists are now able to estimate NPP with instruments, carried by orbiting satellites, that measure the amount of different wavelengths of light reflected by Earth’s surface. This “view from space” allows them to calculate how much sunlight is absorbed by chlorophyll and to map the distribution of photosynthetic biomass—which is correlated with NPP—across the planet. These maps show that NPP is not the same everywhere. As we will see next, patterns of variation in NPP suggest factors that limit ecosystem function.

NPP varies predictably with climate and nutrients

Net primary productivity varies considerably among ecosystem types. Among terrestrial ecosystems, tropical forests are the most productive per unit of area, followed by temperate forests; tundra and deserts are the least productive (**FIGURE 46.1**). Among aquatic ecosystems, swamps and marshes and near-shore algal beds and coral reefs are the most productive, followed by estuarine habitats; open ocean and the benthic zone of the deep ocean are the least productive (although the latter zone is astonishingly high in species richness). You will notice that, despite our best efforts, cultivated land is less productive than many natural ecosystems. Much of this pattern derives from variation in climate and nutrient availability.

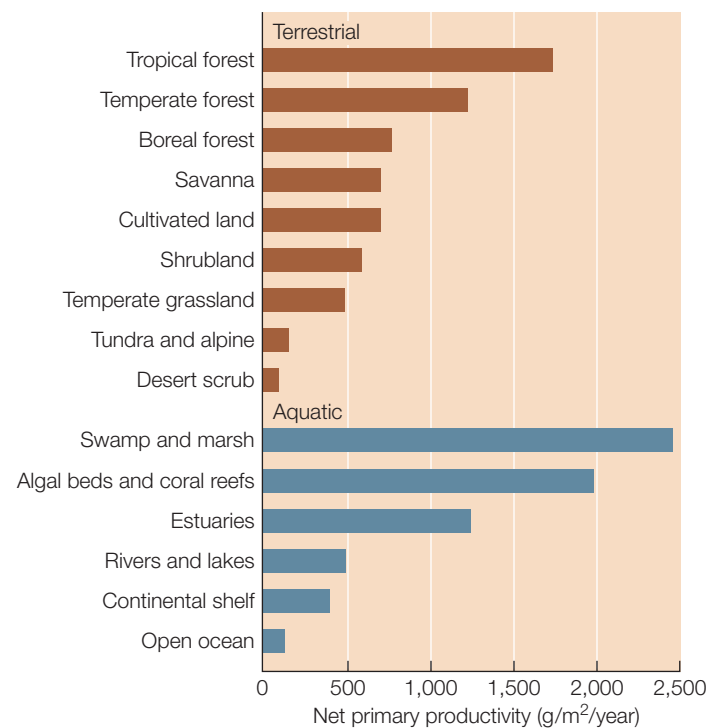

FIGURE 46.1 NPP Varies among Ecosystem Types Net primary productivity is expressed here as grams of biomass produced per square meter of area per year.

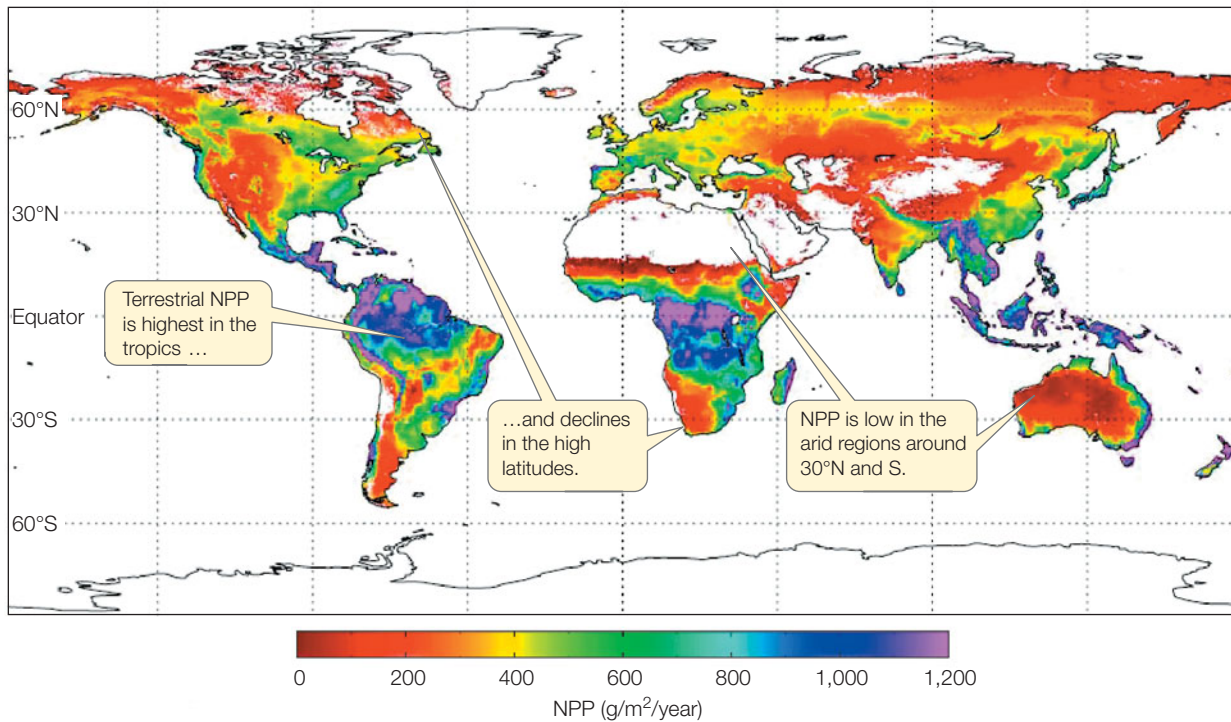

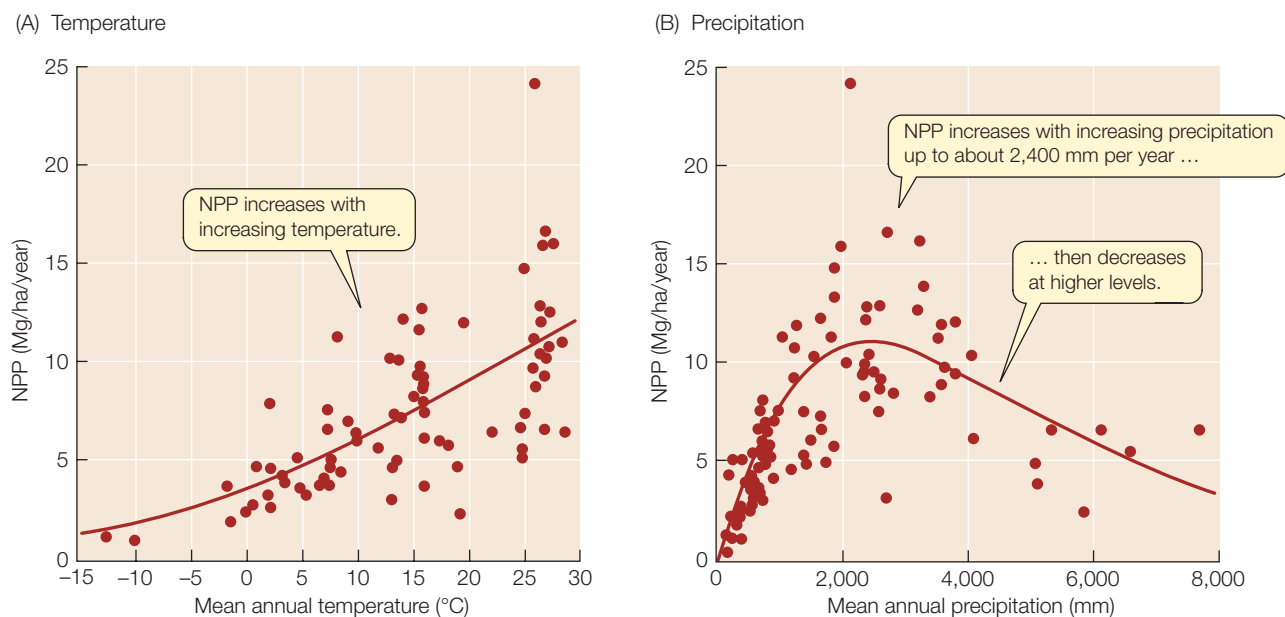

FIGURE 46.2 Terrestrial NPP Corresponds to Climate The map of estimated terrestrial NPP is based on satellite sensor data accumulated over the period 2000–2005. The white spaces on land represent unvegetated areas, including deserts and ice caps. Note the high productivity of the equatorial regions.

Satellite images of terrestrial ecosystems show that NPP varies with latitude (**FIGURE 46.2**). This is what we would expect, given that solar input and climate vary with latitude, as we saw in Chapter 42. If we compare Figure 46.2 with Figure 42.11, we can see that highly productive areas are concentrated in the tropics and that unproductive areas are concentrated at high

latitudes and in the dry subtropics. These trends suggest that terrestrial NPP is affected both by temperature and moisture. Indeed, terrestrial NPP generally increases with temperature (**FIGURE 46.3A**), which makes sense when we consider that the activity of photosynthetic enzymes, like that of other enzymes, increases with temperature up to the critical temperature at which enzymes denature (see Concept 3.4). The critical temperature varies among plant species that are adapted to different

FIGURE 46.3 Terrestrial NPP Varies with Temperature and Precipitation NPP is given in megagrams (1 Mg equals 10^6 g or 1 metric ton per ha per year).

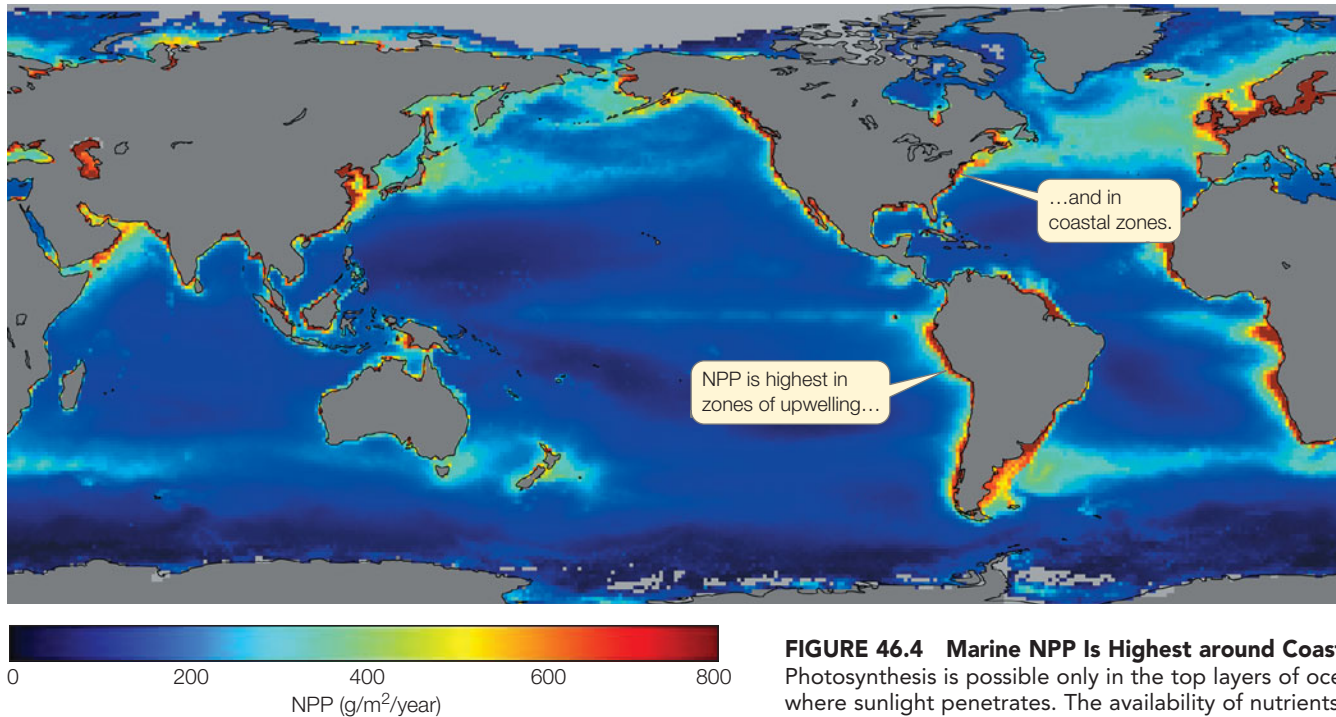

FIGURE 46.4 Marine NPP Is Highest around Coastlines

Photosynthesis is possible only in the top layers of oceans, where sunlight penetrates. The availability of nutrients determines how much NPP occurs in any given part of this photic zone. Highest NPP occurs where runoff from land brings nutrients into shallow coastal waters, and where upwelling of deep waters brings nutrients from the benthic zone closer to the surface.

environments but is usually about 40°C–50°C. Terrestrial NPP also increases with precipitation up to about 2,400 millimeters a year, then decreases at higher levels (FIGURE 46.3B), which also makes sense. Moist soil conditions facilitate water and nutrient uptake by roots and allow plants to maintain turgor pressure without closing their stomata, thus facilitating CO₂ uptake (see Concept 25.3). The decrease in NPP in extremely moist climates may result from increased cloud cover and lower solar input or from a lack of oxygen in saturated soils. Finally, we also know that elements such as nitrogen, phosphorus, and potassium are critical for plant growth and can be in short enough supply to limit NPP. As we saw in Concept 42.3, for example, soils in southwestern Australia are so nutrient-poor that plants cannot afford to waste nitrogen on defensive compounds; instead they allocate scarce nitrogen to proteins that are essential for metabolism. Southwestern Australia has been inactive geologically for hundreds of millions of years; over this long span of time most nutrients have weathered out of the bedrock and have been leached from soils by the movement of water.

Satellite images of oceanic ecosystems, in turn, suggest that aquatic NPP is more strongly a function of nutrient availability than of temperature (FIGURE 46.4). NPP occurs only in the top layers of aquatic systems, where light can penetrate and photosynthesis can occur (the *photic zone*; see Concept 42.3). Nutrients are very limited in this zone. They are most abundant in coastal marine areas and near-shore parts of lakes and in shallow wetlands, where rivers and streams discharge nutrients leached from terrestrial ecosystems, and in areas where water from the bottom of oceans or lakes reaches the surface, bringing with it nutrients from benthic sediments. Shallow

waters and areas of upwelling support high rates of primary productivity by aquatic plants and phytoplankton, which in turn support dense consumer populations. The only productive deep-water areas are rare hydrothermal vents, where chemolithotrophs (see Concept 19.3) generate new biomass by using chemical energy rather than sunlight and by using nutrients in the benthos and in water from the vents.

Do You Understand Concept 46.1?

- In Figure 46.1 we see that NPP is generally higher in freshwater wetlands (swamps and marshes) than in shallow marine waters (algal beds, reefs, and estuaries). Why might this be so?
- Outline an experiment that would allow you to determine what specific nutrient limits NPP in a given terrestrial ecosystem.

We now have an overview of global patterns of ecosystem function, as measured by NPP, and of some of the factors that determine these patterns. We have seen that nutrient availability plays an important role in NPP. This makes sense because nutrients are chemical elements that organisms require for their metabolism and as materials to build their bodies. What are the processes that affect the availability of nutrients?

concept
46.2

Biological, Geological, and Chemical Processes Move Materials through Ecosystems

As we have seen throughout this book, the sun provides a steady input of radiant energy to Earth, some of which is captured by photosynthetic organisms. In chemical form, this energy then fuels the metabolism of all organisms in the community and ultimately is lost as waste heat. In contrast, the chemical elements that make up organisms come from within the Earth system itself. There is essentially a fixed amount of each element because little matter escapes Earth's gravity or enters from space. Whereas Earth is an *open system* with respect to energy, it is a *closed system* with respect to matter. This does not mean the distribution of matter is static, however—energy from the sun and heat from Earth's interior drive biological, geological, and chemical processes that transform matter and move it around the planet. But matter must be in the right place and in the right chemical form for organisms to be able to use it.

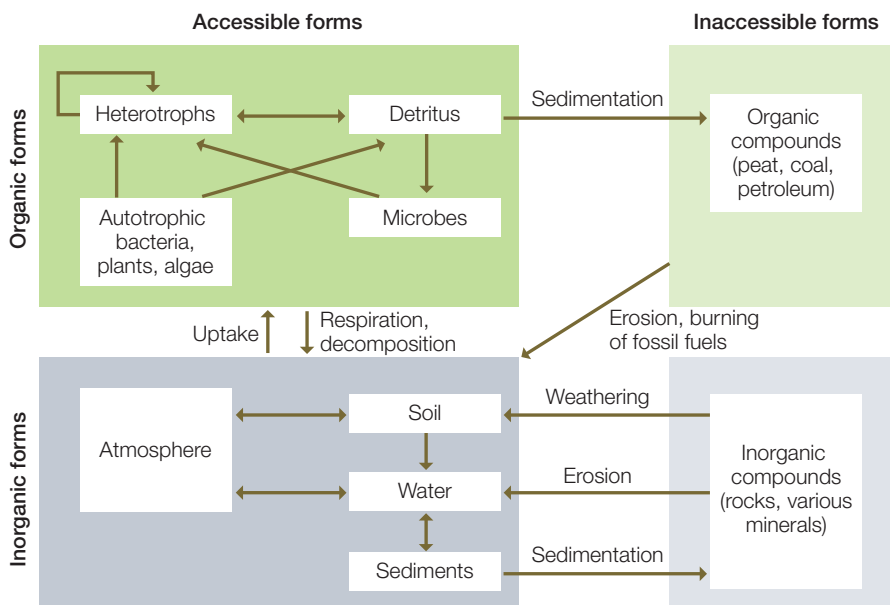

The form and location of elements determine their accessibility to organisms

Imagine an atom. At any time, this atom occurs in a particular molecular form and occupies a particular location in Earth's closed system. It can be part of a living organism or of dead organic matter. It can be part of a gas molecule in the atmosphere or dissolved in a body of fresh or salt water, or a component of soil, sediment, or rock. If in rock, it can be part of the surface crust of Earth or more deeply buried. These alternative forms and locations of matter can be thought of as *compartments*. Atoms cycle among compartments when they are transformed or physically moved (FIGURE 46.5). The rocks that make up continents, for example, have gone through repeated cycles of being buried, compressed, heated, unburied, and eroded (see Figure 18.2).

The chemical form in which an atom exists determines whether it is accessible to life. With rare exceptions, carbon is taken up by autotrophs in the form of CO_2 , and they absorb nutrients such as nitrogen, phosphorus, or potassium in the form of ions dissolved in water (see Concept 25.1). Heterotrophs extract most of the materials they need from living or dead organic matter. Microbes have the most diverse nutritional capabilities of all, as we saw

FIGURE 46.5 Chemical Elements Cycle among Compartments of the Biosphere

The different chemical forms and locations of the elements determine whether or not they are accessible to living organisms. These different forms of matter represent compartments, as in the diagram shown here. Biological, geological, and chemical processes cycle matter among the compartments.

in Concept 19.3. But even when an atom is in the right chemical form, organisms cannot use it if it is in the wrong place. Matter that is buried too deeply, or that occurs in places that are too hot, too cold, or otherwise too hostile, is inaccessible to life.

The processes that supply matter to organisms occur in the *biosphere*, the thin skin at Earth's surface where atmosphere, land, and water are in contact with one another and where organisms live. The biosphere is only about 23 kilometers thick—a mere 1/277 of Earth's radius—extending up to the stratosphere and down to the abyssal zone of the oceans.

Fluxes of matter are driven by biogeochemical processes

Movement of matter among Earth's compartments is caused by processes that are biological, geological, and chemical; thus these movements are called **biogeochemical cycles**. Biological and abiotic chemical processes combine elements with other elements and compounds, converting them between inorganic and organic forms, or between oxidized and reduced states. These reactions often involve the abundant elements oxygen and hydrogen. Chemical processes are also involved in the weathering of rock during soil formation. Geological processes—the circulation of air and water and convective flows within Earth's mantle—move matter around, alternately exposing it to air, water, and solar radiation or to heat and pressure.

LINK Oxidation–reduction (“redox”) reactions are described in Concept 6.1

The total amount, or **pool**, of an element or molecule in a given compartment depends on its flows, or **fluxes**, into and out of the compartment. Unless the fluxes in both directions are identical, the pool will grow or shrink. Oxidation of organic matter by respiration, fire, or fuel combustion, for example, will increase the atmospheric pool of carbon unless photosynthesis

and other biogeochemical processes remove carbon at an identical or greater rate.

All of the materials contained in the bodies of living organisms are ultimately derived from abiotic sources, either atmospheric gases or material that is dissolved in water. Primary producers (see Concept 45.3) take up elements from inorganic pools, accumulating them as biomass. Trophic interactions pass those elements on to heterotrophs, and eventually they enter a pool of dead and waste organic matter. Decomposers break down this dead and waste matter into its constituents, which renders it available again for uptake by primary producers. Much of this *recycling* of materials occurs locally, within the original local ecosystem, but some occurs on a larger scale if the materials diffuse away in gaseous form or are carried out of the local system by wind or water.

Do You Understand Concept 46.2?

- What is the distinction between the concepts of *pool* and *flux* with regard to a given chemical element?
- Explain the statement that energy flows through ecosystems whereas materials cycle within ecosystems.

Now that the basics of biogeochemical cycles have been explained, let's next consider three of these cycles that are especially critical for ecosystem function.

concept 46.3 Certain Biogeochemical Cycles Are Especially Critical for Ecosystems

In Concept 46.2 we saw that the materials that make up living tissue—chemical elements and compounds—cycle through ecosystems. The relevant spatial scale of the cycle and the processes that drive it vary with the material, but all cycles have features in common. As Figure 46.5 suggests, we can describe cycles in terms of the compartments involved, the amounts of the material contained in each compartment at a time (pools), and the rates at which the material enters and leaves those compartments (fluxes). In this concept we will describe cycles for three materials—water, nitrogen, and carbon—that are essential for life. We will point out how each of the three cycles affects physical properties of the Earth system—in particular climate—and how human activities are altering each of the cycles.

Water transports materials among compartments

Water is a most remarkable molecule, essential for life. It makes up more than 70 percent of living biomass. It is the medium for metabolism and the solvent in which biologically accessible forms of many nutrients are dissolved. Precipitation of water as rain or snow transports materials from the atmosphere to Earth's surface, and flowing water is the agent of erosion and sediment transport, responsible for much of the physical movement of materials around the planet. By virtue of its high heat capacity and its ability to change between solid, liquid, and gaseous states at normal Earth temperatures, water redistributes heat around the planet as it circulates through the oceans and atmosphere. And, as we shall soon see, water in the atmosphere is an important player in the global radiation balance.

Earth, the blue planet, contains an enormous amount of water—over 1.4 billion cubic kilometers, which make up 0.02% of Earth's total mass. About 96.5% of Earth's water is in the oceans (FIGURE 46.6). Other compartments include ice and snow (1.76%),

FIGURE 46.6 The Global Water Cycle

The estimated pools in compartments (white boxes) and the annual fluxes between compartments (arrows) are expressed in units of 10^{18} grams.

The Global Water Cycle

groundwater (1.70%), the atmosphere (0.001%), and fresh water in lakes and rivers (surface fresh water; 0.013%). Even though most of biomass is water, only about 0.0001% of Earth's water is found in living organisms.

LINK The molecular nature of water and its crucial role in the evolution of life as we know it is covered in Chapter 2

Some of the movement among these compartments involves gravity-driven flows of liquid water from the atmosphere to Earth's surface (precipitation) and from land to the oceans (in runoff). Other among-compartment fluxes of water, however, are associated with changes in its physical state—from liquid to gas (evaporation and transpiration), from gas to liquid (condensation), between liquid and solid (freezing and thawing), and between solid and gas.

The driving force of the water, or *hydrological*, cycle is solar-powered evaporation that moves water from ocean and land surfaces into the atmosphere. It takes considerable energy—2.24 kJ (about the energy stored in one AA battery)—to evaporate 1 gram of water. On a global scale, the rate of evaporation is enormous. It uses about one-third of the total input of solar energy to Earth's surface. This energy is released again as heat when the water vapor condenses. Fluxes from Earth's surface to the atmosphere and from the atmosphere to the surface are approximately equal on a global basis, although

precipitation exceeds evaporation over land, and evaporation exceeds precipitation over the oceans (see Figure 46.6).

Humans affect the global water cycle when they change how land is used. Reduction in vegetation cover reduces the amount of precipitation that is retained by soil and recycled through the local ecosystem and increases the amount that leaves the local system as surface runoff. As a result, deforestation, overgrazing, and cultivation of crops all tend to dry out local ecosystems. Groundwater pumping depletes aquifers, moving groundwater to the surface, where it either evaporates or runs off into streams and, eventually, into oceans. The water cycle also affects and is affected by the global climate. Warming of the climate is melting polar ice caps and glaciers, increasing the total amount of water in the oceans and causing sea levels to rise. With more liquid water there is more evaporation, and thus more water entering in the atmosphere and more precipitation globally. Water vapor is a *greenhouse gas*, (it absorbs infrared radiation), but it also forms clouds that reflect incoming sunlight. The net effects on climate of such complex changes in the water cycle are difficult to predict.

Nitrogen is often a limiting nutrient

Nitrogen is abundant on earth, yet it is commonly in short supply in biological communities. Unlike water—whose availability to organisms depends only on where it occurs and its

physical state—nitrogen is an element whose accessibility to life depends not only on where it occurs, but also on what other elements it is attached to. As a result, the nitrogen cycle, unlike the water cycle, involves chemical transformations (FIGURE 46.7).

The gas N_2 constitutes about 78 percent of the molecules in Earth's atmosphere, but most organisms cannot use nitrogen in this form because they cannot break the strong triple bond between the two nitrogen atoms. The exceptions are microbes in terrestrial and aquatic ecosystems that reduce N_2 to ammonium (NH_4^+) through a metabolic process called **nitrogen fixation**.

The Global Nitrogen Cycle

INVESTIGATION

FIGURE 46.8 Where Does the Extra Nitrogen Come From? Leaf-cutter ants require more nitrogen than is contained in the fresh leaves they feed to their fungal garden. Perhaps the fungus concentrates nitrogen from the leaves into the fungal structures that the ants eat. If so, spent leaf material in the refuse dump outside the ant nest should be lower in nitrogen than fresh leaves—but the opposite turns out to be true. One possible explanation for this nitrogen enrichment is that ants eat protein-rich insects as well as fungus, and fertilize the fungal garden with their feces. Another is that the fungus absorbs additional nitrogen from the soil. A third possibility is that ant nests harbor nitrogen-fixing organisms.

HYPOTHESIS

Nitrogen-fixing organisms in ant nests supply nitrogen to leaf-cutter ants

METHOD

1. Bring ant colonies into the laboratory and allow them to function in an environment with no insects and no soil (i.e., where the only non-atmospheric source of N is fresh leaves).
2. Measure the nitrogen content of leaves, fungus, ants, and leaf refuse.

RESULTS

The cultivated fungus, the bodies of worker ants, the contents of the refuse dump, and fresh leaves all differed significantly from each other in nitrogen content.

CONCLUSION

Nitrogen is being fixed within the ant nest.

ANALYZE THE DATA

Scientists measured activity of nitrogenase, an enzyme in the bacterial metabolic pathway that fixes atmospheric nitrogen. The results are shown in the figure below. Different letters indicate significant differences in nitrogen content.

- A. Where in the nest is nitrogen fixation occurring?
- B. Taken together, the two graphs in this figure support the hypothesis that the fungus concentrates nitrogen in the fungal structures eaten by the ants. Explain. (Hint: Consider that the four values in the Results graph are all significantly different from each other.)
- C. Can the researchers now conclude that the extra nitrogen comes from nitrogen-fixing bacteria?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

In terrestrial ecosystems, nitrogen fixation is carried out mostly by free-living bacteria in the soil and by symbiotic bacteria associated with plant roots, although it also occurs in other places such as the fungal gardens of leaf-cutter ants (**FIGURE 46.8**). Different microbial species convert ammonium into nitrate (NO_3^-) and other oxides of nitrogen (NO_x) in terrestrial ecosystems. Analogous biochemical processes in aquatic ecosystems are carried out by free-living microorganisms and in some cases by those living in the bodies of phytoplankton. All of these nitrogen-fixing reactions are reversed by another group of microbes in a process called *denitrification*, which ultimately completes the cycle by returning N_2 gas to the atmosphere (see Concept 19.3).

The microbes that contribute to the nitrogen cycle make the rest of life possible because they supply forms of nitrogen that are accessible to primary producers—most notably ammonium and nitrate. Once these soluble chemical forms are taken up by plant roots in terrestrial ecosystems, much of the nitrogen is recycled locally through decomposition of dead organic matter, which again releases ammonium and nitrate. Some nitrogen, however, is leached from soils and carried away by the movement of water, and some of this accessible nitrogen ultimately enters lakes and oceans. In aquatic systems, primary productivity occurs in surface waters, and some nitrogen is recycled locally in these waters. However, much is recycled at greater depths in the water column, as organisms in deep waters intercept and consume sinking detritus. Some of the nitrogen that sinks to the bottom and accumulates in sediments is returned to the surface by upwelling (see Concept 46.1).

LINK The metabolic processes by which microbes transform nitrogen are described in Concepts 19.3 and 25.2

Human activities are affecting nitrogen fluxes and pools. **Fossil fuels** such as coal and petroleum contain nitrogen, so burning them releases oxides of nitrogen, which contribute to atmospheric smog and acid rain. Rice cultivation and raising of livestock also release NO_x , nitrous oxide (N_2O), and ammonia (NH_3) into the atmosphere. This atmospheric nitrogen can be deposited locally or far from the source, in some areas adding as much nitrogen as farmers place on their crops. Humans also fix nitrogen by an industrial process in order to manufacture fertilizer and explosives. The total of industrial nitrogen fixation (see Concept 25.1) and fixation by legume crops such as soybeans now rivals the rate of natural terrestrial fixation (see Figure 46.7). Losses of topsoil and dissolved nitrates from fertilized croplands and deforested areas by wind

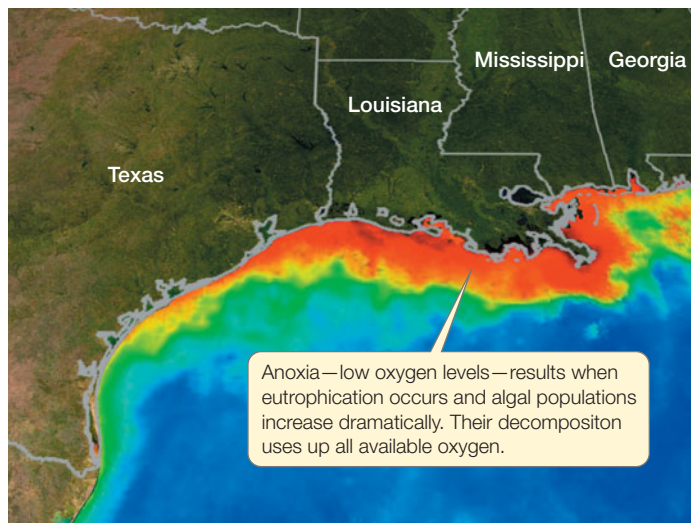

FIGURE 46.9 High Nutrient Input Creates Dead Zones

Runoff from agricultural lands in the midwestern United States carries nitrogen and phosphorus down the Mississippi River and into the Gulf of Mexico. The resulting eutrophication creates a “dead zone” in which few aquatic organisms can survive.

or water runoff are increasingly exporting nitrogen from terrestrial ecosystems and depositing it in aquatic systems.

Although increased nitrogen inputs can increase primary production, too much can be a bad thing. In aquatic systems, nutrient-stimulated increases in primary productivity—called

eutrophication—can result in such rapid growth of phytoplankton that consumers cannot eat them all. Respiration by phytoplankton and by decomposers that process their dead bodies depletes oxygen levels below the tolerances of many aquatic organisms, including fish and crustaceans. This can lead to **dead zones** devoid of aquatic life, for example where the Mississippi River discharges nutrient-rich agricultural runoff into the Gulf of Mexico (**FIGURE 46.9**). In nutrient-poor terrestrial ecosystems, excess nitrogen can change the species composition of plant communities. Species that are adapted to low nutrient levels grow slowly, even when fertilized, and can be easily displaced by faster-growing species that can take advantage of the additional nutrient supply. In the Netherlands, nitrogen deposition from upwind industrial and agricultural regions has caused species-rich plant communities to be replaced by species-poor communities. This terrestrial eutrophication is estimated to have caused 13 percent of the recent loss of plant species diversity in the Netherlands.

Carbon flux is linked to energy flow through ecosystems

All of the macromolecules that make up living organisms contain carbon, and much of the energy that organisms need to fuel their metabolic activities comes from the oxidation of organic carbon compounds. The flux of carbon into, through, and out of communities is therefore intimately linked to energy flow through ecosystems, and biomass is an important pool of the carbon cycle (**FIGURE 46.10**). Carbon occurs in the atmosphere as the gases CO₂ (carbon dioxide) and CH₄ (methane), which are mixed on a global scale by the dynamic circulation of the atmosphere.

FIGURE 46.10 The Global Carbon Cycle The estimated pools in compartments (white boxes) and annual fluxes between compartments (arrows) are expressed in petagrams (Pg; 10¹⁵ grams).

The Global Carbon Cycle

APPLY THE CONCEPT

Certain biogeochemical cycles are especially critical for ecosystems

Figure 46.10 depicts the global carbon cycle, showing organic and inorganic pools in various physical compartments as well as fluxes. Refer to that figure to answer the following questions.

1. What percentage of the flux of carbon from terrestrial ecosystems into the atmosphere is due to human activities?
2. What other flux of carbon from terrestrial ecosystems is being influenced by humans, and how?
3. Given the biogeochemical cycles we have discussed so far, which additional two cycles of materials would you wish to explore next in order to understand ecosystem function, and why? (Hint: consider the major chemical constituents of living tissue, discussed in Concept 2.1.)

These same forms are found dissolved in the oceans and fresh water, and aquatic systems also harbor carbonate (CO_3^{2-}). By far the largest pools of carbon occur in fossil fuels and carbonate rocks.

Fluxes of carbon are driven by biological, chemical, and physical processes. The biochemical process of photosynthesis moves carbon from inorganic compartments in the atmosphere and water into the organic compartment; respiration reverses this flux. CO_2 and CH_4 move from their atmospheric pools into the much larger pools in oceans when they dissolve and return to the atmosphere when they outgas; both of these are purely physical processes. The rate at which CO_2 dissolves slightly exceeds the rate at which it outgasses, for two reasons. First, some of the dissolved CO_2 is converted into organic compounds by primary production; most of this carbon is then recycled in surface and deeper waters through the trophic interactions of aquatic organisms, but gravity moves a steady rain of organic detritus into the benthic zone. Second, some of the CO_2 is transformed through chemical reactions with water and other dissolved elements into relatively insoluble carbonate compounds, especially calcium carbonate, which ultimately also sink to the bottom. Some of the organic detritus that accumulates in sediments is transformed through time and under pressure into fossil fuels, whereas some of the carbonates are transformed into carbonate rocks such as limestone.

Human activities influence the carbon cycle in a number of ways. Anything that changes primary productivity, such as nitrogen deposition or altered land use, potentially alters carbon flux between inorganic and organic compartments. Any activity that affects water runoff, such as deforestation or impoundment or alteration of river flows, affects the movement of carbon between the terrestrial and aquatic compartments. Deforestation and burning of fossil fuels increase the atmospheric pool of CO_2 . The atmospheric pool of CH_4 , in turn, is increased through livestock production, rice cultivation, and water storage in reservoirs, because microbes in the guts of cattle and in waterlogged sediments break down organic compounds anaerobically to produce this gas. Although the atmospheric pool of CH_4 is far smaller than that of CO_2 , both are potent greenhouse gases and affect Earth's radiation balance (see Figure 46.11).

Biogeochemical cycles interact

The fluxes of many materials through ecosystems are positively related. If the rate at which primary producers take up carbon increases, for example, fluxes of nitrogen, phosphorus, and other chemical elements into organic compartments also increase, because all are components of the molecules that make up living tissue. When the rate of decomposition increases, all of these elements move back into inorganic compartments. Similarly, the rates of loss of multiple water-soluble nutrients from the soil all increase or decrease with variation in runoff.

However, materials that are critical for organisms differ in their pools as well as in the rates of chemical and physical transport and transformation among compartments. They also vary in their availability relative to the needs of organisms. What this means is that any number of nutrients can limit biological functions: generally, the limiting one is the one that is in lowest supply relative to demand. It also means that biogeochemical cycles can interact in hard-to-predict ways. Increased atmospheric concentrations of CO_2 , for example, can increase the water-use efficiency of terrestrial plants. These plants obtain the CO_2 they need for photosynthesis by opening their stomata, which also leads to loss of water vapor from their tissues. In a high- CO_2 environment they leave their stomata open for a shorter time and therefore transpire less water, which slows the rate of water movement from soil to the atmosphere.

Do You Understand Concept 46.3?

- Explain why rates of outgassing of CO_2 from oceans and fresh waters are lower than rates of its dissolution in those waters.
- Why is nitrogen often a limiting nutrient for plant growth, even though it is the most abundant element in Earth's atmosphere?
- How is the cycling of water important to the cycling of other materials that are essential for terrestrial and aquatic ecosystems?

concept 46.4 Biogeochemical Cycles Affect Global Climate

Concept 42.2 discussed how variation in the input of solar radiation influences Earth's climate at different latitudes. We now will return to this theme, taking a slightly different perspective. In Concept 46.3 we explained how solar input drives a critical biogeochemical cycle, the hydrological cycle, by providing the energy to transform water from a liquid to a gaseous state. Water vapor in the atmosphere—gaseous water—has an important impact on the climate as a greenhouse gas. You also may recall from Concept 46.3 that atmospheric CO_2 , and CH_4 , are greenhouse gases. What is the meaning of this term, and the implications for climate? Because incoming and outgoing radiation passes through Earth's atmosphere, any interactions between photons and atmospheric gas molecules affect the radiation balance of the planet, as we will now see.

Earth's surface is warm because of the atmosphere

All objects that are warmer than absolute zero—our sun included—emit electromagnetic radiation in wavelengths that range from short (ultraviolet), through wavelengths visible to the human eye, to long wavelengths that we perceive as heat (infrared). The distribution of the wavelengths emitted by an object depends on its temperature. Because the surface of the

sun is so hot—about 6000°C —its distribution peaks in the visible wavelengths. What happens to incoming solar radiation? Approximately 23% of photons hit aerosols (tiny airborne particles and liquid droplets) and gas molecules in the atmosphere and are reflected back into space. Another 8% of photons are reflected back into space when they reach Earth's surface. About 20% are absorbed rather than reflected by gas molecules in the atmosphere. Finally, about 49% of incoming solar energy (167 watts per m^2 , averaged across day and night, all seasons, and all locations) is absorbed by Earth's surface (**FIGURE 46.11**).

Earth's surface, in turn, re-emits photons, but in much longer, less energetic infrared wavelengths. Some of this infrared radiation is absorbed by gas molecules in the atmosphere rather than escaping immediately into space. These molecules are warmed and radiate photons back to Earth's surface, keeping the energy within the Earth system as heat. The warming of Earth that results from retention of heat in its atmosphere is called the **greenhouse effect**. Logically enough, the gases involved are called **greenhouse gases**, and they are those components of the atmosphere that absorb strongly in infrared wavelengths.

We have already mentioned that water vapor, carbon dioxide (CO_2), and methane (CH_4) are greenhouse gases, and it turns out

yourBioPortal.com

Go to **ANIMATED TUTORIAL 46.4**
Earth's Radiation Balance

FIGURE 46.11 Earth's Radiation Balance The average annual energy gain from incoming solar radiation balances the average annual loss from infrared radiation that leaves the Earth system. Gains and losses are given as percentages of the average solar radiant energy striking the top of the atmosphere ($342 \text{ watts}/\text{m}^2$).

that nitrous oxide (N₂O) is as well. Fluxes of these molecules into and out of the atmosphere influence Earth's radiation balance. Without the atmosphere, Earth's average surface temperature would be -18°C—about 34°C colder than it is at present. The greenhouse effect influences any planet with an atmosphere; its magnitude depends on the amount and type of material in the atmosphere. Mars's thin atmosphere warms its surface by only 3°C, whereas the thick atmosphere of Venus warms that planet's surface by a whopping 468°C.

FIGURE 46.12 Atmospheric Greenhouse Gas Concentrations Are Increasing (A) The Keeling curve is based on measurements of atmospheric CO₂ concentrations atop of Mauna Loa, Hawaii, expressed as parts per million by volume of dry air. (B) Measurements of air trapped in glacial ice have allowed researchers to extend our record of greenhouse gas concentrations back 2,000 years.

Recent increases in greenhouse gases are warming Earth's surface

Improved methods for measuring the content of air samples accurately—such as Dave Keeling's precise methods for measuring CO₂—show us that the composition of the atmosphere is changing. Keeling's measurements reveal a steady increase in atmospheric CO₂ over the last half century (FIGURE 46.12A), and analyses of air trapped in glacial ice demonstrate that CO₂ and other greenhouse gases began increasing after about 1880 (FIGURE 46.12B). Average annual global temperatures have followed suit (FIGURE 46.13)—as they must, unless greenhouse gas increases are accompanied by compensating increases in clouds and aerosols that reflect more incoming solar radiation away from Earth.

These higher global temperatures are affecting climate worldwide. A warmer Earth means not only hotter air temperatures, but also a more intense water cycle, with greater overall evaporation and precipitation. Hadley cells (see Concept 42.2) are expected to expand poleward because the warmer tropical air will rise higher in the atmosphere and expand farther toward the poles before sinking. This should cause precipitation to increase near the equator and at high latitudes and to decrease at mid-latitudes. Because warming is uneven in space (the tropical Pacific and western Indian Oceans are warming more than other waters, for example), changes in precipitation will be season- and region-specific. But in general, wet regions are expected to get wetter and dry regions drier. Precipitation trends in the twentieth century appear to support these expectations (FIGURE 46.14). Warming is also expected to increase storm intensity. Recent analyses of the intensities of tropical storms indicate that although the overall hurricane number has not increased, strong hurricanes (category 4 and 5) have become more frequent since the 1970s.

Human activities are contributing to changes in Earth's radiation balance

As we saw in Concept 46.3, human activities are affecting Earth's biogeochemical cycles. Burning of fossil fuels and clearing of forests are adding CO₂ to the atmosphere, and expansion of livestock and wetland crop production is adding CH₄ and N₂O. Other human activities are also influencing Earth's radiation balance. Deposition of dust and dark-colored soot particles ("black carbon") from fossil fuel burning increases the amount of incoming solar energy absorbed by snow and ice, thereby increasing the melting of persistent ice fields such as

FIGURE 46.13 Global Temperatures Are Increasing A global increase in average annual temperature has been occurring in parallel with the increase atmospheric greenhouse gas concentrations.

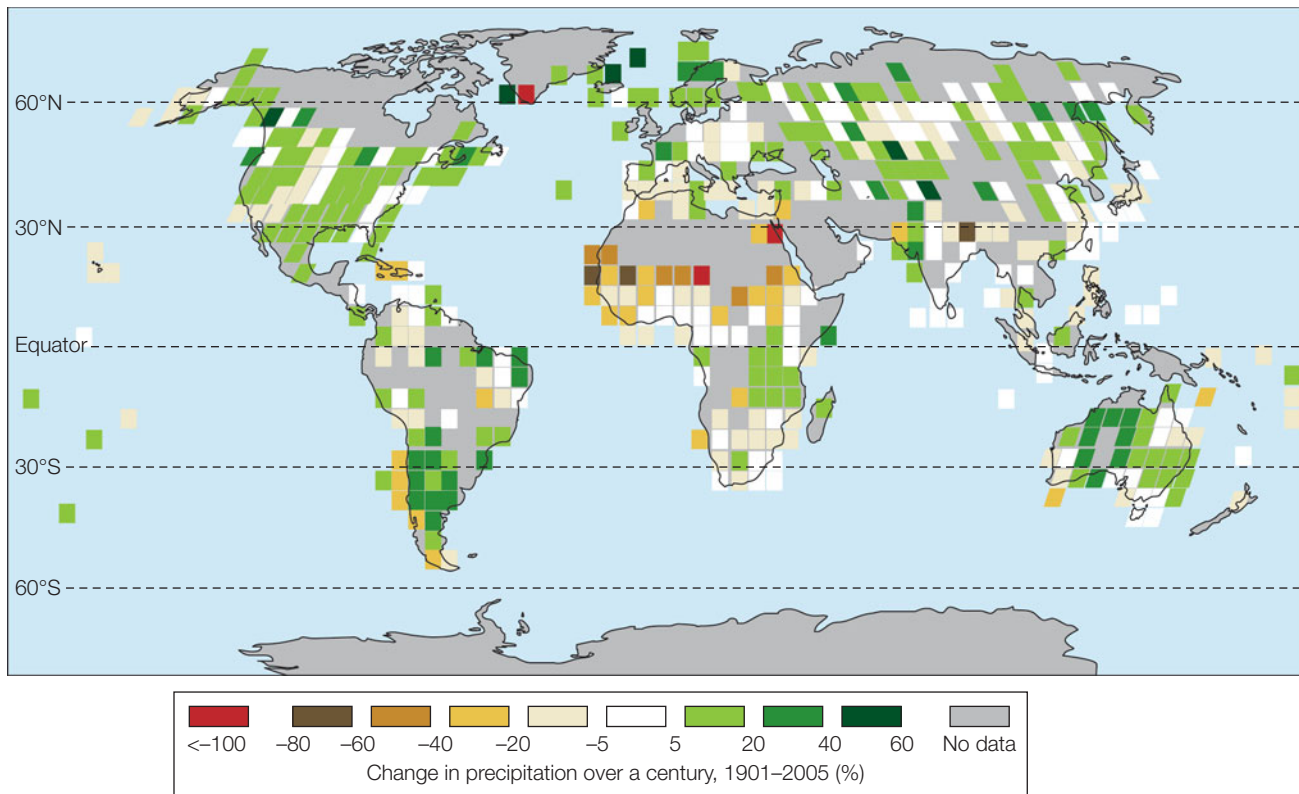

FIGURE 46.14 Global Precipitation Patterns Have Changed Over the past century, precipitation has increased at high latitudes and in some tropical regions, while it has decreased in some already-dry mid-latitudes. Note, however, that much regional variation is apparent.

the Greenland ice sheet and Arctic sea ice, as well as advancing the timing of spring snowmelt in some temperate regions.

It is possible that reflectance of solar radiation is increased sufficiently by other human activities to offset the increase in greenhouse gases and the deposition of soot and dust on snow and ice. Reflectance rises with increasing amounts of aerosols in the atmosphere and with clearing of land. However, when climate scientists incorporate all of these human effects into quantitative computer models of Earth's climate, they conclude that overall, human activities have contributed significantly to recent climate warming (see Apply the Concept, p. 905).

FRONTIERS Our ability to forecast future climates is enhanced by computing power. Global climate models are computer simulations consisting of equations that describe incoming and outgoing radiation, circulation of the atmosphere and oceans, and interactions with Earth's surface. These models divide Earth into grid cells and solve the equations in time steps. Researchers use global climate models to predict how changes in vegetation and greenhouse gases will alter the climate at any location. Millions of calculations for each time step are needed to achieve the desired 1 km² resolution, so it is no surprise that accurate predictions require supercomputers.

Do You Understand Concept 46.4?

- What is the greenhouse effect?
- Is the greenhouse effect something that occurs without humans, or is it caused by humans?
- What factors caused the increases in methane and carbon dioxide in the atmosphere beginning in the 1800s?

Now that we have seen how human activities are changing Earth's biogeochemical cycles, and how those changes are altering Earth's climate, we will consider how ecological systems are likely to respond to those changes.

concept 46.5 Rapid Climate Change Affects Species and Communities

Climate warming is not expected to affect all ecosystems in the same way because the temperature changes are not distributed evenly around the globe or across the seasons. Just as some parts of the planet are getting drier and others are getting wetter (see Figure 46.14), some parts are warming much faster than others. In all cases, however, the recent warming of Earth's climate, and other climate changes, are far more rapid than the changes most organisms have experienced in their evolutionary histories.

APPLY THE CONCEPT

Biogeochemical cycles affect global climate

Shown below are results of computer simulations of Earth's average temperature between 1850 and 2000 (blue-shaded areas), with the actual observed temperatures superimposed (red lines). Shaded regions indicate the range of outcomes from multiple simulations. The simulations were run using

three sets of climate-affecting variables: (A) only natural factors such as solar input, aerosols from volcanic eruptions, and oscillations in ocean circulation; (B) only anthropogenic (human-generated) factors such as land clearing, soot deposition, and emission of aerosols and greenhouse gases; and (C) both natural and anthropogenic factors. Temperatures are expressed as deviation (anomaly) from the average temperature of the last part of the nineteenth century. Using these graphs, answer the following questions and explain your reasoning.

1. What aspects of observed trends in global temperature are not accounted for by natural factors?
2. What aspects of observed trends in global temperature are not accounted for by human-related factors?
3. Which set of factors best accounts for observed global temperature trends?
4. The arrows in panel (C) indicate five major volcanic eruptions. What effect did these natural events have on global temperatures?

Rapid climate change can leave species behind

The life cycles of organisms that live in seasonal environments evolve so that crucial events of the cycle occur at favorable times of the year. Alpine plants, for example, start growing when the snow melts; seeds of desert plants germinate in response to certain combinations of soil temperature and moisture; changes in day length often trigger plant flowering, bird migration, and onset or cessation of insect dormancy. But climate change is altering the timing of some environmental cues. Although species' responses can change over time, evolving to match new cues, the rate of such evolution may be too slow to keep up with an environment that changes too rapidly or that continues to change directionally (consistently warming, for example) for too long.

Over the short term, there is evidence that many species are continuing to track climatic cues so that events in their life histories remain within favorable periods. For example, biological events that mark the end of the winter season in temperate ecosystems—such as the leafing out of trees—have been taking place at earlier dates as the climate has warmed. In Britain, the first flowers of a sample of 385 plant species now appear, on average, 4.5 days earlier than they did only 25 years ago, during which time the average temperature has increased 1°C at the latitude of the study. However, this is an *average* value for advances in flowering, and not all the species responded in the same way—some did not shift their time of first flowering, and some now flower later in the spring rather than earlier. Thus some species may not respond adaptively to climate change at all. Even for those that do, it is unclear

that the adaptive tracking of change can be sustained over the long term.

Changes in seasonal timing can disrupt interspecific interactions

Not all environmental cues respond to the same degree, or in the same direction, to climate change (indeed, some, such as day length, are independent of climate), so temporal relationships among cues are shifting. Because different species make use of different cues, they respond differently to climate change, as we saw with British plant studies. These differences raise the possibility of timing mismatches among species in a community, which can disrupt interactions between consumers and their resources or between mutualists such as plants and pollinators.

A well-documented example of such a mismatch involves oaks, moths, and insect-eating birds. In the Netherlands, the eggs of the winter moth (*Operophtera brumata*) hatch when temperatures warm after a fixed number of frosts, whereas the leaves of the oak trees on which the moths feed (*Quercus robur*) emerge when warm days follow a certain number of cool days. The moths have been hatching earlier, and oak leaves have been emerging earlier, in response to the earlier onset of warm temperatures in the spring. However, because the moths do not use the same cues as the oaks, they have been hatching too early and then starving. Great tits (*Parus major*), which feed on winter moth caterpillars, are not nesting earlier because they use day length to cue egg laying (FIGURE 46.15). These birds are now feeding their nestlings after the peak in caterpillar abundance has passed, and as a result are having lower breeding success.

Climate change can alter community composition by several mechanisms

If local populations cannot respond to changing environmental conditions, they may go extinct, changing the species composition of the community. As we saw in Figure 43.6, researchers found that hotter temperatures during the spring breeding season in Mexico's Yucatán Peninsula are restricting the hours during which *Sceloporus* lizards can forage. In fact, the lizards have gone locally extinct at some sites, and lack of sufficient feeding time to support breeding is implicated as the cause. Extending their analysis to lizards worldwide, the researchers predict that a continued increase in global temperatures will place most lizard populations at risk of extinction by 2080. Losses of lizards will affect populations of their insect prey, of the plants those insects feed on, and of other animals that also eat the insects. As we saw in Concept 45.4, the loss of diversity in communities leads to overall loss of community function.

Altered relationships between environmental cues can also change communities even if species do not go extinct locally. In southwestern North America, the winter rainy season now arrives later in the fall, after soil temperatures have cooled. This shift favors plant species whose seeds use cool-season moisture as the cue to germinate, at the expense of species whose

FIGURE 46.15 Climate Change Affects Life Histories

A long-term study done in the Netherlands shows that warming temperatures have affected the seasonal cycle of the winter moth *Operophtera brumata*, whose caterpillars are now emerging before the leaves on which they feed have expanded. The caterpillars starve, and great tits (*Parus major*), whose nesting habits have not yet adapted to warmer temperatures, have difficulty finding enough caterpillars to feed their nestlings.

germination is cued by warm-season moisture. Thus the relative abundance of the cool-season species is increasing in these communities.

Climate-caused shifts in the geographic distributions of species can also lead to the assembly of novel communities, as was noted in Concept 45.2. Species have moved up mountains as their low-elevation habitats become too warm and higher-elevation habitats become more favorable. Others have moved toward higher latitudes for similar reasons; such poleward shifts are now documented for numerous taxonomic groups. Different species shift to different degrees or not at all (as was true of shifts in timing of life-cycle events), so the mixture of species at any place changes. Distributional shifts also influence species interactions. Warmer temperatures in western North America, for example, are speeding up the life cycle of the mountain bark beetle (*Dendroctonus ponderosae*) and decreasing its winter mortality rate. As a result, beetle populations have increased and expanded, causing widespread tree mortality in pine and spruce forests from New Mexico to Alaska. Loss of the conifers

has cascading effects on the consumers that depend on them, and on water runoff, wildfire frequency, and NPP.

Extreme climate events also have an impact

One of the predictions from climate modeling is that the frequency of extreme climate events will increase. Severe storms, flooding, drought, heat waves, and other such events can elicit sudden shifts in species distributions and in community composition. For example, a brief but intense drought in the 1950s caused a ponderosa pine forest in northern New Mexico to shrink abruptly, and drought-adapted piñon–juniper woodland to expand, by more than 2 kilometers in less than five years. The new community boundary remained stable even after the drought ended. This is the most rapid shift in the boundary between two terrestrial plant communities ever documented at the scale of an entire landscape.

Such a response to an out-of-the-ordinary event might suggest that species are always able to shift their geographic distributions rapidly in response to climate change. But as was true with the response to temporal shifts in cues, it remains virtually certain that many species will be left behind by continued climate change, and that the number of species, their relative abundances, and their interactions will shift.

Do You Understand Concept 46.5?

- Extrapolating from the British data, what change might you anticipate in average first flowering date by the middle of this century, when atmospheric CO₂ is predicted to reach double its preindustrial concentration and temperature in Britain is expected to rise by an additional 3°C?
- How might changes in the seasonal timing of some events (such as the onset of warm weather at the end of winter) affect mutualistic interactions between plants and insect pollinators?

The changes human activities are causing in Earth's biogeochemical cycles and climate have potentially serious ecological effects. What can we do to address these effects?

concept
46.6

Ecological Challenges Can Be Addressed through Science and International Cooperation

The current period of climate change is not unprecedented. Throughout the history of life on Earth, wobble in the planet's orbit around the sun, continental drift, volcanic activity, sunspots, and even asteroid impacts have caused Earth's temperatures to change, precipitating five major episodes of mass extinction (see Figure 18.12). There is even precedent for changes in Earth's atmosphere induced by organisms. The first photosynthetic microbes were responsible for increasing atmospheric oxygen concentrations to a level that was toxic to the

anaerobic prokaryotes that inhabited Earth at the time, and the first land plants caused another rise in oxygen concentrations 250 million years ago. What is unprecedented about present climate change is that it has been precipitated by diverse activities of a single component of the biosphere: *Homo sapiens*.

It is sobering to realize that one species can wield such power. On the other hand, it is encouraging to realize that, of all species on Earth, humans are best able to address the problems they have caused—not only because science equips us to understand the natural world and to devise solutions to problems, but also because *Homo sapiens* has a remarkable capacity for cooperative action. Cooperative interactions are central features of all human societies. While other group-living animals cooperate as well, cooperation with unrelated individuals is especially highly developed in humans. We routinely support cooperative societal ventures, we police bad behavior, we even support scientific discovery—and we are unique, as far as we now know, in caring about other species with which we share Earth.

FRONTIERS Are humans truly cooperative? Biologists are fascinated by social behavior, which is found scattered throughout the tree of life. Recent advances in *game theory* reveal a surprisingly broad range of conditions under which social cooperation, even with strangers, is more adaptive than selfishness. Complementing these theoretical advances, recent studies of human infants show that they help other infants unknown to them, even when they receive no reward. Infant chimpanzees show similar, but less well developed, helping behavior. Such emerging results suggest that *Homo sapiens* has evolved an unusual tendency toward cooperation.

Governments of separate nations have cooperated in several global-scale initiatives to tackle complex environmental issues, from the IGY, which supported the first years of Dave Keeling's work, to the United Nations' Intergovernmental Panel on Climate Change and World Meteorological Organization, which are operating today. Earth's nations have also negotiated international agreements to achieve environmental goals, including the Montreal Protocol to prevent depletion of UV-absorbing atmospheric ozone, the Kyoto Protocol to reduce emissions of greenhouse gases, and the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), which seeks to conserve species by eliminating the economic benefits of exploiting them.

yourBioPortal.com

Go to WEB ACTIVITY 46.1
The Benefits of Cooperation

Nonetheless, humans face huge challenges to achieving effective cooperation on a global scale. A major challenge is that the economic policies of virtually every nation are structured to achieve continual economic growth—ever-increasing production and consumption of goods and services—despite the fact that Earth has a finite capacity to provide those goods and services. We will need to make the transition to sustainable,

steady-state economies, and that will require an overhaul of economic models and institutions. Another, related, challenge is the continued multiplicative growth of the human population (see Concept 43.4). On a crowded planet, with competition among societies for limited resources, cooperation inevitably becomes more difficult. Addressing both challenges will require that we devise international systems for establishing—and enforcing—rules of acceptable behavior among groups and nations.

How did Keeling's research contribute to our understanding of the global ecosystem?

ANSWER Dave Keeling was successful in obtaining long-term measurements of CO₂. His dedication left an important legacy, the Keeling curve (see Figure 46.12A), which documents how atmospheric CO₂ is increasing (Concept 46.4). Almost immediately, Keeling discovered that CO₂ concentrations do not vary erratically, as earlier crude methods of measurement suggested, but instead change seasonally as summer warmth, and the primary productivity that goes with it, shifts from the Northern Hemisphere (where most of Earth's land mass lies) to the Southern Hemisphere (notice the saw-teeth of the Keeling curve). Keeling's measurements quickly contributed to a better understanding of the pools and fluxes of the global carbon cycle (Concept 46.3), including the influence of fossil-fuel burning (currently pegged to add over 8

billion metric tons of carbon to the atmosphere annually). Better understanding of the carbon cycle contributed to greatly improved global climate models. The measurements on Mauna Loa and elsewhere continue to the present day, and they show that atmospheric CO₂ increased from 315 ppm in 1958 to 390 ppm in 2010.

Keeling's results were noticed almost immediately. In 1965 the President's Science Advisory Committee warned of the increased greenhouse effect, and in 1966 the National Academy of Sciences issued a scholarly report on the topic. The first World Climate Conference was held in Geneva, Switzerland, in 1979, at a time when there was growing scientific consensus that climate change poses a critical environmental challenge to humans. The number of scientists studying climate change, and the sophistication of their climate experiments and studies, grew rapidly. Measurements by the end of the twentieth century showed that the average temperature of the planet had increased by 0.7°C since 1900—an increase very close to the predictions of global climate models.

The Keeling curve forms a crucial part of our understanding of the Earth system. It is an example of the carefully documented scientific information that is used by the Intergovernmental Panel on Climate Change (IPCC). The IPCC was formed in 1988 by another scientific collaboration of governments (Concept 46.6)—a sort of “grandchild” of IGY—and its many scientists continue to summarize and report on the latest evidence for natural and human-caused climate change. The 2009 IPCC report predicts a further human-caused increase in global average temperature between 1.8°C and 4.0°C by the end of this century.

We have a civilization based on science and technology, and we've cleverly arranged things so that almost nobody understands science and technology. That is as clear a prescription for disaster as you can imagine. While we might get away with this combustible mixture of ignorance and power for a while, sooner or later it's going to blow up in our faces. The powers of modern technology are so formidable that it's insufficient just to say, 'Well, those in charge, I'm sure, are doing a good job.' This is a democracy, and for us to make sure that the powers of science and technology are used properly and prudently, we ourselves must understand science and technology. We must be involved in the decision-making process.

Carl Sagan

concept 46.1 Climate and Nutrients Affect Ecosystem Function

- An ecological community in its abiotic context is an ecosystem.
- A community's rate of biomass production per unit of area—its net primary productivity (NPP)—is related to its exchange of energy and materials with its abiotic surroundings, and thus is a measure of ecosystem function.
- NPP varies considerably among ecosystem types. **Review Figure 46.1**
- Variation of terrestrial NPP shows that it is influenced by both temperature and precipitation. Soil nutrients also play a role in terrestrial NPP. **Review Figures 46.2 and 46.3**
- Aquatic NPP varies most strongly with availability of light and nutrients. **Review Figures 46.4**

concept 46.2 Biological, Geological, and Chemical Processes Move Materials through Ecosystems

- The molecular form and physical state in which an element exists and the physical compartment of the biosphere in which it is located determine whether the element is accessible to life.
- The transformations of materials and their movements among compartments are called **biogeochemical cycles**. **Review Figure 46.5**
- The **pool**, or amount, of an element or molecule in a compartment depends on its flows, or **fluxes**, into and out of that compartment.

concept 46.3 Certain Biogeochemical Cycles Are Especially Critical for Ecosystems

- Evaporation drives the water cycle, moving water into the atmosphere in gaseous form; precipitation returns liquid water to Earth's surface. These transitions between gaseous and liquid states involve exchanges of heat energy between water molecules and their surroundings. Gravity-driven flows move water from land to the oceans, transporting many other materials as well. **Review Figure 46.6 and ANIMATED TUTORIAL 46.1**
- The availability of nitrogen to living organisms depends on **nitrogen fixation** and other biochemical processes carried out by microbes. These processes change gaseous N_2 into forms that primary producers can absorb and that are recycled locally, and return N_2 to the atmosphere. **Review Figure 46.7 and ANIMATED TUTORIAL 46.2**
- Human activities add various chemical forms of nitrogen to the atmosphere and to aquatic systems, contributing to smog and causing **eutrophication** and oxygen-poor **dead zones** devoid of life. **Review Figure 46.9**
- Photosynthesis and respiration move carbon between the inorganic and organic compartments of the biosphere. As a result, energy flow and the flux of carbon through biological communities are intimately linked.
- Some carbon absorbed from the atmosphere by surface waters is taken up through photosynthesis, some precipitates as calcium carbonate, and some falls to the benthic zone as organic detritus. Calcium carbonate and detritus that accumulate in sediments and soils are transformed into carbonate rocks and **fossil fuels**.

Use of fossil fuels by humans increases the carbon content of the atmosphere. **Review Figure 46.10 and ANIMATED TUTORIAL 46.3**

- The biogeochemical cycles of different materials can interact in ways that are hard to predict.

concept 46.4 Biogeochemical Cycles Affect Global Climate

- Earth absorbs incoming solar energy and re-emits it in infrared wavelengths. Some of this infrared radiation is absorbed by atmospheric gases and is re-radiated back to Earth's surface. The resulting retention of heat within the Earth system is called the **greenhouse effect**. **Review Figure 46.11 and ANIMATED TUTORIAL 46.4**
- Gases such as water vapor, carbon dioxide, methane, and nitrous oxide that absorb strongly in infrared wavelengths are called **greenhouse gases**. Fluxes of these molecules into and out of the atmosphere influence Earth's radiation balance.
- Atmospheric concentrations of CO_2 and other greenhouse gases have been increasing since about 1880, and average annual global temperatures have followed suit. **Review Figures 46.12 and 46.13**
- Global warming is changing Earth's climates. High latitudes are warming more than low latitudes, precipitation patterns are changing, and storm intensities are increasing. **Review Figure 46.14**
- Computer models of the Earth system show that human activities have contributed significantly to the recent warming of the climate.

concept 46.5 Rapid Climate Change Affects Species and Communities

- Climate change is altering the timing of some seasonal environmental cues but not others. Although species can evolve new responses to such cues, the rate of evolution will not keep up with an environment that changes too rapidly.
- Because different species respond to different seasonal cues, altered cues result in timing mismatches among species in a community and thus disrupt their interactions.
- Climate change is altering the distribution and abundance of species, resulting in the assembly of novel communities.
- Climate change is increasing the frequency of extreme weather events, which can cause sudden shifts in species distributions and in community composition.

concept 46.6 Ecological Challenges Can Be Addressed through Science and International Cooperation

- Humans are causing major changes in the biosphere and in other aspects of the Earth system. However, we are also uniquely equipped to address these changes, not only because science enables us to understand the natural world and to devise solutions to problems, but also because of our capacity for cooperative action. **Review WEB ACTIVITY 46.1**

See **WEB ACTIVITY 46.2** for a concept review of this chapter.

Appendix A: The Tree of Life

Phylogeny is the organizing principle of modern biological taxonomy. A guiding principle of modern phylogeny is monophyly. A monophyletic group is considered to be one that contains an ancestral lineage and all of its descendants. Any such group can be extracted from a phylogenetic tree with a single cut.

The tree shown here provides a guide to the relationships among the major groups of extant (living) organisms in the tree of life as we have presented them throughout this book. The position of the branching “splits” indicates the relative branching order of the lineages of life, but the time scale is not meant to be uniform. In addition, the groups appearing at the branch tips do not necessarily carry equal phylogenetic “weight.” For example, the ginkgo [75] is indeed at the apex of its lineage; this gymnosperm group consists of a single living species. In contrast, a phylogeny of the eudicots [83] could continue on from this point to fill many more trees the size of this one.

The glossary entries that follow are informal descriptions of some major features of the organisms described in Part Seven

of this book. Each entry gives the group’s common name, followed by the formal scientific name of the group (in parentheses). Numbers in square brackets reference the location of the respective groups on the tree.

It is sometimes convenient to use an informal name to refer to a collection of organisms that are not monophyletic but nonetheless all share (or all lack) some common attribute. We call these “convenience terms”; such groups are indicated in these entries by quotation marks, and we do not give them formal scientific names. Examples include “prokaryotes,” “protists,” and “algae.” Note that these groups cannot be removed with a single cut; they represent a collection of distantly related groups that appear in different parts of the tree. We also use quotation marks here to designate two groups of fungi that are not believed to be monophyletic.

An interactive version of this tree, with links to much greater detail (such as photos, distribution maps, species lists, and identification keys), can be found at yourBioPortal.com; see also <http://tolweb.org/tree>.

– A –

acorn worms (*Enteropneusta*) Benthic marine hemichordates [119] with an acorn-shaped proboscis, a short collar (neck), and a long trunk.

“algae” Convenience term encompassing various distantly related groups of aquatic, photosynthetic eukaryotes [4].

alveolates (*Alveolata*) [5] Unicellular eukaryotes with a layer of flattened vesicles (alveoli) supporting the plasma membrane. Major alveolate groups include the dinoflagellates [51], apicomplexans [50], and ciliates [49].

amborella (*Amborella*) [78] An understory shrub or small tree found on the South Pacific island of New Caledonia. Thought to be the sister group of the remaining living angiosperms [15].

ambulacrarians (*Ambulacraria*) [29] The echinoderms [118] and hemichordates [119].

amniotes (*Amniota*) [36] Mammals, reptiles, and their extinct close relatives. Characterized by many adaptations to terrestrial life, including an amniotic egg (with a unique set of membranes—the amnion, chorion, and allantois), a water-repellant epidermis (with epidermal scales, hair, or feathers), and, in males, a penis that allows internal fertilization.

amoebozoans (*Amoebozoa*) [84] A group of eukaryotes [4] that use lobe-shaped pseudopods for locomotion and to engulf food. Major amoebozoan groups include the loboseans, plasmodial slime molds, and cellular slime molds.

amphibians (*Amphibia*) [128] Tetrapods [35] with glandular skin that lacks epidermal scales, feathers, or hair. Many amphibian species undergo a complete metamorphosis from an aquatic larval form to a terrestrial adult form, although direct development is also common. Major amphibian groups include frogs and toads (anurans), salamanders, and caecilians.

amphipods (*Amphipoda*) Small crustaceans [116] that are abundant in many marine and freshwater habitats. They are important herbivores, scavengers, and micropredators, and are an important food source for many aquatic organisms.

angiosperms (*Anthophyta* or *Magnoliophyta*) [15] The flowering plants. Major angiosperm groups include the monocots [82], eudicots [83], and magnoliids [81].

animals (*Animalia* or *Metazoa*) [19] Multicellular heterotrophic eukaryotes. The majority of animals are bilaterians [22]. Other groups of animals include the cnidarians [97], ctenophores [96], placozoans [95], and sponges [20]. The closest living relatives of the animals are the choanoflagellates [91].

annelids (*Annelida*) [105] Segmented worms, including earthworms, leeches, and polychaetes. One of the major groups of lophotrochozoans [24].

anthozoans (*Anthozoa*) One of the major groups of cnidarians [97]. Includes the sea anemones, sea pens, and corals.

anurans (*Anura*) Comprising the frogs and toads, this is the largest group of living amphibians [128]. They are tail-less, with a shortened vertebral column and elongate hind legs modified for jumping. Many species have an aquatic larval form known as a tadpole.

apicomplexans (*Apicomplexa*) [50] Parasitic alveolates [5] characterized by the possession of an apical complex at some stage in the life cycle.

arachnids (*Arachnida*) Chelicerates [114] with a body divided into two parts: a cephalothorax that bears six pairs of appendages (four pairs of which are usually used as legs) and an abdomen that bears the genital opening. Familiar arachnids include spiders, scorpions, mites and ticks, and harvestmen.

arbuscular mycorrhizal fungi (*Glomeromycota*) [88] A group of fungi [17] that associate with plant roots in a close symbiotic relationship.

archaeans (*Archaea*) [3] Unicellular organisms lacking a nucleus and lacking peptidoglycan in the cell wall. Once grouped with the bacteria, archaeans possess distinctive membrane lipids.

archosaurs (*Archosauria*) [38] A group of reptiles [37] that includes dinosaurs and crocodilians [133]. Most dinosaur groups became extinct at the end of the Cretaceous; birds [132] are the only surviving dinosaurs.

arrow worms (*Chaetognatha*) [98] Small planktonic or benthic predatory marine worms with fins and a pair of hooked, prey-grasping spines on each side of the head.

The Tree of Life In this rendition, the prokaryotic lineages are shown in black and the eukaryotic lineages are in colors. Among the eukaryotes, the microbial lineages are shown in blue. The four eukaryote groups that contain major radiations of multicellular organisms are shown in brown (brown algae), green (Plantae), orange (fungi), and red (animals).

yourBioPortal.com
 Go to
 THE INTERACTIVE TREE OF LIFE

arthropods (*Arthropoda*) The largest group of ecdysozoans [25]. Arthropods are characterized by a stiff exoskeleton, segmented bodies, and jointed appendages. Includes the chelicerates [114], myriapods [115], crustaceans [116], and hexapods (insects and their relatives) [117].

ascidians (*Asciacea*) “Sea squirts”; the largest group of urochordates [121]. Also known as tunicates, they are sessile (as adults), marine, saclike filter feeders.

- B -

bacteria (*Eubacteria*) [2] Unicellular organisms lacking a nucleus, possessing distinctive ribosomes and initiator tRNA, and generally containing peptidoglycan in the cell wall. Different bacterial groups are distinguished primarily on nucleotide sequence data.

barnacles (*Cirripedia*) Crustaceans [116] that undergo two metamorphoses—first from a feeding planktonic larva to a nonfeeding swimming larva, and then to a sessile adult that forms a “shell” composed of four to eight plates cemented to a hard substrate.

bilaterians (*Bilateria*) [22] Those animal groups characterized by bilateral symmetry and three distinct tissue types (endoderm, ectoderm, and mesoderm). Includes the protostomes [23] and deuterostomes [28].

birds (*Aves*) [132] Feathered, flying (or secondarily flightless) tetrapods [35].

bivalves (*Bivalvia*) Major mollusk [106] group; clams and mussels. Bivalves typically have two similar hinged shells that are each asymmetrical across the midline.

bony vertebrates (*Osteichthyes*) [33] Vertebrates [31] in which the skeleton is usually ossified to form bone. Includes the ray-finned fishes [125], coelacanth [126], lungfishes [127], and tetrapods [35].

brachiopods (*Brachiopoda*) [103] Lophotrochozoans [24] with two similar hinged shells that are each symmetrical across the midline. Superficially resemble bivalve mollusks, except for the shell symmetry.

brittle stars (*Ophiuroidea*) Echinoderms [118] with five long, whip-like arms radiating from a distinct central disk that contains the reproductive and digestive organs.

brown algae (*Phaeophyta*) [54] Multicellular, almost exclusively marine stramenopiles [6] generally containing the pigment fucoxanthin as well as chlorophylls *a* and *c* in their chloroplasts.

bryozoans (*Ectoprocta* or *Bryozoa*) [99] A group of marine and freshwater lophotrochozoans [24] that live in colonies attached to substrata; also known as ectoprocts or moss animals.

- C -

caecilians (*Gymnophiona*) A group of burrowing or aquatic amphibians [128]. They are elongate, legless, with a short tail (or none at all), reduced eyes covered with skin or bone, and a pair of sensory tentacles on the head.

calcareous sponges (*Calcarea*) [94] Filter-feeding marine sponges with spicules composed of calcium carbonate.

cellular slime molds (*Dictyostelida*) Amoebozoans [84] in which individual amoebas aggregate under stress to form a multicellular pseudoplasmodium.

cephalochordates (*Cephalochordata*) [120] A group of weakly swimming, eel-like benthic marine chordates [30]; also called lancelets.

cephalopods (*Cephalopoda*) Active, predatory mollusks [106] in which the molluscan foot has been modified into muscular hydrostatic arms or tentacles. Includes octopuses, squids, and nautiluses.

cercozoans (*Cercozoa*) [56] Unicellular eukaryotes [4] that feed by means of threadlike pseudopods. Group together with foraminiferans [57] and radiolarians [55] to comprise the rhizaria [7].

charophytes (*Charales*) [67] Multicellular green algae with branching, apical growth and plasmodesmata between adjacent cells. The closest living relatives of the land plants [11], they retain the egg in the parent organism.

chelicerates (*Chelicerata*) [114] A major group of arthropods [26] with pointed appendages (chelicerata) used to grasp food (as opposed to the chewing mandibles of most other arthropods). Includes the arachnids, horseshoe crabs, pycnogonids, and extinct sea scorpions.

chimaeras (*Holocephali*) A group of bottom-dwelling, marine, scaleless chondrichthyan fishes [124] with large, permanent, grinding tooth plates (rather than the replaceable teeth found in other chondrichthyans).

chitons (*Polyplocophora*) Flattened, slow-moving mollusks [106] with a dorsal protective calcareous covering made up of eight articulating plates.

chlamydias (*Chlamydiae*) [46] A group of very small Gram-negative bacteria; they live as intracellular parasites of other organisms.

chlorophytes (*Chlorophyta*) [65] The most abundant and diverse group of green algae, including freshwater, marine, and terrestrial forms; some are unicellular, others colonial, and still others multicellular. Chlorophytes use chlorophylls *a* and *c* in their photosynthesis.

choanoflagellates (*Choanozoa*) [91] Unicellular eukaryotes [4] with a single flagellum surrounded by a collar. Most are sessile, some are colonial. The closest living relatives of the animals [19].

chondrichthyans (*Chondrichthyes*) [124] One of the two main groups of jawed vertebrates [32]; includes sharks, rays, and chimaeras. They have cartilaginous skeletons and paired fins.

chordates (*Chordata*) [30] One of the two major groups of deuterostomes [28], characterized by the presence (at some point in development) of a notochord, a hollow dorsal nerve cord, and a post-anal tail. Includes the cephalochordates [120], urochordates [121], and vertebrates [31].

“**chytrids**” [90] Convenience term used for a paraphyletic group of mostly aquatic, microscopic fungi [17] with flagellated gametes. Some exhibit alternation of generations.

ciliates (*Ciliophora*) [49] Alveolates [5] with numerous cilia and two types of nuclei (micronuclei and macronuclei).

clitellates (*Clitellata*) Annelids [105] with gonads contained in a swelling (called a clitellum) toward the head of the animal. Includes earthworms (oligochaetes) and leeches.

club fungi (*Basidiomycota*) [90] Fungi [17] that, if multicellular, bear the products of meiosis on club-shaped basidia and possess a long-lasting dikaryotic stage. Some are unicellular.

club mosses (*Lycopodiophyta*) [71] Vascular plants [12] characterized by microphylls. See lycophytes.

cnidarians (*Cnidaria*) [97] Aquatic, mostly marine eumetazoans [21] with specialized stinging organelles (nematocysts) used for prey capture and defense, and a blind gastrovascular cavity. The closest living relatives of the ctenophores [96].

coelacanth (*Actinista*) [126] A group of marine sarcopterygians [34] that was diverse from the Middle Devonian to the Cretaceous, but is now known from just two living species. The pectoral and anal fins are on fleshy stalks supported by skeletal elements, so they are also called lobe-finned fishes.

coleochaetophytes (*Coleochaetales*) [66] Multicellular green algae characterized by flattened growth form composed of thin-walled cells. Thought to be the sister-group to the charophytes [67] plus land plants [11].

conifers (*Pinophyta* or *Coniferophyta*) [77] Cone-bearing, woody seed plants [13].

copepods (*Copepoda*) Small, abundant crustaceans [116] found in marine, freshwater, or wet terrestrial habitats. They have a single eye, long antennae, and a body shaped like a teardrop.

craniates (*Craniata*) Some biologist exclude the hagfishes [122] from the vertebrates [31], and use the term craniates to refer to the two groups combined.

crenarchaeotes (*Crenarchaeota*) [47] A major and diverse group of archaeans [3], defined on the basis of rRNA base sequences. Many are extremophiles (inhabit extreme environments), but the group may also be the most abundant archaeans in the marine environment.

crinoids (*Crinoidea*) Echinoderms [118] with a mouth surrounded by feeding arms, and a U-shaped gut with the mouth next to the anus. They attach to the substratum by a stalk or are free-swimming. Crinoids were abundant in the middle and late Paleozoic, but only a few hundred species have survived to the present. Includes the sea lilies and feather stars.

crocodilians (*Crocodylia*) [133] A group of large, predatory, aquatic archosaurs [38]. The closest living relatives of birds [132]. Includes alligators, caimans, crocodiles, and gharials.

crustaceans (*Crustacea*) [116] Major group of marine, freshwater, and terrestrial arthropods [26] with a head, thorax, and abdomen (although the head and thorax may be fused), covered with a thick exoskeleton, and with two-part appendages. Crustaceans undergo metamorphosis from a nauplius larva. Includes decapods, isopods, krill, barnacles, amphipods, copepods, and ostracods.

ctenophores (*Ctenophora*) [96] Radially symmetrical, diploblastic marine animals [19], with a complete gut and eight rows of fused plates of cilia (called ctenes).

cyanobacteria (*Cyanobacteria*) [43] A group of unicellular, colonial, or filamentous bacteria that conduct photosynthesis using chlorophyll *a*.

cycads (*Cycadophyta*) [74] Palmlike gymnosperms with large, compound leaves.

cyclostomes (*Cyclostomata*) This term refers to the possibly monophyletic group of lampreys [123] and hagfishes [122]. Molecular data support this group, but morphological data suggest that lampreys are more closely related to jawed vertebrates [32] than to hagfishes.

- D -

decapods (*Decapoda*) A group of marine, freshwater, and semiterrestrial crustaceans [116] in which five of the eight pairs of thoracic appendages function as legs (the other three pairs, called maxillipeds, function as mouthparts). Includes crabs, lobsters, crayfishes, and shrimps.

demosponges (*Demospongiae*) [93] The largest of the three groups of sponges [20], accounting for 90 percent of all sponge species. Demosponges have spicules made of silica, spongin fiber (a protein), or both.

deuterostomes (*Deuterostomia*) [28] One of the two major groups of bilaterians [22], in which the mouth forms at the opposite end of the embryo from the blastopore in early development (contrast with protostomes). Includes the ambulacrarians [29] and chordates [30].

diatoms (*Bacillariophyta*) [53] Unicellular, photosynthetic stramenopiles [6] with glassy cell walls in two parts.

dikaryotic fungi (*Dikarya*) [18] A group of fungi [17] in which two genetically different haploid nuclei coexist and divide within the same hypha; includes club fungi [90] and sac fungi [89].

dinoflagellates (*Dinoflagellata*) [51] A group of alveolates [5] usually possessing two flagella, one in an equatorial groove and the other in a longitudinal groove; many are photosynthetic.

diplomonads (*Diplomonadida*) [58] A group of eukaryotes [4] lacking mitochondria; most have two nuclei, each with four associated flagella.

- E -

ecdysozoans (*Ecdysozoa*) [25] One of the two major groups of protostomes [23], characterized by periodic molting of their exoskeletons. Nematodes [111] and arthropods [26] are the largest ecdysozoan groups.

echinoderms (*Echinodermata*) [118] A major group of marine deuterostomes [28] with fivefold radial symmetry (at some stage of life) and an endoskeleton made of calcified plates and spines. Includes sea stars, crinoids, sea urchins, sea cucumbers, and brittle stars.

elasmobranchs (*Elasmobranchii*) The largest group of chondrichthyan fishes [124]. Includes sharks, skates, and rays. In contrast to the other group of living chondrichthyans (the chimaeras), they have replaceable teeth.

embryophytes See land plants [11].

audicots (*Eudicotyledones*) [83] A group of angiosperms [15] with pollen grains possessing three openings. Typically with two cotyledons, net-veined leaves, taproots, and floral organs typically in multiples of four or five.

euglenids (*Euglenida*) [61] Flagellate excavates characterized by a pellicle composed of spiraling strips of protein under the plasma membrane; the mitochondria have disk-shaped cristae. Some are photosynthetic.

eukaryotes (*Eukarya*) [4] Organisms made up of one or more complex cells in which the genetic material is contained in nuclei. Contrast with archaeans [3] and bacteria [2].

eumetazoans (*Eumetazoa*) [21] Those animals [19] characterized by body symmetry, a gut, a nervous system, specialized types of cell junctions, and well-organized tissues in distinct cell layers (although there have been secondary losses of some of these characteristics in some eumetazoans).

euphyllophytes (*Euphyllophyta*) The group of vascular plants [12] that is sister to the lycophytes [71] and which includes all plants with megaphylls.

euryarchaeotes (*Euryarchaeota*) [48] A major group of archaeans [3], diagnosed on the basis of rRNA sequences. Includes many methanogens, extreme halophiles, and thermophiles.

eutherians (*Eutheria*) A group of viviparous mammals [129], eutherians are well developed at birth (contrast to prototherians and marsupials, the other two groups of mammals). Most familiar mammals outside the Australian and South American regions are eutherians (see Table 23.3).

excavates (*Excavata*) [8] Diverse group of unicellular, flagellate eukaryotes, many of which possess a feeding groove; some lack mitochondria.

- F -

"ferns" Vascular plants [12] usually possessing large, frondlike leaves that unfold from a "fiddlehead." Not a monophyletic group, although most fern species are encompassed in a monophyletic clade, the leptosporangiate ferns [73].

flatworms (*Platyhelminthes*) [100] A group of dorsoventrally flattened and generally elongate soft-bodied lophotrochozoans [24]. May be free-living or parasitic, found in marine, freshwater, or damp terrestrial environments. Major flatworm groups include the tapeworms, flukes, monogeneans, and turbellarians.

flowering plants See angiosperms [15].

flukes (*Trematoda*) A group of wormlike parasitic flatworms [100] with complex life cycles that involve several different host species. May be paraphyletic with respect to tapeworms.

foraminiferans (*Foraminifera*) [57] Amoeboid organisms with fine, branched pseudopods that form a food-trapping net. Most produce external shells of calcium carbonate.

fungi (*Fungi*) [17] Eukaryotic heterotrophs with absorptive nutrition based on extracellular digestion; cell walls contain chitin. Major fungal groups include the microsporidia [85], "chytrids" [86], "zygospore fungi" [87], arbuscular mycorrhizal fungi [88], sac fungi [89], and club fungi [90].

- G -

gastropods (*Gastropoda*) The largest group of mollusks [106]. Gastropods possess a well-defined head with two or four sensory tentacles (often terminating in eyes) and a ventral foot. Most species have a single coiled or spiraled shell. Common in marine, freshwater, and terrestrial environments.

ginkgo (*Ginkgophyta*) [75] A gymnosperm [14] group with only one living species. The ginkgo seed is surrounded by a fleshy tissue not derived from an ovary wall and hence not a fruit.

glass sponges (*Hexactinellida*) [92] Sponges [20] with a skeleton composed of four- and/or six-pointed spicules made of silica.

glaucophytes (*Glaucophyta*) [63] Unicellular freshwater algae with chloroplasts containing traces of peptidoglycan, the characteristic cell wall material of bacteria.

gnathostomes (*Gnathostomata*) See jawed vertebrates [32].

gnetophytes (*Gnetophyta*) [76] A gymnosperm [14] group with three very different lineages; all have wood with vessels, unlike other gymnosperms.

green plants (*Viridiplantae*) [10] Organisms with chlorophylls *a* and *b*, cellulose-containing cell walls, starch as a carbohydrate storage product, and chloroplasts surrounded by two membranes.

gymnosperms (*Gymnospermae*) [14] Seed plants [13] with seeds "naked" (i.e., not enclosed in carpels). Probably monophyletic, but status still in doubt. Includes the conifers [77], gnetophytes [76], ginkgo [75], and cycads [74].

- H -

hadobacteria (*Hadobacteria*) [42] A group of extremophilic bacteria [2] that includes the genera *Deinococcus* and *Thermus*.

hagfishes (*Myxini*) [122] Elongate, slimy-skinned vertebrates [31] with three small accessory hearts, a partial cranium, and no stomach or paired fins. See also craniata; cyclostomes.

hemichordates (*Hemichordata*) [119] One of the two primary groups of ambulacrarians [29]; marine wormlike organisms with a three-part body plan.

heteroloboseans (*Heterolobosea*) [60] Colorless excavates [8] that can transform among amoeboid, flagellate, and encysted stages.

hexapods (*Hexapoda*) [117] Major group of arthropods [26] characterized by a reduction (from the ancestral arthropod condition) to six walking appendages, and the consolidation of three body segments to form a thorax. Includes insects and their relatives (see Table 23.2).

high-GC Gram-positives (*Actinobacteria*) [40] Gram-positive bacteria with a relatively high (G+C)/(A+T) ratio of their DNA, with a filamentous growth habit.

hornworts (*Anthoceroophyta*) [70] Nonvascular plants with sporophytes that grow from the base. Cells contain a single large, platelike chloroplast.

horsehair worms (*Nematomorpha*) [110] A group of very thin, elongate, wormlike freshwater ecdysozoans [25]. Largely nonfeeding as adults, they are parasites of insects and crayfish as larvae.

horseshoe crabs (*Xiphosura*) Marine chelicerates [114] with a large outer shell in three parts: a carapace, an abdomen, and a tail-like telson. There are only five living species, but many additional species are known from fossils.

horsetails (*Sphenophyta* or *Equisetophyta*) [72] Vascular plants [12] with reduced megaphylls in whorls.

hydrozoans (*Hydrozoa*) A group of cnidarians [97]. Most species go through both polyp and mesoda stages, although one stage or the other is eliminated in some species.

hyperthermophilic bacteria [41] A group of thermophilic bacteria [2] that live in volcanic vents, hot springs, and in underground oil reservoirs; includes the genera *Aquifex* and *Thermotoga*.

- I -

insects (*Insecta*) The largest group within the hexapods [117]. Insects are characterized by exposed mouthparts and one pair of antennae containing a sensory receptor called a Johnston's organ. Most have two pairs of wings as adults. There are more described species of insects than all other groups of life [1] combined, and many species remain to be discovered. The major insect groups are described in Table 23.2.

"invertebrates" Convenience term encompassing any animal [19] that is not a vertebrate [31].

isopods (*Isopoda*) Crustaceans [116] characterized by a compact head, unstalked compound eyes, and mouthparts consisting of four pairs of appendages. Isopods are abundant and

widespread in salt, fresh, and brackish water, although some species (the sow bugs) are terrestrial.

- J -

jawed vertebrates (*Gnathostomata*) [32] A major group of vertebrates [31] with jawed mouths. Includes chondrichthyans [124], ray-finned fishes [125], and sarcopterygians [34].

- K -

kinetoplastids (*Kinetoplastida*) [62] Unicellular, flagellate organisms characterized by the presence in their single mitochondrion of a kinetoplast (a structure containing multiple, circular DNA molecules).

kinorhynchs (*Kinorhyncha*) [108] Small (< 1 mm) marine ecdysozoans [25] with bodies in 13 segments and a retractable proboscis.

korarchaeotes (*Korarchaeota*) A group of archaeans [3] known only by evidence from nucleic acids derived from hot springs. Its phylogenetic relationships within the Archaea are unknown.

krill (*Euphausiacea*) A group of shrimplike marine crustaceans [116] that are important components of the zooplankton.

- L -

lampreys (*Petromyzontiformes*) [123] Elongate, eel-like vertebrates [31] that often have rasping and sucking disks for mouths.

lancelets (*Cephalochordata*) See cephalochordates [120].

land plants (*Embryophyta*) [11] Plants with embryos that develop within protective structures; also called embryophytes. Sporophytes and gametophytes are multicellular. Land plants possess a cuticle. Major groups are the liverworts [68], mosses [69], hornworts [70], and vascular plants [12].

larvaceans (*Larvacea*) Solitary, planktonic urochordates [121] that retain both notochords and nerve cords throughout their lives.

lepidosaurs (*Lepidosauria*) [131] Reptiles [37] with overlapping scales. Includes tuataras and squamates (lizards, snakes, and amphisbaenians).

leptosporangiate ferns (*Pteridopsida* or *Polypodiopsida*) [73] Vascular plants [12] usually possessing large, frondlike leaves that unfold from a "fiddlehead," and possessing thin-walled sporangia.

life (*Life*) [1] The monophyletic group that includes all known living organisms. Characterized by a nucleic-acid based genetic system (DNA or RNA), metabolism, and cellular structure. Some parasitic forms, such as viruses, have secondarily lost some of these features and rely on the cellular environment of their host.

liverworts (*Hepatophyta*) [68] Nonvascular plants lacking stomata; stalk of sporophyte elongates along its entire length.

loboseans (*Lobosea*) A group of unicellular amoebozoans [84]; includes the most familiar amoebas (e.g., *Amoeba proteus*).

"lophophorates" Convenience term used to describe several groups of lophotrochozoans [24] that have a feeding structure called a lophophore (a circular or U-shaped ridge around the mouth that bears one or two rows of ciliated, hollow tentacles). Not a monophyletic group.

lophotrochozoans (*Lophotrochozoa*) [24] One of the two main groups of protostomes [23]. This group is morphologically diverse, and is supported primarily on information from gene sequences. Includes bryozoans [99], flatworms [100], rotifers [101], ribbon worms [102], brachiopods [103], phoronids [104], annelids [105], and mollusks [106].

loriciferans (*Loricifera*) [109] Small (< 1 mm) ecdysozoans [25] with bodies in four parts, covered with six plates.

low-GC Gram-positives (*Firmicutes*) [39] A diverse group of bacteria [2] with a relatively low (G+C)/(A+T) ratio of their DNA, often but not always Gram-positive, some producing endospores.

lungfishes (*Dipnoi*) [127] A group of aquatic sarcopterygians [34] that are the closest living relatives of the tetrapods [35]. They have a modified swim bladder used to absorb oxygen from air, so some species can survive the temporary drying of their habitat.

lycophytes (*Lycopodiophyta*) [71] Vascular plants [12] characterized by microphylls; includes club mosses, spike mosses, and quillworts.

- M -

magnoliids (*Magnoliidae*) [81] A major group of angiosperms [15] possessing two cotyledons and pollen grains with a single opening. The group is defined primarily by nucleotide sequence data; it is more closely related to the eudicots and monocots than to three other small angiosperm groups.

mammals (*Mammalia*) [129] A group of tetrapods [35] with hair covering all or part of their skin; females produce milk to feed their developing young. Includes the prototherians, marsupials, and eutherians.

mandibulates (*Mandibulata*) [27] Arthropods [26] that include mandibles as mouth parts. Includes myriapods [115], crustaceans [116], and hexapods [117].

marsupials (*Marsupialia*) Mammals [129] in which the female typically has a marsupium (a pouch for rearing young, which are born at an extremely early stage in development). Includes such familiar mammals as opossums, koalas, and kangaroos.

metazoans (*Metazoa*) See animals [19].

microbial eukaryotes See "protists."

microsporidia (*Microsporidia*) [85] A group of parasitic unicellular fungi [17] that lack mitochondria and have walls that contain chitin.

mollusks (*Mollusca*) [106] One of the major groups of lophotrochozoans [24], mollusks have bodies composed of a foot, a mantle (which often secretes a hard, calcareous shell), and a visceral mass. Includes monoplacophorans, chitons, bivalves, gastropods, and cephalopods.

monilophytes (*Monilophyta*) A group of vascular plants [12], sister to the seed plants [13], characterized by overtopping and possession of megaphylls; includes the horsetails [72] and ferns [73].

monocots (*Monocotyledones*) [82] Angiosperms [15] characterized by possession of a single cotyledon, usually parallel leaf veins, a fibrous root system, pollen grains with a single opening, and floral organs usually in multiples of three.

monogeneans (*Monogenea*) A group of ectoparasitic flatworms [100].

monoplacophorans (*Monoplacophora*) Mollusks [106] with segmented body parts and a single, thin, flat, rounded, bilateral shell.

mosses (*Bryophyta*) [69] Nonvascular plants with true stomata and erect, “leafy” gametophytes; sporophytes elongate by apical cell division.

moss animals See bryozoans [99].

myriapods (*Myriapoda*) [115] Arthropods [26] characterized by an elongate, segmented trunk with many legs. Includes centipedes and millipedes.

– N –

nanoarchaeotes (*Nanoarchaeota*) A group of extremely small, thermophilic archaeans [3] with a much-reduced genome. The only described example can survive only when attached to a host organism.

nematodes (*Nematoda*) [111] A very large group of elongate, unsegmented ecdysozoans [25] with thick, multilayer cuticles. They are among the most abundant and diverse animals, although most species have not yet been described. Include free-living predators and scavengers, as well as parasites of most species of land plants [11] and animals [19].

neognaths (*Neognathae*) The main group of birds [132], including all living species except the ratites (ostrich, emu, rheas, kiwis, cassowaries) and tinamous. See palaeognaths.

– O –

oligochaetes (*Oligochaeta*) Annelid [105] group whose members lack parapodia, eyes, and anterior tentacles, and have few setae. Earthworms are the most familiar oligochaetes.

onychophorans (*Onychophora*) [113] Elongate, segmented ecdysozoans [25] with many pairs of soft, unjointed, claw-bearing legs. Also known as velvet worms.

oomycetes (*Oomycota*) [52] Water molds and relatives; absorptive heterotrophs with nutrient-absorbing, filamentous hyphae.

opisthokonts (*Opisthokonta*) [16] A group of eukaryotes [4] in which the flagellum on motile cells, if present, is posterior. The opisthokonts include the fungi [17], animals [19], and choanoflagellates [91].

ostracods (*Ostracoda*) Marine and freshwater crustaceans [116] that are laterally compressed and protected by two clamlike calcareous or chitinous shells.

– P –

palaeognaths (*Palaeognathae*) A group of secondarily flightless or weakly flying birds [132]. Includes the flightless ratites (ostrich, emu, rheas, kiwis, cassowaries) and the weakly flying tinamous.

parabasalids (*Parabasalia*) [59] A group of unicellular eukaryotes [4] that lack mitochondria; they possess flagella in clusters near the anterior of the cell.

phoronids (*Phoronida*) [104] A small group of sessile, wormlike marine lophotrochozoans [24] that secrete chitinous tubes and feed using a lophophore.

placoderms (*Placodermi*) An extinct group of jawed vertebrates [32] that lacked teeth. Placoderms were the dominant predators in Devonian oceans.

placozoans (*Placozoa*) [95] A poorly known group of structurally simple, asymmetrical, flattened, transparent animals found in coastal marine tropical and subtropical seas. Most evidence suggests that placozoans are the sister-group of eumetazoans [21].

Plantae [9] The most broadly defined plant group. In most parts of this book, we use the word “plant” as synonymous with “land plant” [11], a more restrictive definition.

plasmoidal slime molds (*Myxogastriada*) Amoebozoans [84] that in their feeding stage consist of a coenocyte called a plasmodium.

pogonophorans (*Pogonophora*) Deep-sea annelids [105] that lack a mouth or digestive tract; they feed by taking up dissolved organic matter, facilitated by endosymbiotic bacteria in a specialized organ (the trophosome).

polychaetes (*Polychaeta*) A group of mostly marine annelids [105] with one or more pairs of eyes and one or more pairs of feeding tentacles; parapodia and setae extend from most body segments. May be paraphyletic with respect to the clitellates.

priapulids (*Priapulida*) [107] A small group of cylindrical, unsegmented, wormlike marine ecdysozoans [25] that takes its name from its phallic appearance.

“prokaryotes” Not a monophyletic group; as commonly used, includes the bacteria [2] and archaeans [3]. A term of convenience encompassing all cellular organisms that are not eukaryotes.

proteobacteria (*Proteobacteria*) [44] A large and extremely diverse group of Gram-negative bacteria that includes many pathogens, nitrogen fixers, and photosynthesizers. Includes the alpha, beta, gamma, delta, and epsilon proteobacteria.

“protists” This term of convenience is used to encompass a large number of distinct and distantly related groups of eukaryotes, many but far from all of which are microbial and unicellular. Essentially a “catch-all” term for any eukaryote group not contained within the land plants [11], fungi [17], or animals [19].

protostomes (*Protostomia*) [23] One of the two major groups of bilaterians [22]. In protostomes, the mouth typically forms from the blastopore (if present) in early development (contrast with

deuterostomes). The major protostome groups are the lophotrochozoans [24] and ecdysozoans [25].

prototherians (*Prototheria*) A mostly extinct group of mammals [129], common during the Cretaceous and early Cenozoic. The five living species—four echidnas and the duck-billed platypus—are the only extant egg-laying mammals.

pterobranchs (*Pterobranchia*) A small group of sedentary marine hemichordates [119] that live in tubes secreted by the proboscis. They have one to nine pairs of arms, each bearing long tentacles that capture prey and function in gas exchange.

pycnogonids (*Pycnogonida*) Treated in this book as a group of chelicerates [114], but sometimes considered an independent group of arthropods [26]. Pycnogonids have reduced bodies and very long, slender legs. Also called sea spiders.

– R –

radiolarians (*Radiolaria*) [55] Amoebooid organisms with needlelike pseudopods supported by microtubules. Most have glassy internal skeletons.

ray-finned fishes (*Actinopterygii*) [125] A highly diverse group of freshwater and marine bony vertebrates [33]. They have reduced swim bladders that often function as hydrostatic organs and fins supported by soft rays (lepidotrichia). Includes most familiar fishes.

red algae (*Rhodophyta*) [64] Mostly multicellular, marine and freshwater algae characterized by the presence of phycoerythrin in their chloroplasts.

reptiles (*Reptilia*) [37] One of the two major groups of extant amniotes [36], supported on the basis of similar skull structure and gene sequences. The term “reptiles” traditionally excluded the birds [132], but the resulting group is then clearly paraphyletic. As used in this book, the reptiles include turtles [130], lepidosaurs [131], birds [132], and crocodylians [133].

rhizaria (*Rhizaria*) [7] Mostly amoeboid unicellular eukaryotes with pseudopods, many with external or internal shells. Includes the foraminiferans [57], cercozoans [56], and radiolarians [55].

rhyniophytes (*Rhyniophyta*) A group of early vascular plants [12] that appeared in the Silurian and became extinct in the Devonian. Possessed dichotomously branching stems with terminal sporangia but no true leaves or roots.

ribbon worms (*Nemertea*) [102] A group of unsegmented lophotrochozoans [24] with an eversible proboscis used to capture prey. Mostly marine, but some species live in fresh water or on land.

rotifers (*Rotifera*) [101] Tiny (<0.5 mm) lophotrochozoans [24] with a pseudocoelomic body cavity that functions as a hydrostatic organ and a ciliated feeding organ called the corona that surrounds the head. They live in freshwater and wet terrestrial habitats.

roundworms (*Nematoda*) [111] See nematodes.

- S -

sac fungi (*Ascomycota*) [89] Fungi that bear the products of meiosis within sacs (asci) if the organism is multicellular. Some are unicellular.

salamanders (*Caudata*) A group of amphibians [128] with distinct tails in both larvae and adults and limbs set at right angles to the body.

salps See thaliaceans.

sarcopterygians (*Sarcopterygii*) [34] One of the two major groups of bony vertebrates [33], characterized by jointed appendages (paired fins or limbs).

scyphozoans (*Scyphozoa*) Marine cnidarians [97] in which the medusa stage dominates the life cycle. Commonly known as jellyfish.

sea cucumbers (*Holothuroidea*) Echinoderms [118] with an elongate, cucumber-shaped body and leathery skin. They are scavengers on the ocean floor.

sea spiders See pycnogonids.

sea squirts See ascidians.

sea stars (*Asteroidea*) Echinoderms [118] with five (or more) fleshy “arms” radiating from an indistinct central disk. Also called starfishes.

sea urchins (*Echinoidea*) Echinoderms [118] with a test (shell) that is covered in spines. Most are globular in shape, although some groups (such as the sand dollars) are flattened.

“seed ferns” A paraphyletic group of loosely related, extinct seed plants that flourished in the Devonian and Carboniferous. Characterized by large, frondlike leaves that bore seeds.

seed plants (*Spermatophyta*) [13] Heterosporous vascular plants [12] that produce seeds; most produce wood; branching is axillary (not dichotomous). The major seed plant groups are gymnosperms [14] and angiosperms [15].

sow bugs See isopods.

spirochetes (*Spirochaetes*) [45] Motile, Gram-negative bacteria with a helically coiled structure and characterized by axial filaments.

sponges (*Porifera*) [20] A group of relatively asymmetric, filter-feeding animals that lack a gut or nervous system and generally lack differentiated tissues. Includes glass sponges [92], demosponges [93], and calcareous sponges [94].

springtails (*Collembola*) Wingless hexapods [117] with springing structures on the third and fourth segments of their bodies. Springtails are extremely abundant in some environments (especially in soil, leaf litter, and vegetation).

squamates (*Squamata*) The major group of lepidosaurs [131], characterized by the possession of movable quadrate bones (which allow

the upper jaw to move independently of the rest of the skull) and hemipenes (a paired set of eversible penises, or penes) in males. Includes the lizards (a paraphyletic group), snakes, and amphisbaenians.

star anise (*Austrobaileyales*) [80] A group of woody angiosperms [15] thought to be the sister-group of the clade of flowering plants that includes eudicots [83], monocots [82], and magnoliids [81].

starfish (*Asteroidea*) See sea stars.

stramenopiles (*Heterokonta* or *Stramenopila*) [6] Organisms having, at some stage in their life cycle, two unequal flagella, the longer possessing rows of tubular hairs. Chloroplasts, when present, surrounded by four membranes. Major stramenopile groups include the brown algae [54], diatoms [53], and oomycetes [52].

- T -

tapeworms (*Cestoda*) Parasitic flatworms [100] that live in the digestive tracts of vertebrates as adults, and usually in various other species of animals as juveniles.

tardigrades (*Tardigrada*) [112] Small (< 0.5 mm) ecdysozoans [25] with fleshy, unjointed legs and no circulatory or gas exchange organs. They live in marine sands, in temporary freshwater pools, and on the water films of plants. Also called water bears.

tetrapods (*Tetrapoda*) [35] The major group of sarcopterygians [34]; includes the amphibians [128] and the amniotes [36]. Named for the presence of four jointed limbs (although limbs have been secondarily reduced or lost completely in several tetrapod groups).

thaliaceans (*Thaliacea*) A group of solitary or colonial planktonic marine urochordates [121]. Also called salps.

therians (*Theria*) Mammals [129] characterized by viviparity (live birth). Includes eutherians and marsupials.

theropods (*Theropoda*) Archosaurs [38] with bipedal stance, hollow bones, a furcula (“wish-bone”), elongated metatarsals with three-fingered feet, and a pelvis that points backwards. Includes many well-known extinct dinosaurs (such as *Tyrannosaurus rex*), as well as the living birds [132].

tracheophytes See vascular plants [12].

trilobites (*Trilobita*) An extinct group of arthropods [26] related to the chelicerates [114]. Trilobites flourished from the Cambrian through the Permian.

tuataras (*Rhynchocephalia*) A group of lepidosaurs [131] known mostly from fossils; there are just two living tuatara species. The quadrate bone of the upper jaw is fixed firmly to the skull. Sister group of the squamates.

tunicates See ascidians.

turbellarians (*Turbellaria*) A group of free-living, generally carnivorous flatworms [100]. Their monophyly is questionable.

turtles (*Testudines*) [130] A group of reptiles [37] with a bony carapace (upper shell) and plastron (lower shell) that encase the body in a fashion unique among the vertebrates.

- U -

urochordates (*Urochordata*) [121] A group of chordates [30] that are mostly saclike filter feeders as adults, with motile larval stages that resemble tadpoles.

- V -

vascular plants (*Tracheophyta*) [12] Plants with xylem and phloem. Major groups include the lycophytes [71] and euphyllophytes.

vertebrates (*Vertebrata*) [31] The largest group of chordates [30], characterized by a rigid endoskeleton supported by the vertebral column and an anterior skull encasing a brain. Includes hagfishes [122], lampreys [123], and the jawed vertebrates [32], although some biologists exclude the hagfishes from this group. See also craniates.

- W -

water bears See tardigrades.

water lilies (*Nymphaeaceae*) [79] A group of aquatic, freshwater angiosperms [15] that are rooted in soil in shallow water, with round floating leaves and flowers that extend above the water’s surface. They are the sister-group to most of the remaining flowering plants, with the exception of the genus *Amborella* [78].

- Y -

“yeasts” Convenience term for several distantly related groups of unicellular fungi [17].

- Z -

“zygospore fungi” (*Zygomycota*, if monophyletic) [87] A convenience term for a probably paraphyletic group of fungi [17] in which hyphae of differing mating types conjugate to form a zygosporangium.

Appendix B: Statistics Primer

This appendix is designed to help you conduct simple statistical analyses and understand their application and importance. This introduction will help you complete the Apply the Concept and Analyze the Data problems throughout this book. The formulas for a number of statistical tests are presented here, but the presentation is designed primarily to help you understand the purpose and reasoning of the various tests. Once you understand the basis of the analysis, you may wish to use one of many free, online web sites for conducting the tests and calculating relevant test statistics (such as <http://faculty.vassar.edu/lowry/VassarStats.html>).

Why Do We Do Statistics?

ALMOST EVERYTHING VARIES We live in a variable world, but within the variation we see among biological organisms there are predictable patterns. We use statistics to find and analyze these patterns. Consider any group of common things in nature—all women aged 22, all the cells in your liver, or all the blades of grass in your yard. Although they will have many similar characteristics, they will also have important differences. Men aged 22 tend to be taller than women aged 22, but, of course, not every man will be taller than every woman in this age group.

Natural variation can make it difficult to find general patterns. For example, scientists have determined that smoking increases the risk of getting lung cancer. But we know that not all smokers will develop lung cancer and not all nonsmokers will remain cancer-free. If we compare just one smoker to just one nonsmoker, we may end up drawing the wrong conclusion. So how did scientists discover this general pattern? How many smokers and nonsmokers did they examine before they felt confident about the risk of smoking?

Statistics helps us to find general patterns, even when nature does not always follow those patterns.

AVOIDING FALSE POSITIVES AND FALSE NEGATIVES When a woman takes a pregnancy test, there is some chance that it will be positive even if she is not pregnant, and there is some chance that it will be negative even if she is pregnant. We call these kinds of mistakes *false positives* and *false negatives*.

Doing science is a bit like taking a medical test. We observe patterns in the world, and we try to draw conclusions about how the world works from those observations. Sometimes our observations lead us to draw the wrong conclusions. We might conclude that a phenomenon occurs, when it actually

does not; or we might conclude that a phenomenon does not occur, when it actually does.

For example, the planet Earth has been warming over the past century (see Concept 46.4). Ecologists are interested in whether plant and animal populations have been affected by global warming. If we have long-term information about the locations of species and temperatures in certain areas, we can determine whether species movements coincide with temperature changes. Such information can, however, be very complicated. Without proper statistical methods, one may not be able to detect the true impact of temperature or, instead, may think a pattern exists when it does not.

Statistics helps us to avoid drawing the wrong conclusions.

How Does Statistics Help Us Understand the Natural World?

Statistics is essential to scientific discovery. Most biological studies involve five basic steps, each of which requires statistics:

- **Step 1: Experimental Design**
Clearly define the scientific question and the methods necessary to tackle the question.
- **Step 2: Data Collection**
Gather information about the natural world through experiments and field studies.
- **Step 3: Organize and Visualize the Data**
Use tables, graphs, and other useful representations to gain intuition about the data.
- **Step 4: Summarize the Data**
Summarize the data with a few key statistical calculations.
- **Step 5: Inferential Statistics**
Use statistical methods to draw general conclusions from the data about the way the world works.

Step 1: Experimental Design

We conduct experiments to gain knowledge about the world. Scientists come up with scientific ideas based on prior research and their own observations. These ideas may take the form of a question like “Does smoking cause cancer?,” a hypothesis like “Smoking increases the risk of cancer,” or a prediction like “If a person smokes, he/she will increase his/her chances of developing cancer.” Experiments allow us to test such scientific ideas, but designing a good experiment can be quite challenging.

We use statistics to guide us in designing experiments so that we end up with the right kinds of data. Before embarking on an experiment, we use statistics to determine how much data will be required to test our idea, and to prevent extraneous factors from misleading us. For example, suppose we want to conduct an experiment on fertilizers to test the hypothesis that nitrogen increases plant growth. If we include too few plants, we will not be able to determine whether or not nitrogen has an effect on growth, and the experiment will be for naught. If we include too many plants, we will waste valuable time and resources. Furthermore, we should design the experiment so that we can detect differences that are actually caused by nitrogen fertilization rather than by variation, for example, in sunlight or precipitation experienced by the plants.

Step 2: Data Collection

TAKING SAMPLES When biologists gather information about the natural world, they typically collect a few representative pieces of information. For example, when evaluating the efficacy of a candidate drug for medulloblastoma brain cancer, scientists may test the drug on tens or hundreds of patients, and then draw conclusions about its efficacy for all patients with these tumors. Similarly, scientists studying the relationship between body weight and clutch size (number of eggs) for female spiders of a particular species may examine tens to hundreds of spiders to make their conclusions.

We use the expression “sampling from a population” to describe this general method of taking representative pieces of information from the system under investigation (**FIGURE B1**). The pieces of information in a **sample** are called **observations**. In the cancer therapy example, each observation was the change in a patient’s tumor size six months after initiating treatment, and the population of interest was all individuals with medulloblastoma tumors. In the spider example, each observation was a pair of measurements—body size and clutch size—for a single female spider, and the population of interest was all female spiders of this species.

Sampling is a matter of necessity, not laziness. We cannot hope (and would not want) to collect *all* of the female spiders of the species of interest on Earth! Instead, we use statistics to determine how many spiders we must collect in order to

FIGURE B1 Sampling From a Population Biologists take representative samples from a population, use descriptive statistics to characterize their samples, and then use inferential statistics to draw conclusions about the original population.

TABLE B1 Poinsettia Colors

COLOR	FREQUENCY	PROPORTION
Red	108	0.59
Pink	34	0.19
White	40	0.22
Total	182	1.0

confidently infer something about the general population and then use statistics again to make such inferences.

DATA COME IN ALL SHAPES AND SIZES In statistics, we use the word *variable* to mean a measurable characteristic of an individual or a system. Some variables are on a numerical scale, like the daily high temperature (a numerical value constrained by the precision of our thermometer), or the clutch size of a spider (a whole number: 0, 1, 2, 3, ...). We call these **quantitative variables**. Quantitative variables that only take on whole number values are called **discrete variables**, whereas variables that can also take on any fractional value are called **continuous variables**.

Other variables take categories as values, like a human blood type (A, B, AB, or O) or an ant caste (queen, worker, or male). We call these **categorical variables**. Categorical variables with a natural ordering, like a final grade in Introductory Biology (A, B, C, D, or F), are called **ordinal variables**.

Each class of variables comes with its own set of statistical methods. We will introduce a few common methods in this Appendix that will help you work on the problems presented in this book, but you should consult a biostatistics textbook for more advanced tests and analyses for other data sets and problems.

Step 3: Organize and Visualize the Data

Tables and graphs can help you gain intuition about your data, design appropriate statistical tests, and anticipate the outcome of your analysis. A **frequency distribution** lists all possible

TABLE B2 Fish Weights of *Abramis brama* from Lake Laengelmavesi

WEIGHT (GRAMS)	FREQUENCY	RELATIVE FREQUENCY
201–300	2	0.06
301–400	3	0.09
401–500	8	0.24
501–600	3	0.09
601–700	8	0.24
701–800	3	0.09
801–900	1	0.03
901–1000	6	0.18
Total	34	1.0

FIGURE B2 Bar Charts Compare Categorical Data This bar chart shows the frequency of three poinsettia colors that result from an experimental cross.

values and the number of occurrences of each value in the sample.

TABLE B1 shows a frequency distribution of the colors of 182 poinsettia plants (red, pink, or white) resulting from an experimental cross between two parent plants. For categorical data like this, we can visualize the frequency distribution by constructing a **bar chart**. The heights of the bars indicate the number of observations in each category (**FIGURE B2**). Another way to display the same data is in a **pie chart**, which shows the proportion of each category represented like pieces of a pie (**FIGURE B3**).

For quantitative data, it is often useful to condense your data by grouping (or binning) it into **classes**. In **TABLE B2**, we see a grouped frequency distribution of fish weights for a sample of 34 fish (*Abramis brama*) caught in Lake Laengelmavesi in Finland. The second column (*Frequency*) gives the number of observations in each class and the third column (*Relative Frequency*) gives the overall proportion of observations falling into each class.

Histograms depict frequency distributions for quantitative data. The histogram in **FIGURE B4** shows the relative frequencies of each weight class in this study. When grouping quantitative data, it is necessary to decide how many classes to include.

FIGURE B3 Pie Charts Show Proportions of Categories This pie chart shows the proportions of the three poinsettia colors presented in Table B1.

FIGURE B4 Histograms Depict Frequency Distributions of Quantitative Data This histogram shows the relative frequency of different weight-classes of fish (*Abramis brama*).

It is often useful to look at multiple histograms before deciding which grouping offers the best representation of the data.

Sometimes we wish to compare two quantitative variables. For example, the researchers at Lake Laengelmavesi investigated the relationship between fish weight and length and thus also measured the length of each fish. We can visualize this relationship using a **scatter plot** in which the weight and length of each fish is represented as a single point (**FIGURE B5**). We say that these two variables have a **linear relationship** since the points in their scatter plot fall roughly on a straight line.

Tables and graphs are critical to interpreting and communicating data, and thus should be as self-contained and comprehensible as possible. Their content should be easily understood simply by looking at them. Axes, captions, and units should be clearly labeled, statistical terms should be defined, and appropriate groupings should be used when tabulating or graphing quantitative data.

FIGURE B5 Scatter Plots Contrast Two Variables Scatter plot of *Abramis brama* weights and lengths (measured from nose to end of tail). These two variables have a linear relationship since the data points lie close to a straight line.

Step 4: Summarize the Data

A **statistic** is a numerical quantity calculated from data, while **descriptive statistics** are quantities that describe general patterns in data. Descriptive statistics allow us to make straightforward comparisons between different data sets and concisely communicate basic features of our data.

DESCRIBING CATEGORICAL DATA For categorical variables, we typically use proportions to describe our data. That is, we construct tables containing the proportions of observations in each category. For example, the third column in Table B1 provides the proportions of poinsettia plants in each color category, and the pie chart in Figure B3 provides a visual representation of those proportions.

DESCRIBING QUANTITATIVE DATA For quantitative data, we often start by calculating the average value or **mean** of our sample. This familiar quantity is simply the sum of all the values in the sample divided by the number of observations in our sample (**FIGURE B6**). The mean is only one of several quantities that roughly tell us where the *center* of our data lies. We call these quantities **measures of center**. Other commonly used

FIGURE B7 Measures of Dispersion Two samples with the same mean (black horizontal lines) and range (blue vertical line). Red lines show the deviations of each observation from the mean. Samples with large deviations have large standard deviations. The left sample has a smaller standard deviation than the right sample.

measures of center are the **median**—the value that literally lies in the middle of the sample—and the **mode**—the most frequent value in the sample.

It is often just as important to quantify the variation in the data as it is to calculate its center. There are several statistics that tell us how much the values differ from one another. We call these **measures of dispersion**. The easiest to one understand and calculate is the **range**, which is simply the largest value in the sample minus the smallest value. The most commonly used measure of dispersion is the **standard deviation**, which calculates the extent to which the data are spread out from the mean. A deviation is the difference between an observation and the mean of the sample, and the standard deviation is a number that summarizes all of the deviations. Two samples can have the same range, but very different standard deviations if one is clustered closer to the mean than the other. In **FIGURE B7**, for example, the left sample has a lower standard deviation ($s = 2.6$) than the right sample ($s = 3.6$), even though the two samples have the same means and ranges.

To demonstrate these descriptive statistics, we return to the Lake Laengelmavesi study. The researchers also caught and recorded the weights of six fish in the species *Leusiscus idus*: 270, 270, 306, 540, 800, and 1,000 grams. The mean weight in this sample (equation 1 in Figure B6) is:

$$\bar{x} \frac{\Delta N}{\Delta T} = \frac{(270 + 270 + 306 + 540 + 800 + 1000)}{6} = 531$$

Since there is an even number of observations in the sample, then the median weight is the value halfway between the two middle values:

$$\frac{306 + 540}{2} = 423$$

The mode of the sample is 270, the only value that appears more than once. The standard deviation (equation 2 in Figure B6) is:

RESEARCH TOOLS

FIGURE B6 Descriptive Statistics for Quantitative Data

Below are the equations used to calculate the descriptive statistics we discuss in this appendix. You can calculate these statistics yourself, or use free internet resources to help you make your calculations.

Notation:

$x_1, x_2, x_3, \dots, x_n$ are the n observations of variable X in the sample.

$\sum_{i=1}^n x_i = x_1 + x_2 + x_3 + \dots + x_n$ is the sum of all of the observations. (The Greek letter sigma, Σ , is used to denote "sum of.")

In regression, the independent variable is X , and the dependent variable is Y . b_0 is the vertical intercept of a regression line. b_1 is the slope of a regression line.

Equations

1. Mean:
$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$$

2. Standard deviation:
$$s = \sqrt{\frac{\sum (x_i - \bar{x})^2}{n - 1}}$$

3. Correlation coefficient:
$$r = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 (y_i - \bar{y})^2}}$$

4. Least-squares regression line: $Y = b_0 + b_1 X$
 where $b_1 = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sum (x_i - \bar{x})^2}$ and $b_0 = \bar{y} - b_1 \bar{x}$

FIGURE B8 Correlation coefficients The correlation coefficient (r) indicates both the strength and the direction of the relationship.

$$s = \sqrt{\frac{(270-531)^2 + (270-531)^2 + (306-531)^2 + (540-531)^2 + (800-531)^2 + (1000-531)^2}{5}} = 309.6$$

and the range is $1000 - 270 = 730$.

DESCRIBING THE RELATIONSHIP BETWEEN TWO QUANTITATIVE VARIABLES Biologists are often interested in understanding the relationship between two different quantitative variables: How does the height of an organism relate to its weight? How does air pollution relate to the prevalence of asthma? How does lichen abundance relate to levels of air pollution? Recall that scatter plots visually represent such relationships.

We can quantify the strength of the relationship between two quantitative variables using a single value called the Pearson product-moment **correlation coefficient** (equation 3 in Figure B6). This statistic ranges between -1 and 1 , and tells us how closely the points in a scatter plot conform to a straight line. A negative correlation coefficient indicates that one variable decreases as the other increases; a positive correlation coefficient indicates that the two variables increase together, and a correlation coefficient of zero indicates that there is no linear relationship between the two variables (**FIGURE B8**).

One must always keep in mind that *correlation does not mean causation*. Two variables can be closely related without one causing the other. For example, the number of cavities in a child's mouth correlates positively with the size of their feet. Clearly cavities do not enhance foot growth; nor does foot growth cause tooth decay. Instead the correlation exists because both quantities tend to increase with age.

Intuitively, the straight line that tracks the cluster of points on a scatter plot tells us something about the *typical* relationship between the two variables. Statisticians do not, however, simply eyeball the data and draw a line by hand. They often use a method called least-squares **linear regression** to fit a straight line to the data (equation 4 in Figure B6). This method calculates the line that minimizes the overall vertical distances between the points in the scatter plot and the line itself. These distances are called **residuals** (**FIGURE B9**). Two parameters describe the regression line: b_0 (the vertical intercept of the line,

FIGURE B9 Linear Regression Estimates the Typical Relationship Between Linear-least squares regression line for *Abramis brama* weights and lengths (measured from nose to end of tail). The regression line (blue line) is given by the equation $Y = 26.1 + 0.02X$. It is the line that minimizes the sum of the squares of the residuals (red lines).

or the expected value of variable Y when $X = 0$), and b_1 (the slope of the line, or how much values of Y are expected to change with changes in values of X).

Step 5: Inferential Statistics

Data analysis often culminates with statistical inference—an attempt to draw general conclusions about the system under investigation. As depicted in Figure B1, the primary reason we collect data is to gain insight into the larger system from which the data are collected. When we test a new medulloblastoma brain cancer drug on ten patients, we do not simply want to know the fate of those ten individuals; rather, we hope to predict its efficacy on the much larger group of all medulloblastoma patients.

STATISTICAL HYPOTHESES When it comes to inferring something about the real world from our data, we often have a “*Whether or not*” question in mind. For example, we would like to know whether or not global warming impacts biodiversity; whether or not the clutch size of a spider increases with body size; or whether or not soil nitrogen increases the growth of a particular plant species.

Before making statistical inferences from data, we must formalize our “*Whether or not*” question into a pair of opposing hypotheses—a **null hypothesis** (denoted H_0) and an **alternative hypothesis** (denoted H_A). The alternative hypothesis is the “*Whether*”—it is formulated to describe the effect that we expect our data to support; the null hypothesis is the “*or not*”—it is formulated to represent the absence of the effect. In other words, we typically conduct our experiment seeking to demonstrate something new (the alternative hypothesis) and thereby reject the idea that it does not occur (the null hypothesis).

Suppose, for example, we would like to know *whether or not* a new vaccine is more effective than an existing vaccine at

immunizing children against influenza. Our hypotheses would be as follows:

H_0 : The new vaccine is not more effective than the old vaccine.

H_A : The new vaccine is more effective than the old vaccine.

If we would like to know whether radiation increases the mutation rate in the bacteria *Escherichia coli*, we would set up the following hypotheses:

H_0 : Radiation does not increase the mutation rate of *E. coli*.

H_A : Radiation does increase the mutation rate of *E. coli*.

STATISTICAL BURDEN OF PROOF In the U.S. justice system, people are innocent until proven guilty. In statistics, the world is *null until proven alternative*. Statistics requires overwhelming proof in favor of the alternative hypothesis before rejecting the null hypothesis. In other words, scientists favor existing ideas and resist adopting new ideas until compelling evidence suggests otherwise. This is based on a philosophy that it is worse to accept new claims when they are false than to miss out on discovering some true facts about world.

When testing a new influenza vaccine, the burden of proof is on the new vaccine. Suppose we were to vaccinate three children with the new vaccine (Group A), three with the old vaccine (Group B) and leave three children unvaccinated (Group C). If no children from Group A, one child from Group B, and one child from Group C became infected, would we have enough evidence to conclude that the new vaccine is superior to the old vaccine? No, we would not. If the study were enlarged, and two out of 100 children in group A, seven out of 100 children in group B, and 22 out of 100 children in group C become infected, would we then have sufficient evidence to choose the new vaccine? Perhaps, but we need to use statistics to be sure.

This is the traditional burden of proof in biology and science in general. As a consequence, scientists are more likely to miss out on discovering something new (and true) about the world than they are to make a false discovery. In recent years, scientists have begun to question this approach and develop an alternative statistical approach, called **Bayesian inference**, which makes it easier to favor new hypotheses. In this primer, we discuss only traditional statistical methods, often called **frequentist statistics**.

JUMPING TO THE WRONG CONCLUSIONS There are two ways that a statistical test can go wrong (FIGURE B10). We can reject the null hypothesis when it is actually true (**Type I error**) or we can accept the null hypothesis when it is actually false (**Type II error**). These kinds of errors are analogous to false positives and false negatives in medical testing, respectively. If we mistakenly reject the null hypothesis when it is actually true, then we falsely endorse the incorrect hypothesis. If we are unable to reject the null hypothesis when it is actually false, then we fail to realize a yet undiscovered truth.

Suppose we would like to know whether there are more females than males in a population of 10,000 individuals. To determine the makeup of the population, we choose 20 individuals randomly and record their sex. Our null hypothesis is that there are *not* more females than males; and our alternative hypothesis is that there are. The following scenarios illustrate the possible mistakes we might make:

- *Scenario 1:* The population actually has 40% females and 60% males. Although our random sample of 20 people is likely to be dominated by males, it is certainly possible that, by chance, we will end up choosing more females than males. If this occurs, and we mistakenly reject the null hypothesis (that there are *not* more females than males), then we make a Type I error.
- *Scenario 2:* The population actually has 60% females and 40% males. If, by chance, we end up with a majority of males in our sample and thus fail reject the null hypothesis, then we make a Type II error.

Fortunately, statistics has been developed precisely to avoid these kinds of errors and inform us about the reliability of our conclusions. The methods are based on calculating the **probabilities** of different possible outcomes. Although you may have heard or even used the word “probability” on multiple occasions, it is important that you understand its mathematical meaning. A probability is a numerical quantity that expresses the likelihood of some event. It ranges between zero and one; zero means that there is no chance the event will occur and one means that the event is guaranteed to occur. This only makes sense if there is an element of chance, that is, if it is possible the event will occur and possible that it will not occur. For example, when we flip a fair coin, it will land on heads with probability 0.5 and land on tails with probability 0.5. When we select individuals randomly from a population with 60% females and 40% males, we will encounter a female with probability 0.6 and a male with probability 0.4.

Probability plays a very important role in statistics. To draw conclusions about the real world (the population) from our sample, we first calculate the probability of obtaining our sample if the null hypothesis is true. Specifically, statistical inference is based on answering the following question:

Suppose the null hypothesis is true. What is the probability that a random sample would, by chance, differ from the null hypothesis as much as our sample differs from the null hypothesis?

If our sample is highly improbable under the null hypothesis, then we rule it out in favor of our alternative hypothesis. If,

		The real world	
		Null hypothesis true (not more females)	Null hypothesis false (more females)
Our conclusion	Null hypothesis true (not more females)	✓	Type 2 error (false negative)
	Null hypothesis false (more females)	Type 1 error (false positive)	✓

FIGURE B10 Two Types of Error Possible outcomes of a statistical test. Statistical inference can result in correct and incorrect conclusions about the population of interest.

instead, our sample has a reasonable probability of occurring under the null hypothesis, then we conclude that our data are consistent with the null hypothesis and we do not reject it.

Returning to the sex ratio example, we consider two new scenarios:

- *Scenario 3:* Suppose we want to infer whether or not females constitute the majority of the population (our alternative hypothesis) based on a random sample containing 12 females and eight males. We would calculate the probability that a random sample of 20 people includes at least 12 females assuming that the population, in fact, has a 50:50 sex ratio (our null hypothesis). This probability is 0.13, which is too high to rule out the null hypothesis.
- *Scenario 4:* Suppose now that our sample contains 17 females and three males. If our population is truly evenly divided, then this sample is much less likely than the sample in scenario 3. The probability of such an extreme sample is 0.0002, and would lead us to rule out the null hypothesis and conclude that there are more females than males.

This agrees with our intuition. When choosing 20 people randomly from an evenly divided population, we would be surprised if almost all of them were female, but would not be surprised at all if we ended up with a few more females than males (or a few more males than females). Exactly how many females do we need in our sample before we can confidently infer that they make up the majority of the population? And how confident are we when we reach that conclusion? Statistics allows us to answer these questions precisely.

STATISTICAL SIGNIFICANCE: AVOIDING FALSE POSITIVES Whenever we test hypotheses, we calculate the probability just discussed, and refer to this value as the **P-value** of our test. Specifically, the *P*-value is the probability of getting data as extreme as our data (just by chance) if the null hypothesis is, in fact, true. In other words, it is the likelihood that chance alone would produce data that differ from the null hypothesis as much as our data differ from the null hypothesis. How we measure the difference between our data and the null hypothesis depends on the kind of data in our sample (categorical or quantitative) and the nature of the null hypothesis (assertions about proportions, single variables, multiple variables, differences between variables, correlations between variables, etc.).

For many statistical tests, *P*-values can be calculated mathematically. One option is to quantify the extent to which the data depart from the null hypothesis and then use look-up tables (available in most statistics textbooks, or on the internet) to find the probability that chance alone would produce a difference of that magnitude. Most scientists, however, find *P*-values primarily by using statistical software rather than hand calculations combined with look-up tables. Regardless of the technology, the most important steps of the statistical analysis are still left to the researcher: constructing appropriate null and alternative hypotheses, choosing the correct statistical test, and drawing correct conclusions.

After we calculate a *P*-value from our data, we have to decide whether it is small enough to conclude that our data are inconsistent with the null hypothesis. This is decided by comparing

the *P*-value to a threshold called the **significance level**, which is often chosen even before making any calculations. We reject the null hypothesis only when the *P*-value is less than or equal to the significance level, denoted α . This ensures that, if the null hypothesis is true, we have at most a probability α of accidentally rejecting it. Therefore, the lower the value of α , the less likely you are to make a Type I error (lower left cell of Figure B10). The most commonly used significance level is $\alpha = 0.05$, which limits the probability of a Type I error to 5%.

If our statistical test yields a *P*-value that is less than our significance level α , then we conclude that the effect described by our alternative hypothesis is statistically significant at the level α and we reject the null hypothesis. If our *P*-value is greater than α , then we conclude that we are unable to reject the null hypothesis. In this case, we do not actually reject the alternative hypothesis, rather we conclude that we do not yet have enough evidence to support it.

POWER: AVOIDING FALSE NEGATIVES The **power** of a statistical test is the probability that we will correctly reject the null hypothesis when it is false (lower right cell of Figure B10). Therefore, the higher the power of the test, the less likely we are to make a Type II error (upper right cell of Figure B10). The power of a test can be calculated, and such calculations can be used to improve your methodology. Generally, there are several steps that can be taken to increase power and thereby avoid false negatives:

- **Decrease the significance level, α .** The higher the value of α , the harder it is to reject the null hypothesis, even if it is actually false.
- **Increase the sample size.** The more data one has, the more likely one is to find evidence against the null hypothesis, if it is actually false.
- **Decrease variability in the sample.** The more variation there is in the sample, the harder it is to discern a clear effect (the alternative hypothesis) when it actually exists.

It is always a good idea to design your experiment to reduce any variability that may obscure the pattern you seek to detect. For example, it is possible that the chance of a child contracting influenza varies depending on whether he or she lives in a crowded (e.g., urban) environment or one that is less so (e.g., rural). To reduce variability, a scientist might choose to test a new influenza vaccine only on children from one environment or the other. After you have minimized such extraneous variation, you can use power calculations to choose the right combination of α and sample size to reduce the risks of Type I and Type II errors to desirable levels.

There is a trade-off between Type I and Type II errors: As α increases, the risk of a Type I decreases but the risk of a Type II error increases. As discussed above, scientists tend to be more concerned about Type I errors than Type II errors. That is, they believe that it is worse to mistakenly believe a false hypothesis than it is to fail to make a new discovery. Thus, they prefer to use low values of α . However, there are many real-world scenarios in which it would be worse to make a Type II error than a Type I error. For example, suppose a new cold medication is

being tested for dangerous (life-threatening) side effects. The null hypothesis is that there are no such side effects. A Type II error might lead regulatory agencies to approve a harmful medication that could cost human lives. In contrast, a Type I error would simply mean one less cold medication among the many that already line pharmacy shelves. In such cases, policymakers take steps to avoid a Type II error, even if, in doing so, they increase the risk of a Type I error.

STATISTICAL INFERENCE WITH QUANTITATIVE DATA There are many forms of statistical inference for quantitative data. When measuring a single quantitative variable, like birth weight in lambs, calcium concentration in the blood of pregnant women, or migration rate of birds, we often wish to infer the mean value of the population from which we drew the sample. However, the mean of a randomly chosen sample will not necessarily be the same or even close to the population mean. Suppose we wanted to know the average weight of newborn lambs on a particular farm. By chance, we may end up with a random sample that includes an excess of lightweight lambs and therefore a sample mean that is less than the overall mean in the population.

To infer the population mean from the sample data, we can calculate a **confidence interval for the mean**. This is a statistically derived range of values that is centered on the sample mean and is likely to include the population mean. For example, based on the sample of 34 *Abramis brama* weights from Lake Laengelmavesi (see Table B2; Figure B4), the 95% confidence interval for the mean weight ranges from 554 grams to 698 grams. The true average weight for this species of fish is likely, but not guaranteed, to fall within this range.

RESEARCH TOOLS

FIGURE B11 The *t*-test

What is the *t*-test? It is a standard method for assessing whether the means of two groups are statistically different from each another.

Step 1: State the null and alternative *hypotheses*:

H_0 : The two populations have the same mean.

H_A : The two populations have different means.

Step 2: Choose a significance level, α , to limit the risk of a Type 1 error.

Step 3: Calculate the test statistic: $t_s = \frac{\bar{y}_1 - \bar{y}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}$

Notation: \bar{y}_1 and \bar{y}_2 are the sample means; s_1 and s_2 are the sample standard deviations; and n_1 and n_2 are the sample sizes.

Step 4: Use the test statistic to assess whether the data are consistent with the null hypothesis:

Calculate the *P-value* (P) using statistical software or by hand using statistical tables.

Step 5: Draw conclusions from the test:

If $P \leq \alpha$, then reject H_0 , and conclude that the population distribution is significantly different.

If $P > \alpha$, then we do not have sufficient evidence to conclude that the means differ.

Biologists frequently wish to compare the mean values in two or more groups; for example, newborn lamb weights on several different farms, calcium concentration in women in early and late stages of pregnancy, or migration rates in birds of different species. Based on the means and standard deviations calculated for each of the samples, they infer whether or not the means in the different populations are statistically different from one another. There are several statistical methods for this, and the correct method depends on the number of groups, the experimental design, and the nature of the data.

FIGURE B11 describes the steps of a *t*-test, a simple method for comparing the means in two different groups. To illustrate, we can apply a *t*-test to the Lake Laengelmavesi data to assess whether the two fish species *Abramis brama* and *Leusiscus idus* have significantly different mean weights. We begin by stating our hypotheses and choosing a significance level:

H_0 : *Abramis brama* and *Leusiscus idus* have the same mean weight.

H_A : *Abramis brama* and *Leusiscus idus* have different mean weights.

$\alpha = 0.05$

The test statistic is calculated using the means, standard deviations, and sizes of the two samples:

$$t_s = \frac{626 - 531}{\sqrt{\frac{207^2}{34} + \frac{310^2}{6}}} = 0.724$$

We can use statistical software or one of the free statistical sites on the internet to find the *P*-value for this result to be $P = 0.497$. Since P is considerably greater than α , we fail to reject the null hypothesis and conclude that our study does not provide evidence that the two species have different mean weights.

You may want to consult an introductory statistics textbook to learn more about confidence intervals, *t*-tests, and other basic statistical tests.

STATISTICAL INFERENCE WITH CATEGORICAL DATA With categorical data, we often wish to infer the distribution of the different categories within the populations from which our samples are drawn. In the simplest case, we have a single categorical variable with two or more categories. If there are just two categories, we can construct a **confidence interval for the proportion** of the population that belongs to one of the two categories. This is a statistically derived range of values that is centered on the sample proportion and is likely to include the population proportion. If there are three or more categories, we can use a **chi-square goodness-of-fit** test to determine whether the distribution of the different categories in the population is consistent with a specific distribution.

FIGURE B12 outlines the steps of a chi-square goodness-of-fit-test. As an example, consider the data described in Table B1. Many plant species have simple Mendelian genetic systems in which parent plants produce progeny with three different colors of flowers in a ratio of 2:1:1. However, a botanist believes that these particular poinsettia plants have a different genetic system that does not produce a 2:1:1 ratio of red, pink, and

RESEARCH TOOLS

FIGURE B12 The Chi-Square Goodness-of-Fit Test

What is the chi-square goodness-of-fit test? It is a standard method for assessing whether a sample came from a population with a specific distribution.

Step 1: State the null and alternative *hypotheses*:

H_0 : The population has the specified distribution.

H_A : The population does not have the specified distribution.

Step 2: Choose a significance level, α , to limit the risk of a Type 1 error.

Step 3: Determine the *observed frequency* and *expected frequency* for each category:

The observed frequency of a category is simply the number of observations in the sample of that type.

The expected frequency of a category is the probability of the category specified in H_0 multiplied by the overall sample size.

Step 4: Calculate the test statistic:
$$\chi_s^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i}$$

Notation: C is the total number of categories, O_i is the observed frequency of category i , and E_i is the expected frequency of category i .

Step 5: Use the test statistic to assess whether the data are consistent with the null hypothesis:

Calculate the *P-value* (P) using statistical software or by hand using statistical tables.

Step 6: Draw conclusions from the test:

If $P \leq \alpha$, then reject H_0 , and conclude that the population distribution is significantly different than the distribution specified by H_0 .

If $P > \alpha$, then we do not have sufficient evidence to conclude that population has a different distribution.

white plants. A chi-square goodness-of-fit can be used to assess whether or not the data are consistent with this ratio, and thus whether or not this simple genetic explanation is valid. We start by stating our hypotheses and significance level:

H_0 : The progeny of this type of cross have the following probabilities of each flower color:

$$\Pr\{\text{Red}\} = .50, \Pr\{\text{Pink}\} = .25, \Pr\{\text{White}\} = .25$$

H_A : At least one of the probabilities of H_0 is incorrect.

$$\alpha = 0.05$$

We next use the probabilities in H_0 and the sample size to calculate the expected frequencies:

	Red	Pink	White
Observed	108	34	40
Expected	$(.50)(182) = 91$	$(.25)(182) = 45.5$	$(.25)(182) = 45.5$

Based on these quantities, we calculate the chi-square test statistic:

$$\chi_s^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i} = \frac{(108 - 91)^2}{91} + \frac{(34 - 45.5)^2}{45.5} + \frac{(40 - 45.5)^2}{45.5} = 6.747$$

We find the *P-value* for this result to be $P = 0.0343$ using statistical software. Since P is less than α , we reject the null hypothesis and conclude that the botanist is correct: The plant color patterns cannot be explained by the simple Mendelian genetic model under consideration.

This introduction is only meant to provide a brief introduction to the concepts of statistical analysis, with a few example tests. **FIGURE B13** provides a summary of some of the commonly used statistical tests that you may encounter in biological studies.

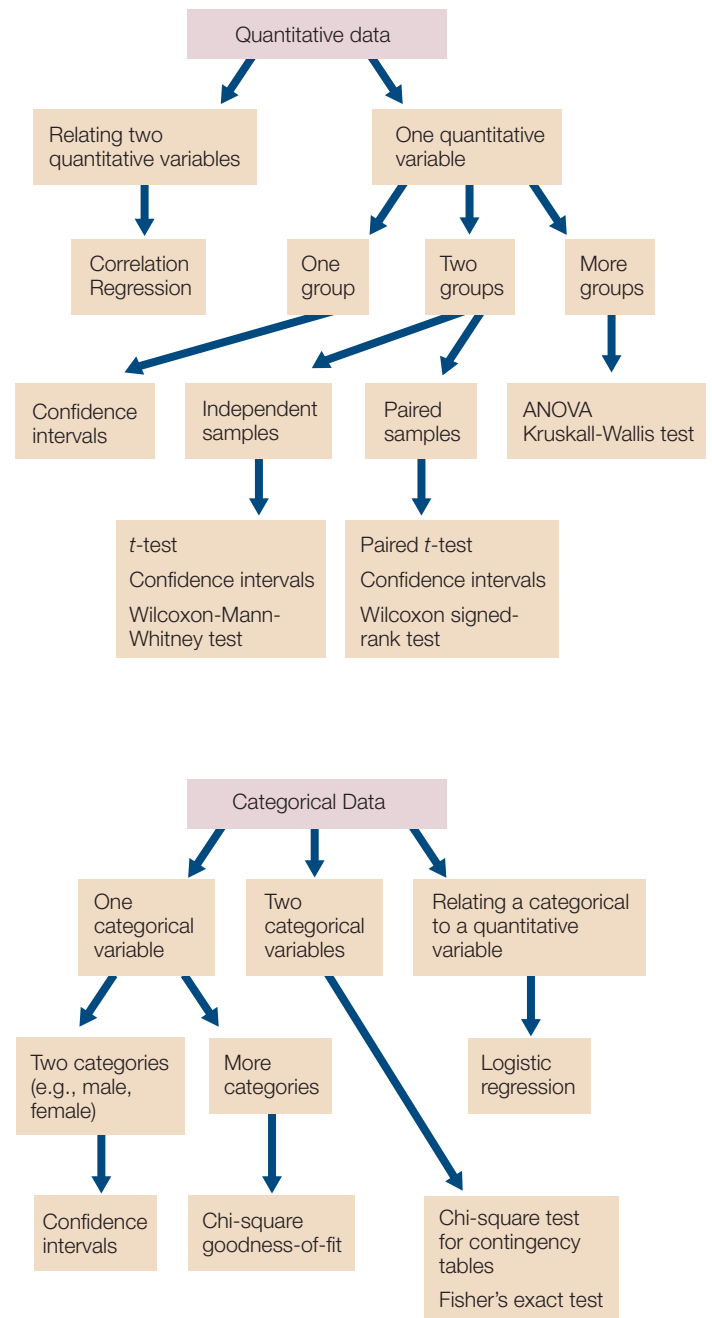

FIGURE B13 Some Common Methods of Statistical Inference This flow-chart shows some of the commonly used methods of statistical inference for different combinations of data. Detailed descriptions of these methods can be found in most introductory biostatistics textbooks.

Appendix C: Some Measurements Used in Biology

MEASURES OF	UNIT	EQUIVALENTS	METRIC → ENGLISH CONVERSION
Length	meter (m)	base unit	1 m = 39.37 inches = 3.28 feet = 1.196 yards
	kilometer (km)	1 km = 1000 (10 ³) m	1 km = 0.62 miles
	centimeter (cm)	1 cm = 0.01 (10 ⁻²) m	1 cm = 0.39 inches
	millimeter (mm)	1 mm = 0.1 cm = 10 ⁻³ m	1 mm = 0.039 inches
	micrometer (μm)	1 μm = 0.001 mm = 10 ⁻⁶ m	
	nanometer (nm)	1 nm = 0.001 μm = 10 ⁻⁹ m	
Area	square meter (m ²)	base unit	1 m ² = 1.196 square yards
	hectare (ha)	1 ha = 10,000 m ²	1 ha = 2.47 acres
Volume	liter (L)	base unit	1 L = 1.06 quarts
	milliliter (mL)	1 mL = 0.001 L = 10 ⁻³ L	1 mL = 0.034 fluid ounces
	microliter (μL)	1 μL = 0.001 mL = 10 ⁻⁶ L	
Mass	gram (g)	base unit	1 g = 0.035 ounces
	kilogram (kg)	1 kg = 1000 g	1 kg = 2.20 pounds
	metric ton (mt)	1 mt = 1000 kg	1 mt = 2,200 pounds = 1.10 ton
	milligram (mg)	1 mg = 0.001 g = 10 ⁻³ g	
	microgram (μg)	1 μg = 0.001 mg = 10 ⁻⁶ g	
Temperature	degree Celsius (°C)	base unit	°C = (°F - 32)/1.8 0°C = 32°F (water freezes) 100°C = 212°F (water boils) 20°C = 68°F ("room temperature") 37°C = 98.6°F (human internal body temperature)
	Kelvin (K)*	K = °C - 273	0 K = -460°F
Energy	joule (J)		1 J ≈ 0.24 calorie = 0.00024 kilocalorie [†]

*0 K (-273°C) is "absolute zero," a temperature at which molecular oscillations approach 0—that is, the point at which motion all but stops.

[†]A *calorie* is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. The *kilocalorie*, or nutritionist's calorie, is what we commonly think of as a calorie in terms of food.

Glossary

- A -

A horizon See top soil.

abiotic (a' bye ah tick) [Gk. *a*: not + *bios*: life] Nonliving. (Contrast with biotic.)

abomasum The true stomach of a ruminant.

abortion Any termination of pregnancy that occurs after a fertilized egg is successfully implanted in the uterus.

abscisic acid (ABA) (ab sighs' ik) A plant growth substance with growth-inhibiting action. Causes stomata to close; involved in a plant's response to salt and drought stress.

abscission (ab sizz' un) [L. *abscisso*: break off] The process by which leaves, petals, and fruits separate from a plant.

absorption (1) Of light: complete retention, without reflection or transmission. (2) Of water or other molecules: soaking up (taking in through pores or by diffusion).

absorption spectrum A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

absorptive heterotroph An organism (usually a fungus) that obtains its food by secreting digestive enzymes into the environment to break down large food molecules, then absorbing the breakdown products.

absorptive state State in which food is in the gut and nutrients are being absorbed. (Contrast with postabsorptive state.)

abyssal zone (uh biss' ul) [Gk. *abyssos*: bottomless] The deepest parts of the ocean.

accessory pigments Pigments that absorb light and transfer energy to chlorophylls for photosynthesis.

accessory sex organs Anatomical structures that allow transfer of sperm from male to female for internal fertilization.

acetyl coenzyme A (acetyl CoA) A compound that reacts with oxaloacetate to produce citrate at the beginning of the citric acid cycle; a key metabolic intermediate in the formation of many compounds.

acetylcholine (ACh) A neurotransmitter that carries information across vertebrate neuromuscular junctions and some other synapses. It is then broken down by the enzyme acetylcholinesterase (AChE).

acid [L. *acidus*: sharp, sour] A substance that can release a proton in solution. (Contrast with base.)

acid growth hypothesis The hypothesis that auxin increases proton pumping, thereby lowering the pH of the cell wall and activating enzymes that loosen polysaccharides. Proposed to explain auxin-induced cell expansion in plants.

acid rain Precipitation that has a lower pH than normal as a result of acid-forming precursor molecules introduced into the atmosphere by human activities.

acidic Having a pH of less than 7.0 (a hydrogen ion concentration greater than 10^{-7} molar). (Contrast with basic.)

acoelomate An animal that does not have a coelom.

acrosome (a' krow soam) [Gk. *akros*: highest + *soma*: body] The structure at the forward tip of an animal sperm which is the first to fuse with the egg membrane and enter the egg cell.

ACTH See corticotropin.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle.

action potential An impulse in a neuron taking the form of a wave of depolarization or hyperpolarization.

action spectrum A graph of a biological process versus light wavelength; shows which wavelengths are involved in the process.

activation energy (E_a) The energy barrier that blocks the tendency for a chemical reaction to occur.

activator A transcription factor that stimulates transcription when it binds to a gene's promoter. (Contrast with repressor.)

active site The region on the surface of an enzyme or ribozyme where the substrate binds, and where catalysis occurs.

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See also primary active transport, secondary active transport; contrast with facilitated diffusion, passive transport.)

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

adaptive immunity In animals, one of two general types of defenses against pathogens. Involves antibody proteins and other proteins that recognize, bind to, and aid in the destruction of specific viruses and bacteria. Present only in vertebrate animals. (Contrast with innate immunity.)

additive growth Population growth in which a constant number of individuals is added to the population during successive time intervals. (Contrast with multiplicative growth.)

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

adenosine triphosphate See ATP.

adiabatic cooling A decrease in air temperature that occurs when air rises and then expands as pressure decreases at higher altitudes.

adrenal gland (a dree' nal) [L. *ad*: toward + *renes*: kidneys] An endocrine gland located near the kidneys of vertebrates, consisting of two glandular parts, the cortex and medulla.

adrenaline See epinephrine.

adrenergic receptors G protein-linked receptor proteins that bind to the hormones epinephrine and norepinephrine, triggering specific responses in the target cells.

adrenocorticotrophic hormone See corticotropin.

adsorption Binding of a gas or a solute to the surface of a solid.

adventitious roots (ad ven ti' shus) [L. *adventitius*: arriving from outside] Roots originating from the stem at ground level or below; typical of the fibrous root system of monocots.

aerenchyma In plants, parenchymal tissue containing air spaces.

aerobic (air oh' bic) [Gk. *aer*: air + *bios*: life] In the presence of oxygen; requiring oxygen. (Contrast with anaerobic.)

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in a neuron that carries impulses to the central nervous system (afferent neuron), or a blood vessel that carries blood to a structure. (Contrast with efferent.)

AIDS Acquired immune deficiency syndrome, a condition caused by human immunodeficiency virus (HIV) in which the body's T-helper cells are reduced, leaving the victim subject to opportunistic diseases.

air sacs Structures in the respiratory system of birds that receive inhaled air; they keep fresh air flowing unidirectionally through the lungs, but are not themselves gas exchange surfaces.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

aleurone layer In some seeds, a tissue that lies beneath the seed coat and surrounds the endosperm. Secretes digestive enzymes that break down macromolecules stored in the endosperm.

allantoic membrane In animal development, an outgrowth of extraembryonic endoderm plus adjacent mesoderm that forms the allantois, a saclike structure that stores metabolic wastes produced by the embryo.

allantois (al' lun toh is) [Gk. *allant*: sausage] An extraembryonic membrane enclosing a sausage-shaped sac that stores the embryo's nitrogenous wastes.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

allele frequency The relative proportion of a particular allele in a specific population.

allergic reaction [Ger. *allergie*: altered] An overreaction of the immune system to amounts of an antigen that do not affect most people; often involves IgE antibodies.

allopatric speciation (al' lo pat' rick) [Gk. *allos*: other + *patria*: homeland] The formation of two species from one when reproductive isolation occurs because of the interposition of (or crossing of) a physical geographic barrier such as a river. Also called geographic speciation. (Contrast with sympatric speciation.)

allopolyploidy The possession of more than two chromosome sets that are derived from more than one species.

allosteric regulation (al lo steer' ik) [Gk. *allos*: other + *stereos*: structure] Regulation of the activity of a protein (usually an enzyme) by the binding of an effector molecule to a site other than the active site.

α (alpha) helix A prevalent type of secondary protein structure; a right-handed spiral.

alternation of generations The succession of multicellular haploid and diploid phases in some sexually reproducing organisms, notably plants.

alternative splicing A process for generating different mature mRNAs from a single gene by splicing together different sets of exons during RNA processing.

altruism Pertaining to behavior that benefits other individuals at a cost to the individual who performs it.

alveolus (al ve' o lus) (plural: alveoli) [L. *alveus*: cavity] A small, baglike cavity, especially the blind sacs of the lung.

amensalism (a men' sul ism) Interaction in which one animal is harmed and the other is unaffected. (Contrast with commensalism, mutualism.)

amine An organic compound containing an amino group (NH₂).

amine hormones Small hormone molecules synthesized from single amino acids (e.g., thyroxine and epinephrine).

amino acid An organic compound containing both NH₂ and COOH groups. Proteins are polymers of amino acids.

amino acid replacement A change in the nucleotide sequence that results in one amino acid being replaced by another.

ammonia NH₃, the most common nitrogenous waste.

ammonotelic (am moan' o teal' ic) [Gk. *telos*: end] Pertaining to an organism in which the final product of breakdown of nitrogen-containing compounds (primarily proteins) is *ammonia*. (Contrast with ureotelic, uricotelic.)

amnion (am' nee on) The fluid-filled sac within which the embryos of reptiles (including birds) and mammals develop.

amniote egg A shelled egg surrounding four extraembryonic membranes and embryo-nourishing yolk. This evolutionary adaptation permitted mammals and reptiles to live and reproduce in drier environments than can most amphibians.

amphipathic (am' fi path' ic) [Gk. *amphi*: both + *pathos*: emotion] Of a molecule, having both hydrophilic and hydrophobic regions.

amplitude The magnitude of change over the course of a regular cycle.

amygdala A component of the limbic system that is involved in fear and fear memory.

amylase (am' ill ase) An enzyme that catalyzes the hydrolysis of starch, usually to maltose or glucose.

anabolic reaction (an uh bah' lik) [Gk. *ana*: upward + *ballein*: to throw] A synthetic reaction in which simple molecules are linked to form more complex ones; requires an input of energy and captures it in the chemical bonds that are formed. (Contrast with catabolic reaction.)

anaerobic (an ur row' bic) [Gk. *an*: not + *aer*: air + *bios*: life] Occurring without the use of molecular oxygen, O₂. (Contrast with aerobic.)

anaphase (an' a phase) [Gk. *ana*: upward] The stage in cell nuclear division at which the first separation of sister chromatids (or, in the first meiotic division, of paired homologs) occurs.

ancestral trait The trait originally present in the ancestor of a given group; may be retained or changed in the descendants of that ancestor.

androgen (an' dro jen) Any of the several male sex steroids (most notably testosterone).

aneuploidy (an' you ploy dee) A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

angiosperms Flowering plants; one of the two major groups of living seed plants. (See also gymnosperms.)

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing peripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

animal hemisphere The metabolically active upper portion of some animal eggs, zygotes, and embryos; does not contain the dense nutrient yolk. (Contrast with vegetal hemisphere.)

anion (an' eye on) [Gk. *ana*: upward progress] A negatively charged ion. (Contrast with cation.)

annual A plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

antenna system See light-harvesting complex.

anterior pituitary The portion of the vertebrate pituitary gland that derives from gut epithelium and produces tropic hormones.

anterior Toward or pertaining to the tip or headward region of the body axis. (Contrast with posterior.)

anther (an' thur) [Gk. *anthos*: flower] A pollen-bearing portion of the stamen of a flower.

antheridium (an' thur id' ee um) [Gk. *antheros*: blooming] The multicellular structure that produces the sperm in nonvascular land plants and ferns.

antibody One of the myriad proteins produced by the immune system that specifically binds to a foreign substance in blood or other tissue fluids and initiates its removal from the body.

anticodon The three nucleotides in transfer RNA that pair with a complementary triplet (a codon) in messenger RNA.

antidiuretic hormone (ADH) A hormone that promotes water reabsorption by the kidney. ADH is produced by neurons in the hypothalamus and released from nerve terminals in the posterior pituitary. Also called vasopressin.

antigen (an' ti jun) Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

antigen-presenting cell In cellular immunity, a cell that ingests and digests an antigen, and then exposes fragments of that antigen to the outside of the cell, bound to proteins in the cell's plasma membrane.

antigenic determinant The specific region of an antigen that is recognized and bound by a specific antibody. Also called an epitope.

antiparallel Pertaining to molecular orientation in which a molecule or parts of a molecule have opposing directions.

antiporter A membrane transport protein that moves one substance in one direction and another in the opposite direction. (Contrast with symporter, uniporter.)

antisense RNA A single-stranded RNA molecule complementary to, and thus targeted against, an mRNA of interest to block its translation.

anus (a' nus) An opening through which solid digestive wastes are expelled, located at the posterior end of a tubular gut.

aorta (a or' tah) [Gk. *aorte*: aorta] The main trunk of the arteries leading to the systemic (as opposed to the pulmonary) circulation.

aortic body A chemosensor in the aorta that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

aortic valve A one-way valve between the left ventricle of the heart and the aorta that prevents backflow of blood into the ventricle when it relaxes.

apex (a' pecks) The tip or highest point of a structure, as of a growing stem or root.

aphasia a deficit in the ability to use or understand words.

aphotic zone In bodies of water (lakes and oceans), the region below the reach of light.

apical (a' pi kul) Pertaining to the *apex*, or tip, usually in reference to plants.

apical dominance In plants, inhibition by the apical bud of the growth of axillary buds.

apical hook A form taken by the stems of many eudicot seedlings that protects the delicate shoot apex while the stem grows through the soil.

apical meristem The meristem at the tip of a shoot or root; responsible for a plant's primary growth.

apomixis (ap oh mix' is) [Gk. *apo*: away from + *mixis*: sexual intercourse] The asexual production of seeds.

apoplast (ap' oh plast) In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

apoptosis (ap uh toh' sis) A series of genetically programmed events leading to cell death.

appendix In the human digestive system, the vestigial equivalent of the cecum, which serves no digestive function.

aquaporin A transport protein in plant and animal cell membranes through which water passes in osmosis.

aquatic (a kwa' tic) [L. *aqua*: water] Pertaining to or living in water. (Contrast with marine, terrestrial.)

aqueous (a' kwee us) Pertaining to water or a watery solution.

aquifer A large pool of groundwater.

archegonium (ar' ke go' nee um) The multicellular structure that produces eggs in nonvascular land plants, ferns, and gymnosperms.

archenteron (ark en' ter on) [Gk. *archos*: first + *enteron*: bowel] The earliest primordial animal digestive tract.

arms race A series of reciprocal adaptations between species involved in antagonistic interactions, in which adaptations that increase the fitness of a consumer species exert selection pressure on its resource species to counter the consumer's adaptation, and vice versa.

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

artery A muscular blood vessel carrying oxygenated blood away from the heart to other parts of the body. (Contrast with vein.)

artificial insemination An infertility treatment that involves the artificial introduction of sperm into the woman's reproductive tract.

artificial selection The selection by plant and animal breeders of individuals with certain desirable traits.

ascoma The fruiting structure of sexually reproducing sac fungi; often a cup-shaped structure.

ascus (ass' cus) (plural: asci) [Gk. *askos*: bladder] In sac fungi, the club-shaped sporangium within which spores (ascospores) are produced by meiosis.

asexual reproduction Reproduction without sex.

assisted reproductive technologies (ARTs) Any of several procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in a female's reproductive tract for development.

association cortex In the vertebrate brain, the portion of the cortex involved in higher-order information processing, so named because it integrates, or associates, information from different sensory modalities and from memory.

associative learning A form of learning in which two unrelated stimuli become linked to the same response.

astrocyte [Gk. *astron*: star] A type of glial cell that contributes to the blood-brain barrier by surrounding the smallest, most permeable blood vessels in the brain.

atom [Gk. *atomos*: indivisible] The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

atomic mass See atomic weight.

atomic number The number of protons in the nucleus of an atom; also equals the number of electrons around the neutral atom. Determines the chemical properties of the atom.

atomic weight The average of the mass numbers of a representative sample of atoms of an element, with all the isotopes in their normally occurring proportions. Also called atomic mass.

ATP (adenosine triphosphate) An energy-storage compound containing adenine, ribose, and three phosphate groups. When it is formed from ADP, useful energy is stored; when it is broken down (to ADP or AMP), energy is released to drive endergonic reactions.

ATP synthase An integral membrane protein that couples the transport of protons with the formation of ATP.

atrial natriuretic peptide A hormone released by the atrial muscle fibers of the heart when they are overly stretched, which decreases reabsorption of sodium by the kidney and thus blood volume.

atrioventricular node A modified node of cardiac muscle that organizes the action potentials that control contraction of the ventricles.

atrium (a' tree um) [L. *atrium*: central hall] An internal chamber. In the hearts of vertebrates, the thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

auditory system A sensory system that uses mechanoreceptors to convert pressure waves into receptor potentials; includes structures that gather sound waves, direct them to a sensory organ, and amplify their effect on the mechanoreceptors.

autocatalysis [Gk. *autos*: self + *kata*: to break down] A positive feedback process in which an activated enzyme acts on other inactive molecules of the same enzyme to activate them.

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

autoimmune diseases Diseases (e.g., rheumatoid arthritis) that result from failure of the immune system to distinguish between self and nonself, causing it to attack tissues in the organism's own body.

autoimmunity An immune response by an organism to its own molecules or cells.

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls such involuntary functions as those of guts and glands. Also called the involuntary nervous system.

autopolyploidy The possession of more than two entire chromosomes sets that are derived from a single species.

autoregulatory mechanisms In mammalian circulatory systems, local control of blood flow through capillary beds by constriction or dilation of incoming arterioles in response to local metabolite concentrations.

autosome Any chromosome (in a eukaryote) other than a sex chromosome.

autotroph (au' tow trowf') [Gk. *autos*: self + *trophe*: food] An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight (photoautotrophs) or chemically reduced matter (see chemolithotrophs). (Contrast with heterotroph.)

auxin (awk' sin) [Gk. *auxein*: to grow] In plants, a substance (the most common being indoleacetic acid) that regulates growth and various aspects of development.

avirulence (Avr) genes Genes in a pathogen that may trigger defenses in plants. See gene-for-gene resistance.

Avogadro's number The number of atoms or molecules in a mole (weighed out in grams) of a substance, calculated to be 6.022×10^{23} .

axillary bud A bud that forms in the angle (axil) where a leaf meets a stem.

axon [Gk. *axle*] The part of a neuron that conducts action potentials away from the cell body.

axon hillock The junction between an axon and its cell body, where action potentials are generated.

axon terminals The endings of an axon; they form synapses and release neurotransmitter.

- B -

B cell A type of lymphocyte involved in the humoral immune response of vertebrates. Upon recognizing an antigenic determinant, a B cell develops into a plasma cell, which secretes an antibody. (Contrast with T cell.)

B horizon See subsoil.

bacillus (bah sil' us) [L: little rod] Any of various rod-shaped bacteria.

bacterial conjugation See conjugation.

bacteriophage (bak teer' ee o fayj) [Gk. *bakterion*: little rod + *phagein*: to eat] Any of a group of viruses that infect bacteria. Also called phage.

bacteroids Nitrogen-fixing organelles that develop from endosymbiotic bacteria.

bark All tissues external to the vascular cambium of a plant.

barometric pressure Atmospheric pressure; the total pressure of the gas mixture in air.

baroreceptor [Gk. *baros*: weight] A pressure-sensing cell or organ. Sometimes called a stress receptor.

basal metabolic rate (BMR) The minimum rate of energy turnover in an awake (but resting) bird or mammal that is not expending energy for thermoregulation.

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar-phosphate backbone.

base pair (bp) In double-stranded DNA, a pair of nucleotides formed by the *complementary base pairing* of a purine on one strand and a pyrimidine on the other.

basic Having a pH greater than 7.0 (i.e., having a hydrogen ion concentration lower than 10^{-7} molar). (Contrast with acidic.)

basidioma (plural: basiomata) A fruiting structure produced by club fungi.

basidium (bass id' ee yum) In club fungi, the characteristic sporangium in which four spores are formed by meiosis and then borne externally before being shed.

basilar membrane A membrane in the human inner ear whose flexion in response to sound waves activates hair cells; flexes at different locations in response to different pitches of sound.

basophil A type of phagocytic white blood cell that releases histamine and may promote T cell development.

BD model The "birth-death model": $N_{t+1} = N_t + B - D$. The most basic mathematical model of population growth.

behaviorism One of two classical approaches to the study of proximate causes of animal behavior, derived from the discoveries of Ivan Pavlov and focused on laboratory studies. (Compare with ethology.)

benefit An improvement in survival and reproductive success resulting from performing a behavior or having a trait.

benthic zone [Gk. *benthos*: bottom] The bottom of the ocean.

β (beta) pleated sheet A type of protein secondary structure; results from hydrogen bonding between polypeptide regions running antiparallel to each other.

bicarbonate ion Ion (HCO_3^-) resulting from dissociation of carbonic acid in water; important in pH regulation and carbon dioxide (CO_2) transport.

BIDE model A model of population growth that takes into account immigration and emigration, in addition to births and deaths.

biennial A plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

bilateral symmetry The condition in which only the right and left sides of an organism, divided by a single plane through the midline, are mirror images of each other.

bilayer A structure that is two layers in thickness. In biology, most often refers to the phospholipid bilayer of membranes. (See phospholipid bilayer.)

bile A secretion of the liver made up of bile salts synthesized from cholesterol, various phospholipids, and bilirubin (the breakdown product of hemoglobin). Emulsifies fats in the small intestine.

binary fission Reproduction of a prokaryote by division of a cell into two comparable progeny cells.

binocular vision Overlapping visual fields of an animal's two eyes; allows the animal to see in three dimensions.

binomial nomenclature A taxonomic naming system in which each species is given two names (a genus name followed by a species name).

biofilm A community of microorganisms embedded in a polysaccharide matrix, forming a highly resistant coating on almost any moist surface.

biogeochemical cycle Movement of inorganic elements such as nitrogen, phosphorus, and carbon through living organisms and the physical environment.

biogeographic region One of several defined, continental-scale regions of Earth, each of which has a biota distinct from that of the others. (Contrast with biome.)

biogeography The scientific study of the patterns of distribution of populations, species, and ecological communities across Earth.

bioinformatics The use of computers and/or mathematics to analyze complex biological information, such as DNA sequences.

biological species concept The definition of a species as a group of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups. (Contrast with lineage species concept; morphological species concept.)

biology [Gk. *bios*: life + *logos*: study] The scientific study of living things.

bioluminescence The production of light by biochemical processes in an organism.

biomass The total weight of all the organisms, or some designated group of organisms, in a given area.

biome (bye' ome) A major division of the ecological communities of Earth, characterized primarily by distinctive vegetation. A given biogeographic region contains many different biomes.

bioremediation The use by humans of other organisms to remove contaminants from the environment.

biosphere (bye' oh sphere) All regions of Earth (terrestrial and aquatic) and Earth's atmosphere in which organisms can live.

biota (bye oh' tah) All of the organisms—animals, plants, fungi, and microorganisms—found in a given area. (Contrast with flora, fauna.)

biotechnology The use of cells or living organisms to produce materials useful to humans.

biotic (bye ah' tick) [Gk. *bios*: life] Alive. (Contrast with abiotic.)

biotic interchange The dispersal of species from two different biotas into the region they had not previously inhabited, as when two formerly separated land masses fuse.

blade The thin, flat portion of a leaf.

blastocoel (blass' toe seal) [Gk. *blastos*: sprout + *koilos*: hollow] The central, hollow cavity of a blastula.

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

blastodisc (blass' toe disk) An embryo that forms as a disk of cells on the surface of a large yolk mass; comparable to a blastula, but occurring in animals such as birds and reptiles, in which the massive yolk restricts complete cleavage.

blastomere Any of the cells produced by the early divisions of a fertilized animal egg.

blastopore The opening created by the invagination of the vegetal pole during gastrulation of animal embryos.

blastula (blass' chu luh) An early stage of the animal embryo; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

block to polyspermy Any of several responses to entry of a sperm into an egg that prevent more than one sperm from entering the egg.

blood A fluid tissue that is pumped around the body; a component of the circulatory system.

blood clotting A cascade of events involving platelets and circulating proteins (clotting factors) that seals damaged blood vessels.

blood-brain barrier A property of blood vessels in the brain that prevents most chemicals from diffusing from the blood into the brain.

blue-light receptors Pigments in plants that absorb blue light (400–500 nm). These pigments mediate many plant responses including photo-tropism, stomatal movements, and expression of some genes.

body plan The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts.

Bohr effect A shift in the O₂ binding curve of hemoglobin in response to excess

H⁺ ions such that the hemoglobin releases more O₂ in tissues where pH is low.

Bohr model A model for atomic structure that depicts the atom as largely empty space, with a central nucleus surrounded by electrons in orbits, or electron shells, at various distances from the nucleus.

bond See chemical bond.

bone A rigid component of vertebrate skeletal systems that contains an extracellular matrix of insoluble calcium phosphate crystals as well as collagen fibers.

bottleneck See population bottleneck.

Bowman's capsule An elaboration of the renal tubule, composed of podocytes, that surrounds and collects the filtrate from the glomerulus.

brain The centralized integrative center of a nervous system.

brainstem The portion of the vertebrate brain between the spinal cord and the forebrain, made up of the medulla, pons, and midbrain.

brassinosteroids Plant steroid hormones that mediate light effects promoting the elongation of stems and pollen tubes.

Broca's area A portion of the human brain essential for speech. Located in the frontal lobe just in front of the primary motor cortex.

bronchioles The smallest airways in a vertebrate lung, branching off the bronchi.

bronchus (plural: bronchi) The major airway(s) branching off the trachea into the vertebrate lung.

brown fat In mammals, fat tissue that is specialized to produce heat. It has many mitochondria and capillaries, and a protein that uncouples oxidative phosphorylation.

budding Asexual reproduction in which a more or less complete new organism grows from the body of the parent organism, eventually detaching itself.

buffer A substance that can transiently accept or release hydrogen ions and thereby resist changes in pH.

bulbourethral glands Secretory structures of the human male reproductive system that produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen.

bulk flow The movement of a solution from a region of higher pressure potential to a region of lower pressure potential.

bundle of His Fibers of modified cardiac muscle that conduct action potentials from the atria to the ventricular muscle mass.

bundle sheath cell Part of a tissue that surrounds the veins of plants.

– C –

C horizon See parent rock.

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and

promotes bone formation. (Contrast with parathyroid hormone.)

calcitriol A hormone derived from vitamin D whose actions include stimulating the cells of the digestive tract to absorb calcium from ingested food.

calorie [L. *calor*: heat] The amount of heat required to raise the temperature of 1 gram of water by 1°C. Physiologists commonly use the kilocalorie (kcal) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie, but refer to it as the *Calorie* (capital C).

Calvin cycle The stage of photosynthesis in which CO₂ reacts with RuBP to form 3PG, 3PG is reduced to a sugar, and RuBP is regenerated, while other products are released to the rest of the plant. Also known as the Calvin-Benson cycle.

calyx (kay' licks) [Gk. *kalyx*: cup] All of the sepals of a flower, collectively.

Cambrian explosion The rapid diversification of multicellular life that took place during the Cambrian period.

cAMP (cyclic AMP) A compound formed from ATP that acts as a second messenger.

cancellous bone A type of bone with numerous internal cavities that make it appear spongy, although it is rigid. (Contrast with compact bone.)

canopy The leaf-bearing part of a tree. Collectively, the aggregate of the leaves and branches of the larger woody plants of an ecological community.

5' cap See G cap.

capillaries [L. *capillaris*: hair] Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins. Capillaries are the site of exchange of materials between the blood and the interstitial fluid.

capillary beds Networks of capillaries where materials are exchanged between the blood and the interstitial fluid.

capsid The outer shell of a virus that encloses its nucleic acid.

carbohydrates Organic compounds containing carbon, hydrogen, and oxygen in the ratio 1:2:1 (i.e., with the general formula C_nH_{2n}O_n). Common examples are sugars, starch, and cellulose.

carbon skeleton The chains or rings of carbon atoms that form the structural basis of organic molecules. Other atoms or functional groups are attached to the carbon atoms.

carbon-fixation reactions The phase of photosynthesis in which chemical energy captured in the light reactions is used to drive the reduction of CO₂ to form carbohydrates.

carboxylase An enzyme that catalyzes the addition of carboxyl groups to a substrate.

cardiac (kar' dee ak) [Gk. *kardia*: heart] Pertaining to the heart and its functions.

cardiac cycle Contraction of the two atria of the heart, followed by contraction of the two ventricles and then relaxation.

cardiac muscle A type of muscle tissue that makes up, and is responsible for the beating of, the heart. Characterized by branching cells with single nuclei and a striated (striped) appearance. (Contrast with smooth muscle, skeletal muscle.)

cardiovascular system [Gk. *kardia*: heart + L. *vasculum*: small vessel] The heart, blood, and vessels are of a circulatory system.

carnivore [L. *carn*: flesh + *vovare*: to devour] An organism that eats animal tissues. (Contrast with detritivore, herbivore, omnivore.)

carotenoid (ka rah' tuh noid) A yellow, orange, or red lipid pigment commonly found as an accessory pigment in photosynthesis; also found in fungi.

carotid body A chemosensor in the carotid artery that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

carpel (kar' pel) [Gk. *karpos*: fruit] The organ of the flower that contains one or more ovules.

carrier (1) In facilitated diffusion, a membrane protein that binds a specific molecule and transports it through the membrane. (2) In respiratory and photosynthetic electron transport, a participating substance such as NAD that exists in both oxidized and reduced forms. (3) In genetics, a person heterozygous for a recessive trait.

carrying capacity (K) The number of individuals in a population that the resources of its environment can support.

cartilage bone A type of bone that begins its development as a cartilaginous structure resembling the future mature bone, then gradually hardens into mature bone. (Contrast with membranous bone.)

cartilage In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

Casparian strip A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

caspase One of a group of proteases that catalyze cleavage of target proteins and are active in apoptosis.

catabolic reaction (kat uh bah' lik) [Gk. *kata*: to break down + *ballein*: to throw] A synthetic reaction in which complex molecules are broken down into simpler ones and energy is released. (Contrast with anabolic reaction.)

catalyst (kat' a list) [Gk. *kata*: to break down] A chemical substance that accelerates a reaction without itself being consumed in the overall course of the reaction. Catalysts lower the activation energy of a reaction. Enzymes are biological catalysts.

cation (cat' eye on) An ion with one or more positive charges. (Contrast with anion.)

caudal [L. *cauda*: tail] Pertaining to the tail, or to the posterior part of the body.

cDNA library A collection of complementary DNAs derived from mRNAs of a particular tissue at a particular time in the life cycle of an organism.

cDNA See complementary DNA.

cecum (see' cum) [L. blind] A blind branch off the large intestine. In many nonruminant mammals, the cecum contains a colony of microorganisms that contribute to the digestion of food.

cell adhesion molecules Molecules on animal cell surfaces that affect the selective association of cells into tissues during development of the embryo. Also a component of desmosomes.

cell cycle checkpoints Points of transition between different phases of the cell cycle, which are regulated by cyclins and cyclin-dependent kinases (Cdk's).

cell cycle The stages through which a cell passes between one division and the next. Includes all stages of interphase and mitosis.

cell division The reproduction of a cell to produce two new cells. In eukaryotes, this process involves nuclear division (mitosis) and cytoplasmic division (cytokinesis).

cell fate The type of cell that an undifferentiated cell in an embryo will become in the adult.

cell junctions Specialized structures associated with the plasma membranes of epithelial cells. Some contribute to cell adhesion, others to intercellular communication.

cell recognition Binding of cells to one another mediated by membrane proteins or carbohydrates.

cell The simplest structural unit of a living organism. In multicellular organisms, the building blocks of tissues and organs.

cell theory States that cells are the basic structural and physiological units of all living organisms, and that all cells come from preexisting cells.

cell wall A relatively rigid structure that encloses cells of plants, fungi, many protists, and most prokaryotes, and which gives these cells their shape and limits their expansion in hypotonic media.

cellular immune response Immune system response mediated by T cells and directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune response.)

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O₂, generating H₂O and releasing energy.

cellular specialization In multicellular organisms, the division of labor such that different cell types become responsible for

different functions (e.g., reproduction or digestion) within the organism.

cellulose (sell' you lowss) A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

central vacuole In plant cells, a large organelle that stores the waste products of metabolism and maintains turgor.

centrifuge [L. *centrum*: center + *fugere*: to flee] A laboratory device in which a sample is spun around a central axis at high speed. Used to separate suspended materials of different densities.

centriole (sen' tree ole) A paired organelle that helps organize the microtubules in animal and protist cells during nuclear division.

centromere (sen' tro meer) [Gk. *centron*: center + *meros*: part] The region where sister chromatids join.

centrosome (sen' tro soam) The major microtubule organizing center of an animal cell.

cephalization (sef ah luh zay' shun) [Gk. *kephale*: head] The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

cerebellum (sair uh bell' um) [L. diminutive of *cerebrum*, brain] The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

cerebral cortex The thin layer of gray matter (neuronal cell bodies) that overlies the cerebrum.

cerebral hemispheres The major information-processing areas of the vertebrate brain. See also cerebrum.

cerebrum (su ree' brum) [L. brain] The dorsal anterior portion of the forebrain, making up the largest part of the brain of mammals; the chief coordination center of the nervous system; consists of two *cerebral hemispheres*.

cervix (sir' vix) [L. neck] The opening of the uterus into the vagina.

cGMP (cyclic guanosine monophosphate) An intracellular messenger that is part of signal transmission pathways involving G proteins. (See G protein.)

channel protein An integral membrane protein that forms an aqueous passageway across the membrane in which it is inserted and through which specific solutes may pass.

character In genetics, an observable feature, such as eye color. (Contrast with trait.)

chemical bond An attractive force stably linking two atoms.

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

chemical synapse Neural junction at which neurotransmitter molecules released from a presynaptic cell induce changes in a postsynaptic cell. (Contrast with electrical synapse.)

chemically gated channel A type of gated channel that opens or closes depending on the presence or absence of a specific molecule, which binds to the channel protein or to a separate receptor that in turn alters the three-dimensional shape of channel protein.

chemiosmosis Formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATP synthase activity.

chemoautotroph See chemolithotroph.

chemoheterotroph An organism that must obtain both carbon and energy from organic substances. (Contrast with chemolithotroph, photoautotroph, photoheterotroph.)

chemolithotroph [Gk. *lithos*: stone, rock] An organism that uses carbon dioxide as a carbon source and obtains energy by oxidizing inorganic substances from its environment; also called chemoautotroph. (Contrast with chemoheterotroph, photoautotroph, photoheterotroph.)

chemoreceptor A sensory receptor cell that senses specific molecules (such as odorant molecules or pheromones) in the environment.

chiasma (kie az' muh) (plural: chiasmata) [Gk. cross] An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

chlorophyll (klor' o fill) [Gk. *chloros*: green + *phyllon*: leaf] Any of several green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

chloroplast [Gk. *chloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

choanocyte (ko' an uh site) The collared, flagellated feeding cells of sponges.

cholecystokinin (ko' luh sis tuh kai' nin) A hormone produced and released by the lining of the duodenum when it is stimulated by undigested fats and proteins. It

stimulates the gallbladder to release bile and slows stomach activity.

chorion (kor' ee on) [Gk. *chorion*: after-birth] The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

chromatid (kro' ma tid) A newly replicated chromosome, from the time molecular duplication occurs until the time the centromeres separate (during anaphase of mitosis or of meiosis II).

chromatin remodeling A mechanism for epigenetic gene regulation by the alteration of chromatin structure.

chromatin The nucleic acid-protein complex that makes up eukaryotic chromosomes.

chromosomal mutation Loss of or changes in position/direction of a DNA segment on a chromosome.

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

chylomicron (ky low my' cron) Particles of lipid coated with protein, produced in the gut from dietary fats and secreted into the extracellular fluids.

chyme (kime) [Gk. *kymus*: juice] Created in the stomach; a mixture of ingested food with the digestive juices secreted by the salivary glands and the stomach lining.

cilium (sil' ee um) (plural: cilia) [L. eyelash] Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than a flagellum.

circadian rhythm (sir kade' ee an) [L. *circa*: approximately + *dies*: day] A rhythm of growth or activity that recurs about every 24 hours.

circannual rhythm [L. *circa*: + *annus*: year] A rhythm of growth or activity that recurs on a yearly basis.

circulatory system A system consisting of a muscular pump (heart), a fluid (blood or hemolymph), and a series of conduits (blood vessels) that transports materials around the body.

citric acid cycle In cellular respiration, a set of chemical reactions whereby acetyl CoA is oxidized to carbon dioxide and hydrogen atoms are stored as NADH and FADH₂. Also called the Krebs cycle.

clade [Gk. *klados*: branch] A monophyletic group made up of an ancestor and all of its descendants.

class I MHC molecules Cell surface proteins that participate in the cellular immune response directed against virus-infected cells.

class II MHC molecules Cell surface proteins that participate in the cell-cell

interactions (of T-helper cells, macrophages, and B cells) of the humoral immune response.

cleavage The first few cell divisions of an animal zygote. See also complete cleavage, incomplete cleavage.

climate The long-term average atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) found in a region. (Contrast with weather.)

climate diagram A way of graphically summarizing the climate in a given location by superimposing graphs of average monthly temperature and average precipitation through a year.

cloaca The opening through which both urinary wastes and digestive wastes are expelled in most amphibians and in reptiles (including birds).

clonal deletion Inactivation or destruction of lymphocyte clones that would produce immune reactions against the animal's own body.

clonal lineages Asexually reproduced groups of nearly identical organisms.

clonal selection Mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

clone [Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

closed circulatory system Circulatory system in which the circulating fluid is contained within a continuous system of vessels. (Contrast with open circulatory system.)

CO (CONSTANS) Gene coding for a transcription factor that activates the synthesis of florigen (FT); involved in the induction of flowering.

co-repressor In the regulation of bacterial operons, a molecule that binds to the repressor, causing it to change shape and bind to the operator, thereby inhibiting transcription.

coccus (kock' us) (plural: cocci) [Gk. *kokkos*: berry, pit] Any of various spherical or spheroidal bacteria.

cochlea (kock' lee uh) [Gk. *kokhlos*: snail] A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

codominance A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

codon Three nucleotides in messenger RNA that direct the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

coelom (see' loam) [Gk. *koiloma*: cavity] An animal body cavity, enclosed by

muscular mesoderm and lined with a mesodermal layer called peritoneum that also surrounds the internal organs.

coenocytic (seen' a sit ik) [Gk. *koinos*: common + *kytos*: container] Referring to the condition, found in some fungal hyphae, of "cells" containing many nuclei but enclosed by a single plasma membrane. Results from nuclear division without cytokinesis.

coenzyme A (CoA) A coenzyme used in various biochemical reactions as a carrier of acyl groups.

coenzyme A nonprotein organic molecule that plays a role in catalysis by an enzyme.

coevolution See reciprocal adaptation.

cofactor An inorganic ion that is weakly bound to an enzyme and required for its activity.

cohesin A protein involved in binding chromatids together.

cohesion The tendency of molecules (or any substances) to stick together.

cohort (co' hort) [L. *cohors*: company of soldiers] A group of similar-aged organisms.

cold-hardening A process by which plants can acclimate to cooler temperatures; requires repeated exposure to cool temperatures over many days.

coleoptile A sheath that surrounds and protects the shoot apical meristem and young primary leaves of a grass seedling as they move through the soil.

collagen [Gk. *kolla*: glue] A fibrous protein found extensively in bone and connective tissue.

collecting duct In vertebrates, a tubule that receives urine produced in the nephrons of the kidney and delivers that fluid to the ureter for excretion.

colenchyma (cull eng' kyma) [Gk. *kolla*: glue + *enchyma*: infusion] A type of plant cell, living at functional maturity, which lends flexible support by virtue of primary cell walls thickened at the corners. (Contrast with parenchyma, sclerenchyma.)

colon [Gk. *kolon*] The portion of the gut between the small intestine and the anus. Also called the large intestine.

commensalism [L. *com*: together + *mensa*: table] A type of interaction between species in which one participant benefits while the other is unaffected.

communication A signal from one organism (or cell) that alters the functioning or behavior of another organism (or cell).

community Any ecologically integrated group of species of microorganisms, plants, and animals inhabiting a given area.

compact bone A type of bone with a solid, hard structure. (Contrast with cancellous bone.)

companion cell In angiosperms, a specialized cell found adjacent to a sieve tube element.

comparative experiment Experimental design in which data from various

unmanipulated samples or populations are compared, but in which variables are not controlled or even necessarily identified. (Contrast with controlled experiment.)

comparative genomics Computer-aided comparison of DNA sequences between different organisms to reveal genes with related functions.

competition In ecology, use of the same resource by two or more species when the resource is present in insufficient supply for the combined needs of the species.

competitive inhibitor A nonsubstrate that binds to the active site of an enzyme and thereby inhibits binding of its substrate. (Contrast with noncompetitive inhibitor.)

complement system A group of eleven proteins that play a role in some reactions of the immune system. The complement proteins are not immunoglobulins.

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

complementary DNA (cDNA) DNA formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

complete cleavage Pattern of cleavage that occurs in eggs that have little yolk. Early cleavage furrows divide the egg completely and the blastomeres are of similar size. (Contrast with incomplete cleavage.)

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

compound (1) A substance made up of atoms of more than one element. (2) Made up of many units, as in the *compound eyes* of arthropods.

condensation reaction A chemical reaction in which two molecules become connected by a covalent bond and a molecule of water is released ($AH + BOH \rightarrow AB + H_2O$). (Contrast with hydrolysis reaction.)

conditional mutation A mutation that results in a characteristic phenotype only under certain environmental conditions.

conditioned reflex A form of associative learning first described by Ivan Pavlov, in which a natural response (such as salivation in response to food) becomes associated with a normally unrelated stimulus (such as a ringing bell).

conduction The transfer of heat from one object to another through direct contact.

cone (1) In conifers, a reproductive structure consisting of spore-bearing scales extending from a central axis. (Contrast with strobilus.) (2) In the vertebrate retina, a type

of photoreceptor cell responsible for color vision.

conidium (ko nid' ee um) (plural: conidia) [Gk. *konis*: dust] A type of haploid fungal spore borne at the tips of hyphae, not enclosed in sporangia.

conjugation (kon ju gay' shun) [L. *conjungere*: yoke together] (1) A process by which DNA is passed from one cell to another through a *conjugation tube*, as in bacteria. (2) A nonreproductive sexual process by which *Paramecium* and other ciliates exchange genetic material.

connective tissue A type of tissue that connects or surrounds other tissues; its cells are embedded in a collagen-containing matrix. One of the four major tissue types in multicellular animals.

consensus sequences Short stretches of DNA that appear, with little variation, in many different genes.

conservation biology An applied science that carries out investigations with the aim of maintaining the diversity of life on Earth.

conserved Pertaining to a gene or trait that has evolved very slowly and is similar or even identical in individuals of highly divergent groups.

conspecifics Individuals of the same species.

constant region The portion of an immunoglobulin molecule whose amino acid composition determines its class and does not vary among immunoglobulins in that class. (Contrast with variable region.)

constitutive Always present; produced continually at a constant rate. (Contrast with inducible.)

constitutive genes Genes that are expressed all the time. (Contrast with inducible genes.)

consumer An organism that eats the tissues of some other organism.

consumer-resource interactions Interactions in which organisms gain their nutrition by eating other living organisms or are eaten themselves.

continental drift The gradual movements of the world's continents that have occurred over billions of years.

contraception Birth control methods that prevent fertilization or implantation (conception).

contractile vacuole (kon trak' tul) A specialized vacuole that collects excess water taken in by osmosis, then contracts to expel the water from the cell.

controlled experiment An experiment in which a sample is divided into groups whereby experimental groups are exposed to manipulations of an independent variable while one group serves as an untreated control. The data from the various groups are then compared to see if there are changes in a dependent variable as a result of the experimental manipulation. (Contrast with comparative experiment.)

controlled system A set of components in a physiological system that is controlled by commands from a regulatory system. (Contrast with regulatory system.)

convection The transfer of heat to or from a surface via a moving stream of air or fluid.

convergent evolution Independent evolution of similar features from different ancestral traits.

copulation Reproductive behavior that results in a male depositing sperm in the reproductive tract of a female.

cork cambium [L. *cambiare*: to exchange] In plants, a lateral meristem that produces secondary growth, mainly in the form of waxy-walled protective cells, including some of the cells that become bark.

cork In plants, a protective outermost tissue layer composed of cells with thick walls waterproofed with suberin.

cornea The clear, transparent tissue that covers the eye and allows light to pass through to the retina.

corolla (ko role' lah) [L. *corolla*: a small crown] All of the petals of a flower, collectively.

coronary artery (kor' oh nair ee) An artery that supplies blood to the heart muscle.

corpus luteum (kor' pus loo' tee um) (plural: corpora lutea) [L. yellow body] A structure formed from a follicle after ovulation; produces hormones important to the maintenance of pregnancy.

corridor A connection between habitat patches through which organisms can disperse; plays a critical role in maintaining subpopulations.

cortex [L. *cortex*: covering, rind] (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal gland (adrenal cortex) and the brain (cerebral cortex).

corticosteroids Steroid hormones produced and released by the cortex of the adrenal gland.

corticotropin A tropic hormone produced by the anterior pituitary hormone that stimulates cortisol release from the adrenal cortex. Also called adrenocorticotrophic hormone (ACTH).

corticotropin-releasing hormone A releasing hormone produced by the hypothalamus that controls the release of cortisol from the anterior pituitary.

cortisol A corticosteroid that mediates stress responses.

cost A decrease in fitness resulting from performing a behavior or having a trait.

cost-benefit approach An approach to evolutionary studies that assumes an animal has a limited amount of time and energy to devote to each of its activities, and that each activity has fitness costs as well as benefits. (See also trade-off.)

cotyledon (kot' ul lee' dun) [Gk. *kotyledon*: hollow space] A "seed leaf." An embryonic organ that stores and digests reserve materials; may expand when seed germinates.

countercurrent exchange See countercurrent flow.

countercurrent flow An arrangement that promotes the maximum exchange of heat, or of a diffusible substance, between two fluids by having the fluids flow in opposite directions through parallel vessels close together.

countercurrent heat exchanger In "hot" fish, an adaptation of the circulatory system such that arterial blood flowing into the muscles is warmed by venous blood flowing out of the muscles, thereby conserving body heat by countercurrent exchange.

countercurrent multiplier The mechanism that increases the concentration of the interstitial fluid in the mammalian kidney through countercurrent flow in the loops of Henle and selective permeability and active transport of ions by segments of the loops of Henle.

covalent bond Chemical bond based on the sharing of electrons between two atoms.

CpG islands DNA regions rich in C residues adjacent to G residues. Especially abundant in promoters, these regions are where methylation of cytosine usually occurs.

critical night length In the photoperiodic flowering response of short-day plants, the length of night above which flowering occurs and below which the plant remains vegetative. (The reverse applies in the case of long-day plants.)

critical period See sensitive period.

crop A simple food storage sac, the first of two stomachlike organs in many animals (including reptiles, earthworms, and various insects). (See also gizzard.)

cross section A section taken perpendicular to the longest axis of a structure. Also called a transverse section.

crossing over The mechanism by which linked genes undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

cryptochromes [Gk. *kryptos*: hidden + *kroma*: color] Photoreceptors mediating some blue-light effects in plants and animals.

ctene (teen) [Gk. *cteis*: comb] In ctenophores, a comblike row of cilia-bearing plates. Ctenophores move by beating the cilia on their eight ctenes.

culture (1) A laboratory association of organisms under controlled conditions. (2) The collection of knowledge, tools, values, and rules that characterize a human society.

cumulus A thick gelatinous layer that protects a mammalian ovum.

currents Circulation patterns in the surface waters of oceans driven by the prevailing winds.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss.

(2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

cyclic AMP See cAMP.

cyclic electron transport In photosynthetic light reactions, the flow of electrons that produces ATP but no NADPH or O₂.

cyclin A protein that activates a cyclin-dependent kinase, bringing about transitions in the cell cycle.

cyclin-dependent kinase (Cdk) A protein kinase whose target proteins are involved in transitions in the cell cycle and which is active only when complexed with additional protein subunits, called cyclins.

cytokine A regulatory protein made by immune system cells that affects other target cells in the immune system.

cytokinesis (sy' toe kine ee' sis) [Gk. *kytos*: container + *kinein*: to move] The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

cytokinin (sy' toe kine' in) A member of a class of plant growth substances that plays roles in senescence, cell division, and other phenomena.

cytoplasm The contents of the cell, excluding the nucleus.

cytoplasmic determinants In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

cytoplasmic segregation The asymmetrical distribution of cytoplasmic determinants in a developing animal embryo.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

cytoskeleton The network of microtubules and microfilaments that gives a eukaryotic cell its shape and its capacity to arrange its organelles and to move.

cytosol The fluid portion of the cytoplasm, excluding organelles and other solids.

cytotoxic T cells (T_C) Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with T-helper cells.)

- D -

DAG See diacylglycerol.

data Quantified observations about a system under study.

daughter chromosomes During mitosis, the separated chromatids from the beginning of anaphase onward.

dead space The lung volume that fails to be ventilated with fresh air (because the lungs are never completely emptied during exhalation).

dead zones Regions in aquatic ecosystems that are devoid of aquatic life because eutrophication has resulted in severe oxygen depletion.

deciduous [L. *deciduus*: falling off]

Pertaining to a woody plant that sheds its leaves but does not die.

declarative memory Memory of people, places, events, and things that can be consciously recalled and described. (Contrast with procedural memory.)

decomposer An organism that metabolizes organic compounds in debris and dead organisms, releasing inorganic material; found among the bacteria, protists, and fungi. *See also* detritivore, saprobe.

defensin A type of protein made by phagocytes that kills bacteria and enveloped viruses by insertion into their plasma membranes.

deficiency disease A condition (e.g., scurvy and beriberi) caused by chronic lack of any essential nutrient.

degeneracy The situation in which a single amino acid may be represented by any of two or more different codons in messenger RNA. Most of the amino acids can be represented by more than one codon.

deletion A mutation resulting from the loss of a continuous segment of a gene or chromosome. Such mutations almost never revert to wild type. (Contrast with duplication, point mutation.)

demethylase An enzyme that catalyzes the removal of the methyl group from cytosine, reversing DNA methylation.

demography The study of population structure and of the processes by which it changes.

denaturation Loss of activity of an enzyme or nucleic acid molecule as a result of structural changes induced by heat or other means.

dendrite [Gk. *dendron*: tree] A fiber of a neuron which often cannot carry action potentials. Usually much branched and relatively short compared with the axon, and commonly carries information to the cell body of the neuron.

denitrification Metabolic activity by which nitrate and nitrite ions are reduced to form nitrogen gas; carried out by certain soil bacteria.

denitrifiers Bacteria that release nitrogen to the atmosphere as nitrogen gas (N₂).

density-dependent Pertaining to a factor with an effect on population size that increases in proportion to population density.

density-independent Pertaining to a factor with an effect on population size that acts independently of population density.

deoxyribonucleic acid *See* DNA.

deoxyribonucleoside triphosphates (dNTPs) The raw materials for DNA synthesis: deoxyadenosine triphosphate (dATP), deoxythymidine triphosphate (dTTP), deoxycytidine triphosphate (dCTP), and deoxyguanosine triphosphate (dGTP). Also called deoxyribonucleotides.

deoxyribose A five-carbon sugar found in nucleotides and DNA.

depolarization A change in the resting potential across a membrane so that the inside of the cell becomes less negative, or even positive, compared with the outside of the cell. (Contrast with hyperpolarization.)

derived trait A trait that differs from the ancestral trait. (Contrast with synapomorphy.)

dermal tissue system The outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system and vascular tissue system.)

desmosome (dez' mo sowm) [Gk. *desmos*: bond + *soma*: body] An adhering junction between animal cells.

determinate growth A growth pattern in which the growth of an organism or organ ceases when an adult state is reached; characteristic of most animals and some plant organs. (Contrast with indeterminate growth.)

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set.

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products of other organisms.

development The process by which a multicellular organism, beginning with a single cell, goes through a series of changes, taking on the successive forms that characterize its life cycle.

developmental module A functional entity in the embryo encompassing genes and signaling pathways that determine a physical structure independently of other such modules.

diabetes mellitus A condition caused by lack of insulin or inability to respond to insulin, characterized by an inability of cells to take up glucose from the blood.

diacylglycerol (DAG) In hormone action, the second messenger produced by hydrolytic removal of the head group of certain phospholipids.

diaphragm (dye' uh fram) [Gk. *diaphrassein*: barricade] (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking the entry of sperm.

diastole (dye ass' toll ee) [Gk. *dilation*] The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

diencephalon The portion of the vertebrate forebrain that develops into the thalamus and hypothalamus.

differential gene expression The hypothesis that, given that all cells contain all

genes, what makes one cell type different from another is the difference in transcription and translation of those genes.

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

diffusion Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present.

digestive vacuole In protists, an organelle specialized for digesting food ingested by endocytosis.

dihybrid cross A mating in which the parents differ with respect to the alleles of two loci of interest.

dikaryon (di care' ee ahn) [Gk. *di*: two + *karyon*: kernel] A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

diploblastic Having two cell layers. (Contrast with triploblastic.)

diploid (dip' loid) [Gk. *diplos*: double] Having a chromosome complement consisting of two copies (homologs) of each chromosome. Designated 2n. (Contrast with haploid.)

directional selection Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection, stabilizing selection.)

disaccharide A carbohydrate made up of two monosaccharides (simple sugars).

discoidal cleavage In animal development, a type of incomplete cleavage that is common in fishes, reptiles, and birds, the eggs of which contain a dense yolk mass.

dispersal Movement of organisms away from a parent organism or from an existing population.

disruptive selection Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection; stabilizing selection.)

distal Away from the point of attachment or other reference point. (Contrast with proximal.)

distal convoluted tubule The portion of a renal tubule from where it reaches the renal cortex, just past the loop of Henle to where it joins a collecting duct. (Compare with proximal convoluted tubule.)

disturbance A short-term event that disrupts populations, communities, or ecosystems by changing the environment.

disulfide bridge The covalent bond between two sulfur atoms (–S–S–) linking two molecules or remote parts of the same molecule.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

DNA fingerprint An individual's unique pattern of allele sequences, commonly short tandem repeats and single nucleotide polymorphisms.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

DNA methylation The addition of methyl groups to bases in DNA, usually cytosine or guanine.

DNA methyltransferase An enzyme that catalyzes the methylation of DNA.

DNA microarray A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed so that hybridization of cell-derived RNA or DNA to the target sequences can be performed.

DNA polymerase Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

DNA transposons Mobile genetic elements that move without making an RNA intermediate. (Contrast with retrotransposons.)

domain (1) An independent structural element within a protein. Encoded by recognizable nucleotide sequences, a domain often folds separately from the rest of the protein. Similar domains can appear in a variety of different proteins across phylogenetic groups (e.g., "homeobox domain"; "calcium-binding domain"). (2) In phylogenetics, the three monophyletic branches of life (Bacteria, Archaea, and Eukarya).

dominance In genetics, the ability of one allelic form of a gene to determine the phenotype of a heterozygous individual in which the homologous chromosomes carry both it and a different (recessive) allele. (Contrast with recessive.)

dormancy A condition in which normal activity is suspended, as in some spores, seeds, and buds.

dorsal [L. *dorsum*: back] Toward or pertaining to the back or upper surface. (Contrast with ventral.)

dorsal lip In amphibian embryos, the dorsal segment of the blastopore. Also called the "organizer," this region directs the development of nearby embryonic regions.

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm's nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg's two polar nuclei to produce the first cell of the triploid endosperm (the tissue that will nourish the growing plant embryo).

double helix Refers to DNA and the (usually right-handed) coil configuration of two complementary, antiparallel strands.

downregulation A negative feedback process in which continuous high concentrations of a hormone can decrease the number of its receptors. (Contrast with upregulation.)

duodenum (do' uh dee' num) The beginning portion of the vertebrate small intestine. (Contrast with ileum, jejunum.)

duplication A mutation in which a segment of a chromosome is duplicated, often by the attachment of a segment lost from its homolog. (Contrast with deletion.)

dynamic instability A property of actin filaments in the cytoskeleton, characterized by rapid shortening or lengthening of individual filaments.

- E -

ecdysone (eck die' sone) [Gk. *ek*: out of + *dryo*: to clothe] In insects, a hormone that induces molting.

ecological efficiency The overall transfer of energy from one trophic level to the next, expressed as the ratio of consumer production to producer production.

ecological system One or more organisms plus the external environment with which they interact.

ecological transition A type of succession in which a community distinctly different from the original community is established after a disturbance.

ecology [Gk. *oikos*: house] The scientific study of the interaction of organisms with their living (biotic) and nonliving (abiotic) environments.

ecosystem (eek' oh sis tum) The organisms of a particular habitat, such as a pond or forest, together with the physical environment in which they live.

ecosystem services Processes by which ecosystems maintain resources that benefit human society.

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

ectotherm [Gk. *ektos*: outside + *thermos*: heat] An animal that is dependent on external heat sources for regulating its body temperature (Contrast with endotherm.)

edema (i dee' mah) [Gk. *oidema*: swelling] Tissue swelling caused by the accumulation of fluid.

effector cells In cellular immunity, B cells and T cells that attack an antigen, either by secreting antibodies that bind to the antigen or by releasing molecules that destroy any cell bearing the antigen.

efferent (ef' ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in a neuron that carries impulses outward from the central nervous system (efferent neuron), or a blood vessel that carries blood away from a structure. (Contrast with afferent.)

efferent neurons In a neural network, nerve cells that carry commands to physiological and behavioral effectors such as muscles and glands.

egg In all sexually reproducing organisms, the female gamete; in birds, reptiles, and some other vertebrates, a structure within which early embryonic development occurs. *See also* amniote egg, ovum.

electrical synapse A type of synapse at which action potentials spread directly from presynaptic cell to postsynaptic cell. (Contrast with chemical synapse.)

electrocardiogram (ECG or EKG) A graphic recording of electrical potentials from the heart.

electrochemical gradient The concentration gradient of an ion across a membrane plus the voltage difference across that membrane.

electroencephalogram (EEG) A graphic recording of electrical potentials from the brain.

electromagnetic radiation A self-propagating wave that travels through space and has both electrical and magnetic properties.

electron A subatomic particle outside the nucleus carrying a negative charge and very little mass.

electron shell The region surrounding the atomic nucleus at a fixed energy level in which electrons orbit.

electron transport The passage of electrons through a series of proteins with a release of energy which may be captured in a concentration gradient or in chemical form such as NADH or ATP.

electronegativity The tendency of an atom to attract electrons when it occurs as part of a compound.

electrophoresis *See* gel electrophoresis.

element A substance that cannot be converted to simpler substances by ordinary chemical means.

elongation (1) In molecular biology, the addition of monomers to make a longer RNA or protein during transcription or translation. (2) Growth of a plant axis or cell primarily in the longitudinal direction.

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as a seed, egg, or uterus.

embryo sac In angiosperms, the female gametophyte. Found within the ovule, it consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

emigration The deliberate and usually oriented departure of an organism from the habitat in which it has been living.

3' end (3 prime) The end of a DNA or RNA strand that has a free hydroxyl group

at the 3' carbon of the sugar (deoxyribose or ribose).

5' end (5 prime) The end of a DNA or RNA strand that has a free phosphate group at the 5' carbon of the sugar (deoxyribose or ribose).

endemic (en dem' ik) [Gk. *endemos*: native] Confined to a particular region, thus often having a comparatively restricted distribution.

endergonic A chemical reaction in which the products have higher free energy than the reactants, thereby requiring free energy input to occur. (Contrast with exergonic.)

endocrine cells Cells that secrete substances into the extracellular fluid. (See also endocrine gland.)

endocrine gland (en' doh krin) [Gk. *endo*: within + *krinein*: to separate] An aggregation of secretory cells that secretes hormones into the blood. The *endocrine system* consists of all *endocrine cells* and endocrine glands in the body that produce and release hormones. (Contrast with exocrine gland.)

endocytosis A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

endodermis In plants, a specialized cell layer marking the inside of the cortex in roots and some stems. Frequently a barrier to free diffusion of solutes.

endomembrane system A system of intracellular membranes that exchange material with one another, consisting of the Golgi apparatus, endoplasmic reticulum, and lysosomes when present.

endometrium The epithelial lining of the uterus.

endoplasmic reticulum (ER) [Gk. *endo*: within + L. *reticulum*: net] A system of membranous tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists in two forms: rough ER, studded with ribosomes; and smooth ER, lacking ribosomes.

endorphins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

endoskeleton [Gk. *endo*: within + *skelos*: hard] An internal skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

endospore [Gk. *endo*: within + *spora*: to sow] In some bacteria, a resting structure that can survive harsh environmental conditions.

endosymbiosis theory [Gk. *endo*: within + *sym*: together + *bios*: life] The theory that the

eukaryotic cell evolved via the engulfing of one prokaryotic cell by another.

endothelium The single layer of epithelial cells lining the interior of a blood vessel.

endotherm [Gk. *endo*: within + *thermos*: heat] An animal that can control its body temperature by the expenditure of its own metabolic energy. (Contrast with ectotherm.)

endotoxin A lipopolysaccharide that forms part of the outer membrane of certain Gram-negative bacteria that is released when the bacteria grow or lyse. (Contrast with exotoxin.)

energetic cost The difference between the energy an animal expends in performing a behavior and the energy it would have expended had it rested.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

enkephalins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

enteric nervous system The nerve nets in the submucosa and between the smooth muscle layers of the vertebrate gut.

enthalpy (H) The total energy of a system.

entrain To phase-advance or phase-delay an organism's circadian clock each day so that it is in phase with the light-dark cycle of the organism's environment.

entropy (S) (en' tro pee) [Gk. *tropein*: to change] A measure of the degree of disorder in any system. Spontaneous reactions in a closed system are always accompanied by an increase in entropy.

environment Whatever surrounds and interacts with or otherwise affects a population, organism, or cell. May be external or internal.

enzyme (en' zime) [Gk. *zyme*: to leaven (as in yeast bread)] A catalytic protein that speeds up a biochemical reaction.

enzyme-substrate complex (ES) An intermediate in an enzyme-catalyzed reaction; consists of the enzyme bound to its substrate(s).

epi- [Gk. upon, over] A prefix used to designate a structure located on top of another; for example, epidermis, epiphyte.

epiblast The upper or overlying portion of the avian blastula which is joined to the hypoblast at the margins of the blastodisc.

epiboly The movement of cells over the surface of the blastula toward the forming blastopore.

epidermis [Gk. *epi*: over + *derma*: skin] In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

epididymis (epuh did' uh mus) [Gk. *epi*: over + *didymos*: testicle] Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

epigenetics The scientific study of changes in the expression of a gene or set of genes that occur without change in the DNA sequence.

epinephrine (ep i nef' rin) [Gk. *epi*: over + *nephros*: kidney] The "fight or flight" hormone produced by the medulla of the adrenal gland; it also functions as a neurotransmitter. (Also known as adrenaline.)

epistasis Interaction between genes in which the presence of a particular allele of one gene determines whether another gene will be expressed.

epithelium A type of animal tissue made up of sheets of cells that lines or covers organs, makes up tubules, and covers the surface of the body; one of the four major tissue types in multicellular animals.

epitope See antigenic determinant.

equilibrium Any state of balanced opposing forces and no net change.

equilibrium potential The membrane potential at which an ion is at electrochemical equilibrium, i.e., there is no net flux of the ion across the membrane.

ER See endoplasmic reticulum.

erection The process by which a penis becomes enlarged and engorged with blood.

error signal In regulatory systems, any difference between the set point of the system and its current condition.

erythrocyte (ur rith' row site) [Gk. *erythros*: red + *kytos*: container] A red blood cell.

erythropoietin A hormone produced by the kidney in response to lack of oxygen that stimulates the production of red blood cells.

esophagus (i soff' i gus) [Gk. *oisophagos*: gullet] That part of the gut between the pharynx and the stomach.

essential amino acids Amino acids that an animal cannot synthesize for itself and must obtain from its food.

essential element A mineral nutrient required for normal growth and reproduction in plants and animals.

essential fatty acids Fatty acids that an animal cannot synthesize for itself and must obtain from its food.

essential mineral See essential element.

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids are formed in this way.

estivation (ess tuh vay' shun) [L. *aestivalis*: summer] A state of dormancy and hypometabolism that occurs during the summer; usually a means of surviving drought and/or intense heat. (Contrast with hibernation.)

estrogen Any of several steroid sex hormones; produced chiefly by the ovaries in mammals.

estrus (es' trus) [L. *oestrus*: frenzy] The period of heat, or maximum sexual receptivity, in some female mammals. Ordinarily,

the estrus is also the time of release of eggs in the female.

ethology [Gk. *ethos*: character + *logos*: study] An approach to the study of animal behavior that focuses on studying many species in natural environments and addresses questions about the evolution of behavior. (Compare with behaviorism.)

ethylene One of the plant growth hormones, the gas $H_2C=CH_2$. Involved in fruit ripening and other growth and developmental responses.

dicots Angiosperms with two embryonic cotyledons; one of the two largest clades of angiosperms. (See also monocots.)

Eukarya One of the three domains of life; organisms made up of one or more eukaryotic cells. (See also eukaryotes.)

eukaryotes (yew car' ree oats) [Gk. *eu*: true + *karyon*: kernel or nucleus] Organisms whose cells contain their genetic material inside a nucleus. Includes all life other than the viruses, archaea, and bacteria. (Contrast with prokaryotes.)

eusocial Pertaining to a social group that includes nonreproductive individuals, as in honey bees.

eustachian tube A connection between the middle ear and the throat that allows air pressure to equilibrate between the middle ear and the outside world.

eutrophication (yoo trofe' ik ay' shun) [Gk. *eu*: truly + *trephein*: to flourish] The addition of nutrient materials to a body of water, resulting in changes in ecological processes and species composition therein.

evaporation The transition of water from the liquid to the gaseous phase.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution; contrast with speciation.)

evolutionary developmental biology (evo-devo) The study of the interplay between evolutionary and developmental processes, with a focus on the genetic changes that give rise to novel morphology. Key concepts of evo-devo include modularity, genetic toolkits, genetic switches, and heterochrony.

evolutionary radiation The proliferation of many species within a single evolutionary lineage.

evolutionary reversal The reappearance of an ancestral trait in a group that had previously acquired a derived trait.

evolutionary theory The understanding and application of the mechanisms of evolutionary change to biological problems.

excitatory Input from a neuron that causes depolarization of the recipient cell.

excited state The state of an atom or molecule when, after absorbing energy, it has more energy than in its normal, ground state.

excretion Release of metabolic wastes by an organism.

excretory systems In animals, organs that maintain the volume, solute concentration, and composition of the extracellular fluid by excreting water, solutes, and nitrogenous wastes in the form of urine.

exergonic A chemical reaction in which the products of the reaction have lower free energy than the reactants, resulting in a release of free energy. (Contrast with endergonic.)

exocrine gland (eks' oh krin) [Gk. *exo*: outside + *krinein*: to separate] Any gland, such as a salivary gland, that secretes to the outside of the body or into the gut. (Contrast with endocrine gland.)

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

exon A portion of a DNA molecule, in eukaryotes, that codes for part of a polypeptide. (Contrast with intron.)

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

exotoxin A highly toxic, usually soluble protein released by living, multiplying bacteria. (Contrast with endotoxin.)

experiment A testing process to support or disprove hypotheses and to answer questions. The basis of the scientific method. See comparative experiment, controlled experiment.

expiratory reserve volume The amount of air that can be forcefully exhaled beyond the normal tidal expiration. (Contrast with inspiratory reserve volume, tidal volume, vital capacity.)

exponential growth See multiplicative growth.

expression vector A DNA vector, such as a plasmid, that carries a DNA sequence for the expression of an inserted gene into mRNA and protein in a host cell.

expressivity The degree to which a genotype is expressed in the phenotype; may be affected by the environment.

extensor A muscle that extends an appendage.

external fertilization The release of gametes into the environment; typical of aquatic animals. Also called spawning. (Contrast with internal fertilization.)

external gills Highly branched and folded extensions of the body surface that provide a large surface area for gas exchange with water; typical of larval amphibians and many larval insects.

extinction The termination of a lineage of organisms.

extracellular matrix A material of heterogeneous composition surrounding cells and performing many functions including adhesion of cells.

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups phylogenetically as amniotes. (See amnion, allantois, chorion, and yolk sac.)

extreme halophiles A group of euryarchaeotes that live exclusively in very salty environments.

extremophiles Archaea and bacteria that live and thrive under conditions (e.g., extremely high temperatures) that would kill most organisms.

eye cups Photosensory organs in flatworms; components of one of the simplest visual systems in animals.

- F -

F-box A protein domain that facilitates protein-protein interactions necessary for protein degradation. Often involved in the regulation of gene expression (through the breakdown of regulatory proteins such as repressors), especially in plants.

F₁ The first filial generation; the immediate progeny of a parental (P) mating.

F₂ The second filial generation; the immediate progeny of a mating between members of the F₁ generation.

facilitated diffusion Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, diffusion.)

facultative anaerobe A prokaryote that can shift its metabolism between anaerobic and aerobic modes depending on the presence or absence of O₂. (Alternatively, facultative aerobe.)

fast-twitch fibers Skeletal muscle fibers that can generate high tension rapidly, but fatigue rapidly ("sprinter" fibers). Characterized by an abundance of enzymes of glycolysis. (Compare to slow-twitch fibers.)

fat A triglyceride that is solid at room temperature. (Contrast with oil.)

fate map A diagram of the blastula showing which cells (blastomeres) are "fated" to contribute to specific tissues and organs in the mature body.

fatty acid A molecule made up of a long nonpolar hydrocarbon chain and a polar carboxyl group. Found in many lipids.

fauna (faw' nah) All the animals found in a given area. (Contrast with flora.)

FD (FLOWERING LOCUS D) Gene coding for a transcription factor in the shoot apical meristem that binds to florigen (FT); involved in the induction of flowering.

feces [L. *faeces*: dregs] Waste excreted from the digestive system.

fecundity (m_x) The average number of offspring produced by each female.

feedback information In regulatory systems, information about the relationship

between the set point of the system and its current state.

feedback inhibition A mechanism for regulating a metabolic pathway in which the end product of the pathway can bind to and inhibit the enzyme that catalyzes the first committed step in the pathway. Also called end-product inhibition.

feedforward information In regulatory systems, information that changes the set point of the system.

fermentation (fur men tay' shun) [L. *fermentum*: yeast] The anaerobic degradation of a substance such as glucose to smaller molecules such as lactic acid or alcohol with the extraction of energy.

fertilization Union of gametes. Also known as syngamy.

fertilizer Any of a number of substances added to soil to improve the soil's capacity to support plant growth. May be organic or inorganic.

fetus Medical and legal term for the stages of a developing human embryo from about the eighth week of pregnancy (the point at which all major organ systems have formed) to the moment of birth.

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves as a support function in xylem. (See also muscle fiber.)

fibrin A protein that polymerizes to form long threads that provide structure to a blood clot.

fibrinogen A circulating protein that can be stimulated to fall out of solution and provide the structure for a blood clot.

fibrous root system A root system typical of monocots composed of numerous thin adventitious roots that are all roughly equal in diameter. (Contrast with taproot system.)

Fick's law of diffusion An equation that describes the factors that determine the rate of diffusion of a molecule from an area of higher concentration to an area of lower concentration.

fight-or-flight response A rapid physiological response to a sudden threat mediated by the hormone epinephrine.

filament In flowers, the part of a stamen that supports the anther.

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device.

first filial generation See F_1 .

first law of thermodynamics The principle that energy can be neither created nor destroyed.

first polar body In oogenesis, the daughter cell of the first meiotic division that receives almost no cytoplasm.

fission See binary fission.

fitness The contribution of a genotype or phenotype to the genetic composition of subsequent generations, relative to the

contribution of other genotypes or phenotypes. (See also inclusive fitness.)

fixed action pattern In ethology, a genetically determined behavior that is performed without learning, stereotypic (performed the same way each time), and not modifiable by learning.

flagellum (fla jell' um) (plural: flagella) [L. *flagellum*: whip] Long, whiplike appendage that propels cells. Prokaryotic flagella differ sharply from those found in eukaryotes.

flexor A muscle that flexes an appendage.

flora (flore' ah) All of the plants found in a given area. (Contrast with fauna.)

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

floral organ identity genes In angiosperms, genes that determine the fates of floral meristem cells; their expression is triggered by the products of meristem identity genes.

florigen A plant hormone involved in the conversion of a vegetative shoot apex to a flower.

flower The sexual structure of an angiosperm.

fluid feeder An animal that feeds on fluids it extracts from the bodies of other organisms; examples include nectar-feeding birds and blood-sucking insects.

fluid mosaic model A molecular model for the structure of biological membranes consisting of a fluid phospholipid bilayer in which suspended proteins are free to move in the plane of the bilayer.

flux In ecology, the flow of an element into or out of a compartment of the biosphere.

follicle [L. *folliculus*: little bag] In female mammals, an immature egg surrounded by nutritive cells.

follicle-stimulating hormone (FSH) A gonadotropin produced by the anterior pituitary.

food vacuole Membrane-enclosed structure formed by phagocytosis in which engulfed food particles are digested by the action of lysosomal enzymes.

food web The complete set of food links between species in a community; a diagram indicating which ones are the eaters and which are eaten.

forebrain The region of the vertebrate brain that comprises the cerebrum, thalamus, and hypothalamus.

fossil Any recognizable structure originating from an organism, or any impression from such a structure, that has been preserved over geological time.

fossil fuels Fuels, including oil, natural gas, coal, and peat, formed over geologic time from organic material buried in anaerobic sediments.

founder effect Random changes in allele frequencies resulting from establishment

of a population by a very small number of individuals.

fovea [L. *fovea*: a small pit] In the vertebrate retina, the area of most distinct vision.

frame-shift mutation The addition or deletion of a single or two adjacent nucleotides in a gene's sequence. Results in the misreading of mRNA during translation and the production of a nonfunctional protein. (Contrast with missense mutation, nonsense mutation, silent mutation.)

Frank-Starling law The stroke volume of the heart increases with increased return of blood to the heart.

free energy (G) Energy that is available for doing useful work, after allowance has been made for the increase or decrease of disorder.

frontal lobe The largest of the brain lobes in humans; involved with feeling and planning functions; includes the primary motor cortex.

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

FT (FLOWERING LOCUS T) Gene that codes for florigen, a small, diffusible protein involved in the induction of flowering.

functional genomics The assignment of functional roles to the proteins encoded by genes identified by sequencing entire genomes.

functional group A characteristic combination of atoms that contribute specific properties when attached to larger molecules.

- G -

G cap A chemically modified GTP added to the 5' end of mRNA; facilitates binding of mRNA to ribosome and prevents mRNA breakdown.

G protein A membrane protein involved in signal transduction; characterized by binding GDP or GTP.

G protein-linked receptors A class of receptors that change configuration upon ligand binding such that a G protein binding site is exposed on the cytoplasmic domain of the receptor, initiating a signal transduction pathway.

G1 In the cell cycle, the gap between the end of mitosis and the onset of the S phase.

G1-S transition In the cell cycle, the point at which G1 ends and the S phase begins.

G2 In the cell cycle, the gap between the S (synthesis) phase and the onset of mitosis.

gain of function mutation A mutation that results in a protein with a new function. (Contrast with loss of function mutation.)

gallbladder In the human digestive system, an organ in which bile is stored.

gametangium (gam uh tan' gee um) (plural: gametangia) [Gk. *gamos*: marriage + *angeion*: vessel] Any plant or fungal structure within which a gamete is formed.

gamete (gam' eet) [Gk. *gamete/gametes*: wife, husband] The mature sexual reproductive cell: the egg or the sperm.

gametogenesis (ga meet' oh jen' e sis) The specialized series of cellular divisions that leads to the production of gametes. (See also oogenesis, spermatogenesis.)

gametophyte (ga meet' oh fyte) In plants and photosynthetic protists with alternation of generations, the multicellular haploid phase that produces the gametes. (Contrast with sporophyte.)

ganglion (gang' glee un) (plural: ganglia) [Gk. tumor] A cluster of neurons that have similar characteristics or function.

ganglion cells Cells at the front of the human retina that transmit information from the bipolar cells to the brain.

gap genes In *Drosophila* (fruit fly) development, segmentation genes that define broad areas along the anterior–posterior axis of the early embryo. Part of a developmental cascade that includes maternal effect genes, pair rule genes, segment polarity genes, and Hox genes.

gap junction A 2.7-nanometer gap between plasma membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

gastric pits Deep infoldings in the walls of the stomach lined with secretory cells.

gastrin A hormone secreted by cells in the lower region of the stomach that stimulates the secretion of digestive juices as well as movements of the stomach.

gastrovascular cavity Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

gastrulation Development of a blastula into a gastrula. In embryonic development, the process by which a blastula is transformed by massive movements of cells into a *gastrula*, an embryo with three germ layers and distinct body axes.

gated channel A membrane protein that changes its three-dimensional shape, and therefore its ion conductance, in response to a stimulus. When open, it allows specific ions to move across the membrane.

gel electrophoresis (e lek' tro fo ree' sis) [L. *electrum*: amber + Gk. *phorein*: to bear] A technique for separating molecules (such as DNA fragments) from one another on the basis of their electric charges and molecular weights by applying an electric field to a gel.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

gene duplication The generation of extra copies of a gene in a genome over evolutionary time. A mechanism by which genomes can acquire new functions.

gene family A set of similar genes derived from a single parent gene; need not be on the same chromosomes. The vertebrate globin genes constitute a classic example of a gene family.

gene flow Exchange of genes between populations through migration of individuals or movements of gametes.

gene pool All of the different alleles of all of the genes existing in all individuals of a population.

gene tree A graphic representation of the evolutionary relationships of a single gene in different species or of the members of a gene family.

gene-for-gene resistance In plants, a mechanism of resistance to pathogens in which resistance is triggered by the specific interaction of the products of a pathogen's *Avr* genes and a plant's *R* genes.

general transcription factors In eukaryotes, transcription factors that bind to the promoters of most protein-coding genes and are required for their expression. Distinct from transcription factors that have specific regulatory effects only at certain promoters or classes of promoters.

genetic code The set of instructions, in the form of nucleotide triplets, that translate a linear sequence of nucleotides in mRNA into a linear sequence of amino acids in a protein.

genetic drift Changes in gene frequencies from generation to generation as a result of random (chance) processes.

genetic linkage Association between genes on the same chromosome such that they do not show random assortment and seldom recombine; the closer the genes, the lower the frequency of recombination.

genetic map The positions of genes along a chromosome as revealed by recombination frequencies.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated with the presence of other linked genes on that chromosome.

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

genetic structure The frequencies of different alleles at each locus and the frequencies of different genotypes in a Mendelian population.

genetic switches Mechanisms that control how the genetic toolkit is used, such as promoters and the transcription factors that bind them. The signal cascades that converge on and operate these switches

determine when and where genes will be turned on and off.

genetic toolkit A set of developmental genes and proteins that is common to most animals and is hypothesized to be responsible for the evolution of their differing developmental pathways.

genetics The scientific study of the structure, functioning, and inheritance of genes, the units of hereditary information.

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

genomic equivalence The principle that no information is lost from the nuclei of cells as they pass through the early stages of embryonic development.

genomic library All of the cloned DNA fragments generated by the breakdown of genomic DNA into smaller segments.

genomics The scientific study of entire sets of genes and their interactions.

genotype (jean' oh type) [Gk. *gen*: to produce + *typos*: impression] An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

genotype frequency The proportion of a genotype among individuals in a population.

genus (jean' us) (plural: genera) [Gk. *genos*: stock, kind] A group of related, similar species recognized by taxonomists with a distinct name used in binomial nomenclature.

geographic range The region within which a species occurs.

germ cell [L. *germen*: to beget] A reproductive cell or gamete of a multicellular organism. (Contrast with somatic cell.)

germ layers The three embryonic layers formed during gastrulation (ectoderm, mesoderm, and endoderm). Also called cell layers or tissue layers.

germ line mutation Mutation in a cell that produces gametes (i.e., a germ line cell). (Contrast with somatic mutation.)

germination Sprouting of a seed or spore.

gestation (jes tay' shun) [L. *gestare*: to bear] The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

ghrelin A hormone produced and secreted by cells in the stomach that stimulates appetite.

gibberellin (jib er el' lin) A class of plant growth hormones playing roles in stem elongation, seed germination, flowering of certain plants, etc.

gill An organ specialized for gas exchange with water.

gizzard (giz' erd) [L. *gigeria*: cooked chicken parts] The second of two stomachlike organs in birds, other reptiles, earthworms, and various insects, that grinds up food,

sometimes with the aid of fragments of stone. (*See also* crop.)

glia (glee' uh) [Gk. *glia*: glue] Cells of the nervous system that do not conduct action potentials.

glomerular filtration rate (GFR) The rate at which the blood is filtered in the glomeruli of the kidney.

glomerulus (glo mare' yew lus) [L. *glomus*: ball] Sites in the kidney where blood filtration takes place. Each glomerulus consists of a knot of capillaries served by afferent and efferent arterioles.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

glucocorticoids One of two main types of corticosteroid hormones. Produced and released by the cortex of the adrenal gland and involved in regulating blood glucose and fat, protein, and carbohydrate metabolism. (*See also* mineralocorticoids.)

gluconeogenesis The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

glucose [Gk. *gleukos*: sugar, sweet] The most common monosaccharide; the monomer of the polysaccharides starch, glycogen, and cellulose.

glyceraldehyde 3-phosphate (G3P) A phosphorylated three-carbon sugar; an intermediate in glycolysis and photosynthetic carbon fixation.

glycerol (gliss' er ole) A three-carbon alcohol with three hydroxyl groups; a component of phospholipids and triglycerides.

glycogen (gly' ko jen) An energy storage polysaccharide found in animals and fungi; a branched-chain polymer of glucose, similar to starch.

glycolipid A lipid to which sugars are attached.

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

glycoprotein A protein to which sugars are attached.

glycosidic linkage Bond between carbohydrate (sugar) molecules through an intervening oxygen atom (–O–).

glycosylation The addition of carbohydrates to another type of molecule, such as a protein.

glyoxysome (gly ox' ee soam) An organelle found in plants, in which stored lipids are converted to carbohydrates.

Golgi apparatus (goal' jee) A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells; functions in secretion from the cell by exocytosis.

gonad (go' nad) [Gk. *gone*: seed] An organ that produces gametes in animals: either an ovary (female gonad) or testis (male gonad).

gonadotropin A type of trophic hormone that stimulates the gonads.

gonadotropin-releasing hormone (GnRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to secrete ("release") gonadotropins.

Gondwana The large southern land mass that existed from the Cambrian (540 mya) to the Jurassic (138 mya). Present-day remnants are South America, Africa, India, Australia, and Antarctica.

graded membrane potentials Small local changes in membrane potential caused by opening or closing of ion channels.

grafting Artificial transplantation of tissue from one organism to another. In horticulture, the transfer of a bud or stem segment from one plant onto the root of another as a form of asexual reproduction.

Gram stain A differential purple stain useful in characterizing bacteria. The peptidoglycan-rich cell walls of Gram-positive bacteria stain purple; cell walls of Gram-negative bacteria generally stain orange.

gravitropism [Gk. *tropos*: to turn] A directed plant growth response to gravity.

gray crescent In frog development, a band of diffusely pigmented cytoplasm on the side of the egg opposite the site of sperm entry. Arises as a result of cytoplasmic rearrangements that establish the anterior–posterior axis of the zygote.

gray matter In the nervous system, tissue that is rich in neuronal cell bodies. (Contrast with white matter.)

greenhouse effect The warming of Earth that results from retention of heat in its atmosphere; caused by the presence of greenhouse gases in the atmosphere.

greenhouse gases Gases in the atmosphere, such as carbon dioxide and methane, that are transparent to sunlight, but trap heat radiating from Earth's surface, causing heat to build up at Earth's surface.

gross primary productivity (GPP) The rate at which the primary producers in a community turn solar energy into stored chemical energy via photosynthesis.

ground meristem That part of an apical meristem that gives rise to the ground tissue system of the primary plant body.

ground tissue system Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

growth An increase in the size of the body and its organs by cell division and cell expansion.

growth factor A chemical signal that stimulates cells to divide.

growth hormone A peptide hormone released by the anterior pituitary that stimulates many anabolic processes.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

guard cells In plants, specialized, paired epidermal cells that surround and control the opening of a stoma (pore). *See* stoma.

gustation The sense of taste.

gut An animal's digestive tract.

gymnosperms Seed plants that do not produce flowers or fruits; one of the two major groups of living seed plants. (*See also* angiosperms.)

- H -

habitat patches Areas of suitable habitat for a species that are separated by areas of unsuitable habitat.

habitat The particular environment in which an organism lives. A *habitat patch* is an area of a particular habitat surrounded by other habitat types that may be less suitable for that organism.

Hadley cells Patterns of vertical atmospheric circulation that influence surface winds and precipitation patterns according to latitude.

hair cell A type of mechanoreceptor in animals. Detects sound waves and other forms of motion in air or water.

half-life The time required for half of a sample of a radioactive isotope to decay to its stable, nonradioactive form, or for a drug or other substance to reach half its initial dosage.

halophyte (hal' oh fyte) [Gk. *halos*: salt + *phyton*: plant] A plant that grows in a saline (salty) environment.

Hamilton's rule The principle that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness of the performer and the recipient must be greater than the cost to the performer.

haplodiploidy A sex determination mechanism in which diploid individuals (which develop from fertilized eggs) are female and haploid individuals (which develop from unfertilized eggs) are male; typical of hymenopterans.

haploid (hap' loid) [Gk. *haploides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated $1n$ or n . (Contrast with diploid.)

haplotype Linked nucleotide sequences that are usually inherited as a unit (as a "sentence" rather than as individual "words").

Hardy-Weinberg equilibrium In a sexually reproducing population, the allele frequency at a given locus that is not being acted on by agents of evolution; the conditions that would result in no evolution in a population.

haustorium (haw stor' ee um) (plural: haustoria)[L. *haustus*: draw up] A specialized hypha or other structure by which fungi and some parasitic plants draw nutrients from a host plant.

heart In circulatory systems, a muscular pump that moves extracellular fluid around the body.

heat budget equation An expression of the balance between thermal energy flowing into the body of an animal from the environment and from metabolism, and the thermal energy leaving the body.

heat of vaporization The energy that must be supplied to convert a molecule from a liquid to a gas at its boiling point.

heat shock proteins Chaperone proteins expressed in cells exposed to high or low temperatures or other forms of environmental stress.

helical Shaped like a screw or spring (helix); this shape occurs in DNA and proteins.

helper T cells See T-helper cells.

hemiparasite A parasitic plant that can photosynthesize, but derives water and mineral nutrients from the living body of another plant. (Contrast with holoparasite.)

hemizygous (hem' ee zie' gus) [Gk. *hemi*: half + *zygotos*: joined] In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

hemoglobin (hee' mo glow bin) [Gk. *haema*: blood + L. *globus*: globe] Oxygen-transporting protein found in the red blood cells of vertebrates (and found in some invertebrates).

Hensen's node In avian embryos, a structure at the anterior end of the primitive groove; determines the fates of cells passing over it during gastrulation.

hepatic (heh pat' ik) [Gk. *hepar*: liver] Pertaining to the liver.

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

heritable trait A trait that is at least partly determined by genes.

hermaphroditism (her maf' row dite ism) The coexistence of both female and male sex organs in the same organism.

hetero- [Gk.: *heteros*: other, different] A prefix indicating two or more different conditions, structures, or processes. (Contrast with homo-.)

heterochrony Alteration in the timing of developmental events, leading to different results in the adult organism.

heterocyst A large, thick-walled cell type in the filaments of certain cyanobacteria that performs nitrogen fixation.

heteromorphic (het' er oh more' fik) [Gk. *heteros*: different + *morphe*: form] Having a different form or appearance, as two heteromorphic life stages of a plant. (Contrast with isomorphic.)

heterosis The superior fitness of heterozygous offspring as compared with that of their dissimilar homozygous parents. Also called hybrid vigor.

heterosporous (het' er os' por us) Producing two types of spores, one of which gives rise to a female megaspore and the other to a male microspore. (Contrast with homosporous.)

heterotroph (het' er oh trof) [Gk. *heteros*: different + *trophe*: feed] An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

heterotypic Pertaining to adhesion of cells of different types.

heterozygous (het' er oh zie' gus) [Gk. *heteros*: different + *zygotos*: joined] In diploid organisms, having different alleles of a given gene on the pair of homologs carrying that gene. (Contrast with homozygous.)

heterozygous carrier An individual that carries a recessive allele for a phenotype of interest (e.g., a genetic disease); the individual does not show the phenotype, but may have progeny with the phenotype if the other parent also carries the recessive allele.

hexose [Gk. *hex*: six] A sugar containing six carbon atoms.

hibernation [L. *hibernum*: winter] The state of inactivity of some animals during winter; marked by a drop in body temperature and metabolic rate. (Contrast with estivation)

high-density lipoproteins (HDLs) Lipoproteins that remove cholesterol from tissues and carry it to the liver; HDLs are the "good" lipoproteins associated with good cardiovascular health.

highly repetitive sequences Short (less than 100 bp), nontranscribed DNA sequences, repeated thousands of times in tandem arrangements.

hindbrain The region of the developing vertebrate brain that gives rise to the medulla, pons, and cerebellum.

hippocampus [Gk. sea horse] A part of the forebrain that takes part in long-term memory formation.

histamine (hiss' tah meen) A substance released by damaged tissue, or by mast cells in response to allergens. Histamine increases vascular permeability, leading to edema (swelling). (Contrast with histone deacetylase.)

histone acetyltransferases Enzymes involved in chromatin remodeling. Add acetyl groups to the tail regions of histone proteins.

histone Any one of a group of proteins forming the core of a nucleosome, the structural unit of a eukaryotic chromosome.

histone deacetylase In chromatin remodeling, an enzyme that removes acetyl groups from the tails of histone proteins. (Contrast with histone acetyltransferases.)

HIV Human immunodeficiency virus, the retrovirus that causes acquired immune deficiency syndrome (AIDS).

holoparasite A fully parasitic plant (i.e., one that does not perform photosynthesis).

homeobox 180-base-pair segment of DNA found in certain homeotic genes; regulates the expression of other genes and thus controls large-scale developmental processes.

homeostasis (home' ee o sta' sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature, by means of physiological or behavioral feedback responses.

homeotic genes Genes that act during development to determine the formation of an organ from a region of the embryo.

homeotic mutation Mutation in a homeotic gene that results in the formation of a different organ than that normally made by a region of the embryo.

homing In animal navigation, the ability to return to a nest site, burrow, or other specific location.

homo- [Gk. *homos*: same] A prefix indicating two or more similar conditions, structures, or processes. (Contrast with hetero-.)

homolog (1) In cytogenetics, one of a pair (or larger set) of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent. (2) In evolutionary biology, one of two or more features in different species that are similar by reason of descent from a common ancestor.

homologous pair A pair of matching chromosomes made up of a chromosome from each of the two sets of chromosomes in a diploid organism.

homologous recombination Exchange of segments between two DNA molecules based on sequence similarity between the two molecules. The similar sequences align and crossover. Used to create knockout mutants in mice and other organisms.

homology (ho mol' o jee) [Gk. *homologia*: of one mind; agreement] A similarity between two or more features that is due to inheritance from a common ancestor. The structures are said to be *homologous*, and each is a *homolog* of the others.

homoplasy (home' uh play zee) [Gk. *homos*: same + *plastikos*: shape, mold] The presence in multiple groups of a trait that is not inherited from the common ancestor of those groups. Can result from convergent evolution, evolutionary reversal, or parallel evolution.

homosporous Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterosporous.)

homozygous (home' oh zie' gus) [Gk. *homos*: same + *zygotos*: joined] In diploid organisms, having identical alleles of a given gene on both homologous chromosomes. An individual may be a homozygote

with respect to one gene and a heterozygote with respect to another. (Contrast with heterozygous.)

horizons The horizontal layers of a soil profile, including the topsoil (A horizon), subsoil (B horizon) and parent rock or bedrock (C horizon).

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

host An organism that harbors a parasite or symbiont and provides it with nourishment.

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal groups. Hox genes contain the homeobox domain and specify pattern and axis formation in these animals.

human chorionic gonadotropin (hCG) A hormone secreted by the placenta which sustains the corpus luteum and helps maintain pregnancy.

Human Genome Project A publicly and privately funded research effort, successfully completed in 2003, to produce a complete DNA sequence for the entire human genome.

humoral immune response The response of the immune system mediated by B cells that produces circulating antibodies active against extracellular bacterial and viral infections. (Contrast with cellular immune response.)

humus (hew' mus) The partly decomposed remains of plants and animals on the surface of a soil.

hybrid (high' brid) [L. *hybrida*: mongrel] (1) The offspring of genetically dissimilar parents. (2) In molecular biology, a double helix formed of nucleic acids from different sources.

hybrid vigor See heterosis.

hybrid zone A region of overlap in the ranges of two closely related species where the species may hybridize.

hybridize (1) In genetics, to combine the genetic material of two distinct species or of two distinguishable populations within a species. (2) In molecular biology, to form a double-stranded nucleic acid in which the two strands originate from different sources.

hydrocarbon A compound containing only carbon and hydrogen atoms.

hydrogen bond A weak electrostatic bond which arises from the attraction between the slight positive charge on a hydrogen atom and a slight negative charge on a nearby oxygen or nitrogen atom.

hydrological cycle The movement of water from the oceans to the atmosphere, to the soil, and back to the oceans.

hydrolysis reaction (high drol' uh sis) [Gk. *hydro*: water + *lysis*: break apart] A chemical reaction that breaks a bond by inserting the components of water (AB +

H₂O → AH + BOH). (Contrast with condensation reaction.)

hydrophilic (high dro fill' ik) [Gk. *hydro*: water + *philia*: love] Having an affinity for water. (Contrast with hydrophobic.)

hydrophobic (high dro foe' bik) [Gk. *hydro*: water + *phobia*: fear] Having no affinity for water. Uncharged and nonpolar groups of atoms are hydrophobic. (Contrast with hydrophilic.)

hydroponic Pertaining to a method of growing plants with their roots suspended in nutrient solutions instead of soil.

hydrostatic pressure Pressure generated by compression of liquid in a confined space. Generated in plants, fungi, and some protists with cell walls by the osmotic uptake of water. Generated in animals with closed circulatory systems by the beating of a heart.

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

hydroxyl group The —OH group found on alcohols and sugars.

hyper- [Gk. *hyper*: above, over] Prefix indicating above, higher, more. (Contrast with hypo-.)

hyperaccumulators Species of plants that store large quantities of heavy metals such as arsenic, cadmium, nickel, aluminum, and zinc.

hyperpolarization A change in the resting potential across a membrane so that the inside of a cell becomes more negative compared with the outside of the cell. (Contrast with depolarization.)

hypersensitive response A defensive response of plants to microbial infection in which phytoalexins and pathogenesis-related proteins are produced and the infected tissue undergoes apoptosis to isolate the pathogen from the rest of the plant.

hypertonic Having a greater solute concentration. Said of one solution compared with another. (Contrast with hypotonic, isotonic.)

hypha (high' fuh) (plural: hyphae) [Gk. *hyphē*: web] In the fungi and oomycetes, any single filament.

hypo- [Gk. *hypo*: beneath, under] Prefix indicating underneath, below, less. (Contrast with hyper-.)

hypoblast The lower tissue portion of the avian blastula which is joined to the epiblast at the margins of the blastodisc.

hypothalamus The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

hypothesis A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

hypotonic Having a lesser solute concentration. Said of one solution in comparing

it to another. (Contrast with hypertonic, isotonic.)

hypoxia A deficiency of oxygen.

- I -

ileum The final segment of the small intestine. (See also duodenum, jejunum.)

imbibition Water uptake by a seed; first step in germination.

immediate memory A form of memory for events happening in the present that is almost perfectly photographic, but lasts only seconds.

immune system [L. *immunis*: exempt from] A system in an animal that recognizes and attempts to eliminate or neutralize foreign substances such as bacteria, viruses, and pollutants.

immunity In animals, the ability to avoid disease when invaded by a pathogen by deploying various defense mechanisms.

immunoassay The use of antibodies to measure the concentration of an antigen in a sample.

immunoglobulins A class of proteins containing a tetramer consisting of four polypeptide chains—two identical light chains and two identical heavy chains—held together by disulfide bonds; active as receptors and effectors in the immune system.

immunological memory The capacity to more rapidly and massively respond to a second exposure to an antigen than occurred on first exposure.

imperfect flower A flower lacking either functional stamens or functional carpels. (Contrast with perfect flower.)

implantation The process by which the early mammalian embryo becomes attached to and embedded in the lining of the uterus.

imprinting In animal behavior, a rapid form of learning in which an animal learns, during a brief critical period, to make a particular response, which is maintained for life, to some object or other organism.

in vitro [L. in glass] A biological process occurring outside of the organism, in the laboratory. (Contrast with in vivo.)

in vitro evolution A method based on natural molecular evolution that uses artificial selection in the laboratory to rapidly produce molecules with novel enzymatic and binding functions.

in vivo [L. alive] A biological process occurring within a living organism or cell. (Contrast with in vitro.)

inbreeding Breeding among close relatives.

inclusive fitness The sum of an individual's genetic contribution to subsequent generations both via production of its own offspring and via its influence on the survival of relatives who are not direct descendants.

incomplete cleavage A pattern of cleavage that occurs in many eggs that have a lot of yolk, in which the cleavage furrows do not penetrate all of it. (See also discoidal

cleavage, superficial cleavage; contrast with complete cleavage.)

incomplete dominance Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

incomplete metamorphosis Insect development in which changes between instars are gradual.

independent assortment During meiosis, the random separation of genes carried on nonhomologous chromosomes into gametes so that inheritance of these genes is random. This principle was articulated by Mendel as his second law.

indeterminate growth A open-ended growth pattern in which an organism or organ continues to grow as long as it lives; characteristic of some animals and of plant shoots and roots. (Contrast with determinate growth.)

individual fitness That component of inclusive fitness resulting from an organism producing its own offspring. (Contrast with kin selection.)

induced fit A change in the shape of an enzyme caused by binding to its substrate that exposes the active site of the enzyme.

induced mutation A mutation resulting from exposure to a mutagen from outside the cell. (Contrast with spontaneous mutation.)

induced pluripotent stem cells (iPS cells) Multipotent or pluripotent animal stem cells produced from differentiated cells in vitro by the addition of several genes that are expressed.

induced responses Defensive responses that a plant produces only in the presence of a pathogen, in contrast to constitutive defenses, which are always present.

inducer (1) A compound that stimulates the synthesis of a protein. (2) In embryonic development, a substance that causes a group of target cells to differentiate in a particular way.

inducible genes Genes that are expressed only when their products are needed. (Contrast with constitutive genes.)

inducible Produced only in the presence of a particular compound or under particular circumstances. (Contrast with constitutive.)

induction In embryonic development, the process by which a factor produced and secreted by certain cells determines the fates of other cells.

inflammation A nonspecific defense against pathogens; characterized by redness, swelling, pain, and increased temperature.

inflorescence A structure composed of several to many flowers.

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

ingroup In a phylogenetic study, the group of organisms of primary interest. (Contrast with outgroup.)

inhibitor A substance that blocks a biological process.

inhibitory Input from a neuron that causes hyperpolarization of the recipient cell.

initiation complex In protein translation, a combination of a small ribosomal subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

initiation In molecular biology, the beginning of transcription or translation.

initiation site The place within a promoter where transcription begins.

innate immunity In animals, one of two general types of defenses against pathogens. Nonspecific and present in most animals. (Contrast with adaptive immunity.)

inner cell mass Derived from the mammalian blastula (blastocyst), the inner cell mass that will give rise to the yolk sac (via hypoblast) and embryo (via epiblast).

inorganic fertilizer A chemical or combination of chemicals applied to soil or plants to make up for a plant nutrient deficiency. Often contains the macronutrients nitrogen, phosphorus, and potassium (N-P-K).

inspiratory reserve volume The amount of air that can be inhaled above the normal tidal inspiration. (Contrast with expiratory reserve volume, tidal volume, vital capacity.)

instar (in' star) An immature stage of an insect between molts.

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

integral membrane proteins Proteins that are at least partially embedded in the plasma membrane. (Contrast with peripheral membrane proteins.)

integrin In animals, a transmembrane protein that mediates the attachment of epithelial cells to the extracellular matrix.

integument [L. *integumentum*: covering] A protective surface structure. In gymnosperms and angiosperms, a layer of tissue around the ovule which will become the seed coat.

intercostal muscles Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

interference RNA (RNAi) See RNA interference.

interferon A glycoprotein produced by virus-infected animal cells; increases the resistance of neighboring cells to the virus.

intermediate filaments Components of the cytoskeleton whose diameters fall between those of the larger microtubules and those of the smaller microfilaments.

internal environment In multicellular organisms, the extracellular fluid surrounding the cells.

internal fertilization The release of sperm into the female reproductive tract; typical of most terrestrial animals. (Contrast with external fertilization.)

internal gills Gills enclosed in protective body cavities; typical of mollusks, arthropods, and fishes.

interneuron A neuron that communicates information between two other neurons.

internode The region between two nodes of a plant stem.

interphase In the cell cycle, the period between successive nuclear divisions during which the chromosomes are diffuse and the nuclear envelope is intact. During interphase the cell is most active in transcribing and translating genetic information.

interspecific competition Competition between members of two or more species. (Contrast with intraspecific competition.)

interspecific interactions Interactions between members of different species.

interstitial fluid Extracellular fluid that is not contained in the vessels of a circulatory system.

intertidal zone A nearshore region of oceans that is periodically exposed to the air as the tides rise and fall.

intestine The portion of the gut following the stomach, in which most digestion and absorption occurs.

intraspecific competition Competition among members of the same species. (Contrast with interspecific competition.)

intron Portion of a of a gene within the coding region that is transcribed into pre-mRNA but is spliced out prior to translation. (Contrast with exon.)

invasive species An exotic species that reproduces rapidly, spreads widely, and has negative effects on the native species of the region to which it has been introduced.

invasiveness The ability of a pathogen to multiply in a host's body. (Contrast with toxigenicity.)

inversion A rare 180° reversal of the order of genes within a segment of a chromosome.

involution Cell movements that occur during gastrulation of frog embryos, giving rise to the archenteron.

ion (eye' on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

ion exchange A process by which protons produced by a plant root displace mineral cations from clay particles in the surrounding soil.

ionic bond An electrostatic attraction between positively and negatively charged ions.

ionotropic receptors A receptor that directly alters membrane permeability to a type of ion when it combines with its ligand.

iris (eye' ris) [Gk. *iris*: rainbow] The round, pigmented membrane that surrounds the pupil of the eye and adjusts its aperture to regulate the amount of light entering the eye.

island biogeography A theory proposing that the number of species on an island (or in another geographically defined and isolated area) represents a balance, or equilibrium, between the rate at which species immigrate to the island and the rate at which resident species go extinct.

islets of Langerhans Clusters of hormone-producing cells in the pancreas.

iso- [Gk. *iso*: equal] Prefix used for two separate entities that share some element of identity.

isomers Molecules consisting of the same numbers and kinds of atoms, but differing in the bonding patterns by which the atoms are held together.

isomorphic (eye so more' fik) [Gk. *isos*: equal + *morphe*: form] Having the same form or appearance, as when the haploid and diploid life stages of an organism appear identical. (Contrast with heteromorphic.)

isotonic Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

isotope (eye' so tope) [Gk. *isos*: equal + *topos*: place] Isotopes of a given chemical element have the same number of protons in their nuclei (and thus are in the same position on the periodic table), but differ in the number of neutrons.

isozymes Enzymes of an organism that have somewhat different amino acid sequences but catalyze the same reaction.

- J -

jasmonate Also called jasmonic acid, a plant hormone involved in triggering responses to pathogen attack as well as other processes.

jejunum (jih jew' num) The middle division of the small intestine, where most absorption of nutrients occurs. (*See also* duodenum, ileum.)

jelly coat The outer protective layer of a sea urchin egg, which triggers an acrosomal reaction in sperm.

joint In skeletal systems, a junction between two or more bones.

juvenile hormone In insects, a hormone maintaining larval growth and preventing maturation or pupation.

- K -

karyogamy The fusion of nuclei of two cells. (Contrast with plasmogamy.)

karyotype The number, forms, and types of chromosomes in a cell.

kidneys A pair of excretory organs in vertebrates.

kilocalorie (kcal) *See* calorie.

kin selection That component of inclusive fitness resulting from helping the survival of relatives containing the same alleles by descent from a common ancestor. (Contrast with individual fitness.)

kinase *See* protein kinase.

kinetic energy (kuh-net' ik) [Gk. *kinetos*: moving] The energy associated with movement. (Contrast with potential energy.)

kinetochore (kuh net' oh core) Specialized structure on a centromere to which microtubules attach.

knockout A molecular genetic method in which a single gene of an organism is permanently inactivated.

Koch's postulates A set of rules for establishing that a particular microorganism causes a particular disease.

Krebs cycle *See* citric acid cycle.

- L -

lagging strand In DNA replication, the daughter strand that is synthesized in discontinuous stretches. (*See* Okazaki fragments.)

large intestine *See* colon.

larva (plural: larvae) [L. *lares*: guiding spirits] An immature stage of any animal that differs dramatically in appearance from the adult.

lateral [L. *latus*: side] Pertaining to the side.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

lateral line A sensory system in fishes consisting of a canal filled with water and hair cells running down each side under the surface of the skin, which senses disturbances in the surrounding water.

lateral meristem Either of the two meristems, the vascular cambium and the cork cambium, that give rise to a plant's secondary growth.

lateral root A root extending outward from the taproot in a taproot system; typical of eudicots.

lateralization A phenomenon in humans in which language functions come to reside in one cerebral hemisphere, usually the left.

laticifers (luh tiss' uh furs) In some plants, elongated cells containing secondary plant products such as latex.

Laurasia The northernmost of the two large continents produced by the breakup of Pangaea.

law of independent assortment *See* independent assortment.

law of segregation *See* segregation.

laws of thermodynamics [Gk. *thermos*: heat + *dynamis*: power] Laws derived from studies of the physical properties of energy and the ways energy interacts with matter. (*See also* first law of thermodynamics, second law of thermodynamics.)

leaching In soils, a process by which mineral nutrients in upper soil horizons are dissolved in water and carried to deeper horizons, where they are unavailable to plant roots.

leading strand In DNA replication, the daughter strand that is synthesized continuously. (Contrast with lagging strand.)

leaf (plural: leaves) In plants, the chief organ of photosynthesis.

leaf primordium (plural: primordia) An outgrowth on the side of the shoot apical meristem that will eventually develop into a leaf.

leghemoglobin In nitrogen-fixing plants, an oxygen-carrying protein in the cytoplasm of nodule cells that transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

lek A display ground within which male animals compete for and defend small display areas as a means of demonstrating their territorial prowess and winning opportunities to mate.

lens In the vertebrate eye, a crystalline protein structure that makes fine adjustments in the focus of images falling on the retina.

lenticel (len' ti sill) In plants, a spongy region in the periderm that allows gas exchange.

leptin A hormone produced by fat cells that is believed to provide feedback information to the brain about the status of the body's fat reserves.

leukocyte *See* white blood cell.

lichen (lie' kun) An organism resulting from the symbiotic association of a fungus and either a cyanobacterium or a unicellular alga.

life cycle The entire span of the life of an organism from the moment of fertilization (or asexual generation) to the time it reproduces in turn.

life history strategy The way in which an organism partitions its time and energy among growth, maintenance, and reproduction.

life history The time course of growth and development, reproduction, and death during an average individual organism's life.

life table A summary of information about the progression of individuals in a population through the various stages of their life cycles.

ligament A band of connective tissue linking two bones in a joint.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

light reactions The initial phase of photosynthesis, in which light energy is converted into chemical energy.

light-harvesting complex In photosynthesis, a group of different molecules that cooperate to absorb light energy and transfer it to a reaction center. Also called *antenna system*.

lignin A complex, hydrophobic polyphenolic polymer in plant cell walls that cross-links other wall polymers, strengthening the walls, especially in wood.

limbic system A group of evolutionarily primitive structures in the vertebrate telencephalon that are involved in emotions, drives, instinctive behaviors, learning, and memory.

limnetic zone The open-water region of a lake.

lineage A series of populations, species, or genes descended from a single ancestor over evolutionary time.

lineage species concept The definition of a species as a branch on the tree of life, which has a history that starts at a speciation event and ends either at extinction or at another speciation event. (Contrast with biological species concept; morphological species concept.)

linkage See genetic linkage.

lipase (lip' ase; lye' pase) An enzyme that digests fats.

lipid (lip' id) [Gk. *lipos*: fat] Nonpolar, hydrophobic molecules that include fats, oils, waxes, steroids, and the phospholipids that make up biological membranes.

lipid bilayer See phospholipid bilayer.

lipoproteins Lipids packaged inside a covering of protein so that they can be circulated in the blood.

littoral zone The nearshore region of a lake that is shallow and is affected by wave action and fluctuations in water level.

liver A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

loam A type of soil consisting of a mixture of sand, silt, clay, and organic matter. One of the best soil types for agriculture.

locus (low' kus) (plural: loci, low' sigh) In genetics, a specific location on a chromosome. May be considered synonymous with *gene*.

logistic growth Growth, especially in the size of an organism or in the number of organisms in a population, that slows steadily as the entity approaches its maximum size. (Contrast with multiplicative growth.)

long-day plant (LDP) A plant that requires long days (actually, short nights) in order to flower. (Compare to short-day plant.)

long-term potentiation (LTP) A long-lasting increase in the responsiveness of a neuron resulting from a period of intense stimulation.

loop of Henle (hen' lee) Long, hairpin loop of the mammalian renal tubule that runs from the cortex down into the medulla

and back to the cortex; creates a concentration gradient in the interstitial fluids in the medulla.

lophophore A U-shaped fold of the body wall with hollow, ciliated tentacles that encircles the mouth of animals in several different groups. Used for filtering prey from the surrounding water.

loss of function mutation A mutation that results in the loss of a functional protein. (Contrast with gain of function mutation.)

low-density lipoproteins (LDLs) Lipoproteins that transport cholesterol around the body for use in biosynthesis and for storage; LDLs are the "bad" lipoproteins associated with a high risk of cardiovascular disease.

lumen (loo' men) [L. *lumen*: light] The open cavity inside any tubular organ or structure, such as the gut or a renal tubule.

lung An internal organ specialized for respiratory gas exchange with air.

luteinizing hormone (LH) A gonadotropin produced by the anterior pituitary that stimulates the gonads to produce sex hormones.

lymph [L. *lymphā*: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

lymph node A specialized structure in the vessels of the lymphatic system. Lymph nodes contain lymphocytes, which encounter and respond to foreign cells and molecules in the lymph as it passes through the vessels.

lymphatic system A system of vessels that returns interstitial fluid to the blood.

lymphocyte One of the two major classes of white blood cells; includes T cells, B cells, and other cell types important in the immune system.

lymphoid tissues Tissues of the immune system that are dispersed throughout the body, consisting of the thymus, spleen, bone marrow, and lymph nodes.

lysis (lie' sis) [Gk. *lysis*: break apart] Bursting of a cell.

lysogeny A form of viral replication in which the virus becomes incorporated into the host chromosome and remains inactive. Also called a lysogenic cycle. (Contrast with lytic cycle.)

lysosome (lie' so soam) [Gk. *lysis*: break away + *soma*: body] A membrane-enclosed organelle originating from the Golgi apparatus and containing hydrolytic enzymes. (Contrast with secondary lysosome.)

lysozyme (lie' so zyme) An enzyme in saliva, tears, and nasal secretions that hydrolyzes bacterial cell walls.

lytic cycle A viral reproductive cycle in which the virus takes over a host cell's synthetic machinery to replicate itself, then bursts (lyses) the host cell, releasing the new viruses. (Contrast with lysogeny.)

- M -

M phase The portion of the cell cycle in which mitosis takes place.

macroevolution [Gk. *makros*: large] Evolutionary changes occurring over long time spans and usually involving changes in many traits. (Contrast with microevolution.)

macromolecule A giant (molecular weight > 1,000) polymeric molecule. The macromolecules are the proteins, polysaccharides, and nucleic acids.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

macrophage (mac' roh faj) Phagocyte that engulfs pathogens by endocytosis.

maintenance methylase An enzyme that catalyzes the methylation of the new DNA strand when DNA is replicated.

major histocompatibility complex (MHC) A complex of linked genes, with multiple alleles, that control a number of cell surface antigens that identify self and can lead to graft rejection.

malnutrition A condition caused by lack of any essential nutrient.

Malpighian tubule (mal pee' gy un) A type of protonophridium found in insects.

map unit The distance between two genes as calculated from genetic crosses; a recombination frequency.

marine [L. *mare*: sea, ocean] Pertaining to or living in the ocean. (Contrast with aquatic, terrestrial.)

mass extinction A period of evolutionary history during which rates of extinction are much higher than during intervening times.

mass number The sum of the number of protons and neutrons in an atom's nucleus.

mast cells Cells, typically found in connective tissue, that release histamine in response to tissue damage.

maternal effect genes Genes coding for morphogens that determine the polarity of the egg and larva in fruit flies. Part of a developmental cascade that includes gap genes, pair rule genes, segment polarity genes, and Hox genes.

mating type A particular strain of a species that is incapable of sexual reproduction with another member of the same strain but capable of sexual reproduction with members of other strains of the same species.

maximum likelihood A statistical method of determining which of two or more hypotheses (such as phylogenetic trees) best fit the observed data, given an explicit model of how the data were generated.

mechanically gated channel A molecular channel that opens or closes in response to mechanical force applied to the plasma membrane in which it is inserted.

mechanoreceptor A cell that is sensitive to physical movement and generates action potentials in response.

medulla (meh dull' luh) (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brainstem that connects to the spinal cord.

medusa (plural: medusae) In cnidarians, a free-swimming, sexual life cycle stage shaped like a bell or an umbrella.

megagametophyte In heterosporous plants, the female gametophyte; produces eggs. (Contrast with microgametophyte.)

megaphyll The generally large leaf of a fern, horsetail, or seed plant, with several to many veins. (Contrast with microphyll.)

megaspore [Gk. *me-gas*: large + *spora*: to sow] In plants, a haploid spore that produces a female gametophyte.

megastrobilus In conifers, the female (seed-bearing) cone. (Contrast with microstrobilus.)

meiosis (my oh' sis) [Gk. *meiosis*: diminution] Division of a diploid nucleus to produce four haploid daughter cells. The process consists of two successive nuclear divisions with only one cycle of chromosome replication. In *meiosis I*, homologous chromosomes separate but retain their chromatids. The second division *meiosis II*, is similar to mitosis, in which chromatids separate.

melatonin A hormone released by the pineal gland. Involved in photoperiodicity and circadian rhythms.

membrane potential The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

membranous bone A type of bone that develops by forming on a scaffold of connective tissue. (Contrast with cartilage bone.)

memory cells Long-lived lymphocytes produced after exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

Mendel's laws See independent assortment; segregation.

menopause In human females, the end of fertility and menstrual cycling.

menstruation The process by which the endometrium breaks down, and the sloughed-off tissue, including blood, flows from the body.

meristem [Gk. *meristos*: divided] Plant tissue made up of undifferentiated actively dividing cells.

meristem culture A method for the asexual propagation of plants, in which pieces of shoot apical meristem are cultured to produce plantlets.

meristem identity genes In angiosperms, a group of genes whose expression initiates flower formation, probably by switching

meristem cells from a vegetative to a reproductive fate.

mesenchyme (mez' en kyme) [Gk. *mesos*: middle + *enchyma*: infusion] Embryonic or unspecialized cells derived from the mesoderm.

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

mesoglea (mez' uh glee uh) [Gk. *mesos*: middle + *gloia*, glue] A thick, gelatinous noncellular layer that separates the two cellular tissue layers of ctenophores, cnidarians, and scyphozoans.

mesophyll (mez' uh fill) [Gk. *mesos*: middle + *phyllon*: leaf] Chloroplast-containing, photosynthetic cells in the interior of leaves.

messenger RNA (mRNA) Transcript of a region of one of the strands of DNA; carries information (as a sequence of codons) for the synthesis of one or more proteins.

meta- [Gk.: between, along with, beyond] Prefix denoting a change or a shift to a new form or level; for example, as used in metamorphosis.

metabolic pathway A series of enzyme-catalyzed reactions so arranged that the product of one reaction is the substrate of the next.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

metabolome The quantitative description of all the small molecules in a cell or organism.

metabolomics The study of the metabolome as it relates to the physiological state of a cell or organism.

metabotropic receptor A receptor that that indirectly alters membrane permeability to a type of ion when it combines with its ligand.

metagenomics The practice of analyzing DNA from environmental samples without isolating intact organisms.

metamorphosis (met' a mor' fo sis) [Gk. *meta*: between + *morphe*: form, shape] A change occurring between one developmental stage and another, as for example from a tadpole to a frog. (See complete metamorphosis, incomplete metamorphosis.)

metanephridia The paired excretory organs of annelids.

metaphase (met' a phase) The stage in nuclear division at which the centromeres of the highly supercoiled chromosomes are all lying on a plane (the metaphase plane or plate) perpendicular to a line connecting the division poles.

metapopulation A population divided into subpopulations, among which there are occasional exchanges of individuals.

methylation The addition of a methyl group ($-\text{CH}_3$) to a molecule.

MHC See major histocompatibility complex.

micelle A particle of lipid covered with bile salts that is produced in the duodenum and facilitates digestion and absorption of lipids.

microevolution Evolutionary changes below the species level, affecting allele frequencies. (Contrast with macroevolution.)

microfibril Crosslinked cellulose polymers, forming strong aggregates in the plant cell wall.

microfilament In eukaryotic cells, a fibrous structure made up of actin monomers. Microfilaments play roles in the cytoskeleton, in cell movement, and in muscle contraction.

microgametophyte In heterosporous plants, the male gametophyte; produces sperm. (Contrast with megagametophyte.)

microglia Glial cells that act as macrophages and mediators of inflammatory responses in the central nervous system.

micronutrient In plants, a mineral element required in concentrations of less than 100 micrograms per gram of plant dry matter; in animals, a mineral element required in concentrations of less than 100 micrograms per day. (Contrast with macronutrient.)

microphyll A small leaf with a single vein, found in club mosses and their relatives. (Contrast with megaphyll.)

micropyle (mike' roh pile) [Gk. *mikros*: small + *pylon*: gate] Opening in the integument(s) of a seed plant ovule through which pollen grows to reach the female gametophyte within.

microRNA A small, noncoding RNA molecule, typically about 21 bases long, that binds to mRNA to inhibit its translation.

microspore [Gk. *mikros*: small + *spora*: to sow] In plants, a haploid spore that produces a male gametophyte.

microstrobilus In conifers, male pollen-bearing cone. (Contrast with megastrobilus.)

microtubules Tubular structures found in centrioles, spindle apparatus, cilia, flagella, and cytoskeleton of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

microvilli (sing.: microvillus) Projections of epithelial cells, such as the cells lining the small intestine, that increase their surface area.

midbrain One of the three regions of the vertebrate brain. Part of the brainstem, it serves as a relay station for sensory signals sent to the cerebral hemispheres.

middle lamella (la mell' ah) [L. *lamina*: thin sheet] A layer of polysaccharides that separates plant cells; a shared middle lamella lies outside the primary walls of the two cells.

mineral nutrients Inorganic ions required by organisms for normal growth and reproduction.

mineralocorticoids One of two main types of corticosteroid hormones. Produced and released by the cortex of the adrenal gland and involved in regulating salt and water balance of the extracellular fluid. (See also glucocorticoids.)

mismatch repair A mechanism that scans DNA after it has been replicated and corrects any base-pairing mismatches.

missense mutation A change in a gene's sequence that changes the amino acid at that site in the encoded protein. (Contrast with frame-shift mutation, nonsense mutation, silent mutation.)

mitochondrial matrix The fluid interior of the mitochondrion, enclosed by the inner mitochondrial membrane.

mitochondrion (my' toe kon' dree un) (plural: mitochondria) [Gk. *mitos*: thread + *chondros*: grain] An organelle in eukaryotic cells that contains the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

mitosis (my toe' sis) [Gk. *mitos*: thread] Nuclear division in eukaryotes leading to the formation of two daughter nuclei, each with a chromosome complement identical to that of the original nucleus.

model systems Also known as model organisms, these include the small group of species that are the subject of extensive research. They are organisms that adapt well to laboratory situations and findings from experiments on them can apply across a broad range of species. Classic examples include white rats and the fruit fly *Drosophila*.

moderately repetitive sequences DNA sequences repeated 10–1,000 times in the eukaryotic genome. They include the genes that code for rRNAs and tRNAs, as well as the DNA in telomeres.

Modern Synthesis An understanding of evolutionary biology that emerged in the early twentieth century as the principles of evolution were integrated with the principles of modern genetics.

modularity In evolutionary developmental biology, the principle that the molecular pathways that determine different developmental processes operate independently from one another. See also developmental module.

mole A quantity of a compound whose weight in grams is numerically equal to its molecular weight expressed in atomic mass units. Avogadro's number of molecules: 6.023×10^{23} molecules.

molecular clock The approximately constant rate of divergence of macromolecules from one another over evolutionary time; used to date past events in evolutionary history.

molecular evolution The scientific study of the mechanisms and consequences of the evolution of macromolecules.

molecular toolkit See genetic toolkit.

molecular weight The sum of the atomic weights of the atoms in a molecule.

molecule A chemical substance made up of two or more atoms joined by covalent bonds or ionic attractions.

molting The process of shedding part or all of an outer covering, as the shedding of feathers by birds or of the entire exoskeleton by arthropods.

monocots Angiosperms with a single embryonic cotyledon; one of the two largest clades of angiosperms. (See also eudicots.)

monoculture In agriculture, a large-scale planting of a single species of domesticated crop plant.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

monohybrid cross A mating in which the parents differ with respect to the alleles of only one locus of interest.

monomer [Gk. *mono*: one + *meros*: unit] A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

monophyletic (mon' oh fi h leht' ik) [Gk. *mono*: one + *phylon*: tribe] Pertaining to a group that consists of an ancestor and all of its descendants. (Contrast with paraphyletic, polyphyletic.)

monosaccharide A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

monosomic Pertaining to an organism with one less than the normal diploid number of chromosomes.

monosynaptic reflex A neural reflex that begins in a sensory neuron and makes a single synapse before activating a motor neuron.

morphogen A diffusible substance whose concentration gradient determines a developmental pattern in animals and plants.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

morphological species concept The definition of a species as a group of individuals that look alike. (Contrast with biological species concept; lineage species concept.)

morphology (more fol' o jee) [Gk. *morphe*: form + *logos*: study, discourse] The scientific study of organic form, including both its development and function.

mosaic development Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

motif See structural motif.

motile (mo' tul) Able to move from one place to another. (Contrast with sessile.)

motor cortex The region of the cerebral cortex that contains motor neurons that directly stimulate specific muscle fibers to contract.

motor end plate The depression in the postsynaptic membrane of the neuromuscular junction where the terminals of the motor neuron sit.

motor neuron A neuron carrying information from the central nervous system to a cell that produces movement.

motor proteins Specialized proteins that use energy to change shape and move cells or structures within cells.

motor unit A motor neuron and the muscle fibers it controls.

mouth An opening through which food is taken in, located at the anterior end of a tubular gut.

mRNA See messenger RNA.

mucosa The innermost layer of the vertebrate gut. (See also mucosal epithelium.)

mucosal epithelium An epithelial cell layer containing cells that secrete mucus; found in the digestive and respiratory tracts. Also called mucosa.

mucus A slippery substance secreted by mucous membranes (e.g., mucosal epithelium). A barrier defense against pathogens in innate immunity in animals.

multiplicative growth Population growth in which a constant multiple of the population size is added to the population during successive time intervals. Also known as exponential growth. (Contrast with additive growth.)

multipotent Having the ability to differentiate into a limited number of cell types. (Contrast with pluripotent, totipotent.)

muscle fiber A single muscle cell. In the case of skeletal muscle, a syncytial, multinucleate cell.

muscle tissue Excitable tissue that can contract through the interactions of actin and myosin; one of the four major tissue types in multicellular animals. There are three types of muscle tissue: skeletal, smooth, and cardiac.

mutagen (mute' ah jen) [L. *mutare*: change + Gk. *genesis*: source] Any agent (e.g., a chemical, radiation) that increases the mutation rate.

mutation A change in the genetic material not caused by recombination.

mutualism A type of interaction between species that benefits both species.

mycelium (my seel' ee yum) [Gk. *mykes*: fungus] In the fungi, a mass of hyphae.

mycorrhiza (my' ko ryé' za) (plural: mycorrhizae) [Gk. *mykes*: fungus + *rhiza*: root] An association of the root of a plant with the mycelium of a fungus.

myelin (my' a lin) Concentric layers of plasma membrane that form a sheath around some axons; myelin provides the axon with electrical insulation and increases the rate of transmission of action potentials.

MyoD The protein encoded by the *myo*-blast determining gene. A transcription factor involved in the differentiation of myoblasts (muscle precursor cells).

myofibril (my' oh fy' bril) [Gk. *mys*: muscle + L. *fibrilla*: small fiber] A polymeric unit of actin or myosin in a muscle.

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

myosin One of the two contractile proteins of muscle.

- N -

natural history The characteristics of a group of organisms, such as how the organisms get their food, reproduce, behave, regulate their internal environments (their cells, tissues, and organs), and interact with other organisms.

natural killer cell A type of lymphocyte that attacks virus-infected cells and some tumor cells as well as antibody-labeled target cells.

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

necrosis (nec roh' sis) [Gk. *nekros*: death] Premature cell death caused by external agents such as toxins.

negative feedback In regulatory systems, information that decreases a regulatory response, returning the system to the set point. (Contrast with positive feedback.)

negative regulation A type of gene regulation in which a gene is normally transcribed, and the binding of a repressor protein to the promoter prevents transcription. (Contrast with positive regulation.)

nematocyst (ne mat' o sist) [Gk. *nema*: thread + *kystis*: cell] An elaborate, threadlike structure produced by cells of jellyfishes and other cnidarians, used chiefly to paralyze and capture prey.

nephron (nef' ron) [Gk. *nephros*: kidney] The functional unit of the kidney, consisting of a structure for receiving a filtrate of blood and a tubule that reabsorbs selected parts of the filtrate.

Nernst equation A mathematical statement that calculates the potential across a membrane permeable to a single type of ion that differs in concentration on the two sides of the membrane.

nerve A structure consisting of many neuronal axons and connective tissue.

nervous tissue Tissue specialized for processing and communicating information; one of the four major tissue types in multicellular animals.

net primary productivity (NPP) The rate at which energy captured by photosynthesis is incorporated into the bodies of primary producers through growth and reproduction.

neural crest cells During vertebrate neuralation, cells that migrate outward from the neural plate and give rise to connections between the central nervous system and the rest of the body.

neural network An organized group of neurons that contains three functional categories of neurons—afferent neurons, interneurons, and efferent neurons—and is capable of processing information.

neural tube An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior-posterior body axis.

neurohormone A chemical signal produced and released by neurons that subsequently acts as a hormone.

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

neuron (noor' on) [Gk. *neuron*: nerve] A nervous system cell that can generate and conduct action potentials along an axon to a synapse with another cell.

neurotransmitter A substance produced in and released by a neuron (the presynaptic cell) that diffuses across a synapse and excites or inhibits another cell (the postsynaptic cell).

neurulation Stage in vertebrate development during which the nervous system begins to form.

neutral allele An allele that does not alter the functioning of the proteins for which it codes.

neutral theory A view of molecular evolution that postulates that most mutations do not affect the amino acid being coded for, and that such mutations accumulate in a population at rates driven by genetic drift and mutation rates.

neutron (new' tron) One of the three fundamental particles of matter (along with protons and electrons), with mass slightly larger than that of a proton and no electrical charge.

next-generation DNA sequencing A rapid, relatively low cost method for sequencing DNA that involves attaching short, single-stranded DNA fragments to a solid surface. A primer and DNA polymerase are added, and tagged nucleotides are detected by a laser as they are added to the complementary DNA strand. Enables

the analysis of many sequences in parallel, which are then assembled by a computer.

niche (nitch) [L. *nidus*: nest] The set of physical and biological conditions a species requires to survive, grow, and reproduce.

nitrate reduction The process by which nitrate (NO_3^-) is reduced to ammonia (NH_3).

nitric oxide (NO) An unstable molecule (a gas) that serves as a second messenger causing smooth muscle to relax. In the nervous system it operates as a neurotransmitter.

nitrifiers Chemolithotrophic bacteria that oxidize ammonia to nitrate in soil and in seawater.

nitrogen fixation Conversion of atmospheric nitrogen gas (N_2) into a more reactive and biologically useful form (ammonia), which makes nitrogen available to living things. Carried out by nitrogen-fixing bacteria, some of them free-living and others living within plant roots.

nitrogenase An enzyme complex found in nitrogen-fixing bacteria that mediates the stepwise reduction of atmospheric N_2 to ammonia and which is strongly inhibited by oxygen.

nitrogenous wastes The potentially toxic nitrogen-containing end products of protein and nucleic acid catabolism. Eliminated from the body by excretion.

node [L. *nodus*: knob, knot] In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached.

node of Ranvier A gap in the myelin sheath covering an axon; the point where the axonal membrane can fire action potentials.

nodule A specialized structure in the roots of nitrogen-fixing plants that houses nitrogen-fixing bacteria, in which oxygen is maintained at a low level by leghemoglobin.

non-REM sleep A state of deep, restorative sleep characterized by high-amplitude slow waves in the EEG. (Contrast with REM sleep.)

noncompetitive inhibitor A nonsubstrate that inhibits the activity of an enzyme by binding to a site other than its active site. (Contrast with competitive inhibitor.)

noncyclic electron transport In photosynthesis, the flow of electrons that forms ATP, NADPH, and O_2 .

nondisjunction Failure of sister chromatids to separate in meiosis II or mitosis, or failure of homologous chromosomes to separate in meiosis I. Results in aneuploidy.

nonpolar Having electric charges that are evenly balanced from one end to the other. (Contrast with polar.)

nonrandom mating Selection of mates on the basis of a particular trait or group of traits.

nonsense mutation Change in a gene's sequence that prematurely terminates translation by changing one of its codons to a stop codon.

nonsynonymous substitution A change in a gene from one nucleotide to another that changes the amino acid specified by the corresponding codon (i.e., AGC → AGA, or serine → arginine). (Contrast with synonymous substitution.)

norepinephrine A neurotransmitter found in the central nervous system and also at the postganglionic nerve endings of the sympathetic nervous system. Also called noradrenaline.

normal flora Microorganisms that normally live and reproduce on or in the body without causing disease, and which form a nonspecific defense against pathogens by competing with them for space and nutrients.

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

nucleic acid hybridization A technique in which a single-stranded nucleic acid probe is made that is complementary to, and binds to, a target sequence, either DNA or RNA. The resulting double-stranded molecule is a hybrid.

nucleoid (new' klee oid) The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

nucleolus (new klee' oh lus) A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

nucleoside A nucleotide without the phosphate group; a nitrogenous base attached to a sugar.

nucleosome A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

nucleotide substitution A change of one base pair to another in a DNA sequence.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

null hypothesis In statistics, the premise that any differences observed in an experiment are simply the result of random differences that arise from drawing two finite samples from the same population.

nutrient A food substance; or, in the case of mineral nutrients, an inorganic element required for completion of the life cycle of an organism.

- O -

obligate anaerobe An anaerobic prokaryote that cannot survive exposure to O₂.

occipital lobe One of the four lobes of the brain's cerebral hemisphere; processes visual information.

odorant A molecule that can bind to an olfactory receptor.

oil A triglyceride that is liquid at room temperature. (Contrast with fat.)

Okazaki fragments Newly formed DNA making up the lagging strand in DNA replication. DNA ligase links Okazaki fragments together to give a continuous strand.

olfactory [L. *olfacere*: to smell] Pertaining to the sense of smell (*olfaction*).

oligodendrocyte A type of glial cell that myelinates axons in the central nervous system.

oligosaccharide A polymer containing a small number of monosaccharides.

omasum One of the four chambers of the stomach in ruminants; concentrates food by water absorption before it enters the true stomach (abomasum).

ommatidia [Gk. *omma*: eye] The units that make up the compound eye of some arthropods.

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that eats both animal and plant material. (Contrast with carnivore, detritivore, herbivore.)

oncogene [Gk. *onkos*: mass, tumor + *genes*: born] A gene that codes for a protein product that stimulates cell proliferation. Mutations in oncogenes that result in excessive cell proliferation can give rise to cancer.

one gene—one polypeptide The idea, since shown to be an oversimplification, that each gene in the genome encodes only a single polypeptide—that there is a one-to-one correspondence between genes and polypeptides.

oocyte See primary oocyte, secondary oocyte.

oogenesis (oh' eh jen e sis) [Gk. *oon*: egg + *genesis*: source] Gametogenesis leading to production of an ovum.

oogonium (oh' eh go' nee um) (plural: oogonia) (1) In some algae and fungi, a cell in which an egg is produced. (2) In animals, the diploid progeny of a germ cell in females.

ootid In oogenesis, the daughter cell of the second meiotic division that differentiates into the mature ovum.

open circulatory system Circulatory system in which extracellular fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the circulatory system to be

pumped out again. (Contrast with closed circulatory system.)

operator The region of an operon that acts as the binding site for the repressor.

operon A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

opportunity cost The sum of the benefits an animal forfeits by not being able to perform some other behavior during the time when it is performing a given behavior.

opsin (op' sin) [Gk. *opsis*: sight] The protein portion of the visual pigment rhodopsin; associated with the pigment molecule 11-*cis*-retinal. (See rhodopsin.)

orbital A region in space surrounding the atomic nucleus in which an electron is most likely to be found.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

organ identity genes In angiosperms, genes that specify the different organs of the flower. (Compare with homeotic genes.)

organ of Corti Structure in the inner ear that transforms mechanical forces produced from pressure waves ("sound waves") into action potentials that are sensed as sound.

organ system An interrelated and integrated group of tissues and organs that work together in a physiological function.

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

organic (1) Pertaining to any chemical compound that contains carbon. (2) Pertaining to any aspect of living matter, e.g., to its evolution, structure, or chemistry.

organic fertilizers Substances added to soil to improve the soil's fertility; derived from partially decomposed plant material (compost) or animal waste (manure).

organism Any living entity.

organizer Region of the early amphibian embryo that directs early embryonic development. Also known as the primary embryonic organizer.

organogenesis The formation of organs and organ systems during development.

origin of replication (ori) DNA sequence at which helicase unwinds the DNA double helix and DNA polymerase binds to initiate DNA replication.

orthologs Genes that are related by orthology.

orthology (or thol' o jee) Type of homology in which the divergence of homologous genes can be traced to speciation events.

osmoconformer An aquatic animal that equilibrates the osmolarity of its

extracellular fluid to be the same as that of the external environment. (Contrast with osmoregulator.)

osmolarity The concentration of osmotically active particles in a solution.

osmoregulation Regulation of the chemical composition of the body fluids of an organism.

osmoregulator An aquatic animal that actively regulates the osmolarity of its extracellular fluid. (Contrast with osmoconformer.)

osmosis (oz mo' sis) [Gk. *osmos*: to push] Movement of water across a differentially permeable membrane, from one region to another region where the water potential is more negative.

ossicle (oss' ick ul) [L. *os*: bone] The calcified construction unit of echinoderm skeletons.

osteoblast (oss' tee oh blast) [Gk. *osteon*: bone + *blastos*: sprout] A cell that lays down the protein matrix of bone.

osteoclast (oss' tee oh clast) [Gk. *osteon*: bone + *klastos*: broken] A cell that dissolves bone.

osteocyte An osteoblast that has become enclosed in lacunae within the bone it has built.

outgroup In phylogenetics, a group of organisms used as a point of reference for comparison with the groups of primary interest (the ingroup).

oval window The flexible membrane that, when moved by the bones of the middle ear, produces pressure waves in the inner ear.

ovarian cycle In human females, the monthly cycle of events by which eggs and hormones are produced. (Contrast with uterine cycle).

ovary (oh' var ee) [L. *ovum*: egg] Any female organ, in plants or animals, that produces an egg.

overtopping Plant growth pattern in which one branch differentiates from and grows beyond the others.

oviduct In mammals, the tube serving to transport eggs to the uterus or to the outside of the body.

oviparity Reproduction in which eggs are released by the female and development is external to the mother's body. (Contrast with viviparity.)

ovulation Release of an egg from an ovary.

ovule (oh' vule) In plants, a structure comprising the megasporangium and the integument, which develops into a seed after fertilization.

ovum (oh' vum) (plural: ova) [L. egg] The female gamete.

oxidation (ox i day' shun) Relative loss of electrons in a chemical reaction; either outright removal to form an ion, or the sharing of electrons with substances having a greater affinity for them, such as oxygen.

Most oxidations, including biological ones, are associated with the liberation of energy. (Contrast with reduction.)

oxidative phosphorylation ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

oxygenase An enzyme that catalyzes the addition of oxygen to a substrate from O₂.

oxytocin A hormone released by the posterior pituitary that promotes social bonding.

- P -

pacemaker cells Cardiac cells that can initiate action potentials without stimulation from the nervous system, allowing the heart to initiate its own contractions.

pair rule genes In *Drosophila* (fruit fly) development, segmentation genes that divide the early embryo into units of two segments each. Part of a developmental cascade that includes maternal effect genes, gap genes, segment polarity genes, and Hox genes.

paleomagnetic dating A method for determining the age of rocks based on properties relating to changes in the patterns of Earth's magnetism over time.

pancreas (pan' cree us) A gland located near the stomach of vertebrates that secretes digestive enzymes into the small intestine and releases insulin into the bloodstream.

Pangaea (pan jee' uh) [Gk. *pan*: all, every] The single land mass formed when all the continents came together in the Permian period.

para- [Gk. *para*: akin to, beside] Prefix indicating association in being along side or accessory to.

parabronchi Passages in the lungs of birds through which air flows.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

parallel phenotypic evolution The repeated evolution of similar traits, especially among closely related species; facilitated by conserved developmental genes.

paraphyletic (par' a fi h leht' ik) [Gk. *para*: beside + *phylon*: tribe] Pertaining to a group that consists of an ancestor and some, but not all, of its descendants. (Contrast with monophyletic, polyphyletic.)

parasite An organism that consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

parasympathetic nervous system The division of the autonomic nervous system that works in opposition to the sympathetic nervous system. (Contrast with sympathetic nervous system.)

parathyroid glands Four glands on the posterior surface of the thyroid gland that produce and release parathyroid hormone.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that stimulates osteoclast activity and raises blood calcium levels. Also called parathormone.

parenchyma (pair eng' kyma) A plant tissue composed of relatively unspecialized cells without secondary walls.

parent rock The soil horizon consisting of the rock that is breaking down to form the soil. Also called bedrock, or the C horizon.

parental (P) generation The individuals that mate in a genetic cross. Their offspring are the first filial (F₁) generation.

parietal lobe One of four lobes of the cerebral hemisphere; processes complex stimuli and includes the primary somatosensory cortex.

parsimony Preferring the simplest among a set of plausible explanations of any phenomenon.

parthenocarpy Formation of fruit from a flower without fertilization.

parthenogenesis [Gk. *parthenos*: virgin] Production of an organism from an unfertilized egg.

partial pressure of oxygen The contribution of O₂ to total air pressure; about 159 mm Hg at sea level.

particulate theory In genetics, the theory that genes are physical entities that retain their identities after fertilization.

passive transport Diffusion across a membrane; may or may not require a channel or carrier protein. (Contrast with active transport.)

pathogen (path' o jen) [Gk. *pathos*: suffering + *genesis*: source] An organism that causes disease.

pathogenesis-related (PR) proteins A component of the hypersensitive response of plants to pathogens. Some PR proteins function as direct defenses against pathogens, others initiate other defensive responses.

pattern formation In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

pedigree The pattern of transmission of a genetic trait within a family.

pelagic zone [Gk. *pelagos*: sea] The open ocean.

penetrance The proportion of individuals with a particular genotype that show the expected phenotype.

penis An accessory sex organ of male animals that enables the male to deposit sperm in the female's reproductive tract.

pentaradial symmetry Symmetry in five or multiples of five; a feature of adult echinoderms.

pentose [Gk. *penta*: five] A sugar containing five carbon atoms.

pepsin [Gk. *pepsis*: digestion] An enzyme in gastric juice that digests protein.

pepsinogen Inactive secretory product that is converted into pepsin by low pH or by enzymatic action.

peptide hormones Relatively large hormone molecules made up of amino acids; encoded by genes and produced by translation.

peptide linkage The bond between amino acids in a protein; formed between a carboxyl group and amino group ($-\text{CO}-\text{NH}-$) with the loss of water molecules.

peptidoglycan The cell wall material of many bacteria, consisting of a single enormous molecule that surrounds the entire cell.

peptidyl transferase A catalytic function of the large ribosomal subunit that consists of two reactions: breaking the bond between an amino acid and its tRNA in the P site, and forming a peptide bond between that amino acid and the amino acid attached to the tRNA in the A site.

per capita birth rate (b) In population growth models, the number of offspring that an average individual produces in some time interval.

per capita death rate (d) In population growth models, the average individual's chance of dying in some time interval.

per capita growth rate (r) In population models, the average individual's contribution to total population growth rate.

perennial (per ren' ee al) [L. *per*: throughout + *annus*: year] A plant that survives from year to year. (Contrast with annual, biennial.)

perfect flower A flower with both stamens and carpels; a hermaphroditic flower. (Contrast with imperfect flower.)

pericycle [Gk. *peri*: around + *kyklos*: ring or circle] In plant roots, tissue just within the endodermis, but outside of the root vascular tissue. Meristematic activity of pericycle cells produces lateral root primordia.

periderm The outer tissue of the secondary plant body, consisting primarily of cork.

period (1) A category in the geological time scale. (2) The duration of a single cycle in a cyclical event, such as a circadian rhythm.

peripheral membrane proteins Proteins associated with but not embedded within the plasma membrane. (Contrast with integral membrane proteins.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

peristalsis (pair' i stall' sis) Wavelike muscular contractions proceeding along a tubular organ, propelling the contents along the tube.

peritoneum The mesodermal lining of the body cavity in coelomate animals.

peroxisome An organelle that houses reactions in which toxic peroxides are formed and then converted to water.

petal [Gk. *petalon*: spread out] In an angiosperm flower, a sterile modified leaf, nonphotosynthetic, frequently brightly colored, and often serving to attract pollinating insects.

petiole (pet' ee ole) [L. *petiolus*: small foot] The stalk of a leaf.

P_{fr} See phytochrome.

pH The negative logarithm of the hydrogen ion concentration; a measure of the acidity of a solution. A solution with pH = 7 is said to be neutral; pH values higher than 7 characterize basic solutions, while acidic solutions have pH values less than 7.

phage (fayj) See bacteriophage.

phagocyte [Gk. *phagein*: to eat + *kystos*: sac] One of two major classes of white blood cells; one of the nonspecific defenses of animals; ingests invading microorganisms by phagocytosis.

phagocytosis Endocytosis by a cell of another cell or large particle.

pharmacogenomics The study of how an individual's genetic makeup affects his or her response to drugs or other agents, with the goal of predicting the effectiveness of different treatment options.

pharming The use of genetically modified animals to produce medically useful products in their milk.

pharynx [Gk. throat] The part of the gut between the mouth and the esophagus.

phenotype (fee' no type) [Gk. *phanein*: to show] The observable properties of an individual resulting from both genetic and environmental factors. (Contrast with genotype.)

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

phosphate group The functional group $-\text{OPO}_3\text{H}_2$.

phosphodiester linkage The connection in a nucleic acid strand, formed by linking two nucleotides.

phospholipid A lipid containing a phosphate group; an important constituent of cellular membranes. (See lipid.)

phospholipid bilayer The basic structural unit of biological membranes; a sheet of phospholipids two molecules thick in which the phospholipids are lined up with their hydrophobic "tails" packed tightly together and their hydrophilic, phosphate-containing "heads" facing outward. Also called lipid bilayer.

phosphorylation Addition of a phosphate group.

photic zone The region of lakes and oceans that is penetrated by light and therefore supports photosynthetic organisms.

photoautotroph An organism that obtains energy from light and carbon from carbon dioxide. (Contrast with chemolithotroph, chemoheterotroph, photoheterotroph.)

photoheterotroph An organism that obtains energy from light but must obtain its carbon from organic compounds. (Contrast with chemolithotroph, chemoheterotroph, photoautotroph.)

photomorphogenesis In plants, a process by which physiological and developmental events are controlled by light.

photon (foe' ton) [Gk. *photos*: light] A quantum of visible radiation; a "packet" of light energy.

photoperiodicity Control of an organism's physiological or behavioral responses by the length of the day or night (photoperiod).

photoreceptor (1) In plants, a pigment that triggers a physiological response when it absorbs a photon. (2) In animals, a sensory receptor cell that senses and responds to light energy.

photosensitivity The ability to detect light.

photosynthesis (foe tow sin' the sis) [literally, "synthesis from light"] Metabolic processes carried out by green plants and cyanobacteria, by which visible light is trapped and the energy used to convert CO_2 into organic compounds.

photosystem [Gk. *phos*: light + *systema*: assembly] A light-harvesting complex in the chloroplast thylakoid composed of pigments and proteins.

photosystem I In photosynthesis, the complex that absorbs light at 700 nm, passing electrons to ferredoxin and thence to NADPH.

photosystem II In photosynthesis, the complex that absorbs light at 680 nm, passing electrons to the electron transport chain in the chloroplast.

phototropins A class of blue light receptors that mediate phototropism and other plant responses.

phototropism [Gk. *photos*: light + *tropē*: turning] A directed plant growth response to light.

phycobilin Photosynthetic pigment that absorbs red, yellow, orange, and green light and is found in cyanobacteria and some red algae.

phylogenetic tree A graphic representation of lines of descent among organisms or their genes.

phylogeny (fy loj' e nee) [Gk. *phylon*: tribe, race + *genesis*: source] The evolutionary history of a particular group of organisms or their genes.

physical geography The study of the distributions of Earth's climates and surface features.

physiology (fiz' ee ol' o jee) [Gk. *physis*: natural form] The scientific study of the functions of living organisms and the individual organs, tissues, and cells of which they are composed.

phytoalexins Substances toxic to pathogens, produced by plants in response to fungal or bacterial infection.

phytochrome (fy' tow krome) [Gk. *phyton*: plant + *chroma*: color] A plant pigment regulating a large number of developmental and other phenomena in plants. It has two isomers: P_r , which absorbs red light, and P_{fr} , which absorbs far red light. P_{fr} is the active form.

phytomers In plants, the repeating modules that compose a shoot, each consisting of one or more leaves, attached to the stem at a node; an internode; and one or more axillary buds.

phytoplankton Photosynthetic plankton.

phytoremediation A form of bioremediation that uses plants to clean up environmental pollution.

pigment A substance that absorbs visible light.

piloting A form of navigation in which an animal finds its way by knowing and remembering the structure of its environment.

pineal gland Gland located between the cerebral hemispheres that secretes melatonin.

pinocytosis Endocytosis by a cell of liquid containing dissolved substances.

pistil [L. *pistillum*: pestle] The structure of an angiosperm flower within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually differentiated into ovary, style, and stigma.

pith In plants, relatively unspecialized tissue found within a cylinder of vascular tissue.

pituitary gland A small gland attached to the base of the brain in vertebrates. Its hormones control the activities of other glands. Also known as the hypophysis.

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

plankton Free-floating small aquatic organisms. Photosynthetic members of the plankton are referred to as phytoplankton.

planula (plan' yew la) [L. *planum*: flat] A free-swimming, ciliated larval form typical of the cnidarians.

plaque (plack) [Fr.: a metal plate or coin] (1) A circular clearing in a layer (lawn) of bacteria growing on the surface of a nutrient agar gel. (2) An accumulation of prokaryotic organisms on tooth enamel. Acids produced by these microorganisms cause tooth decay. (3) A region of arterial wall invaded by fibroblasts and fatty deposits.

plasma (plaz' muh) The liquid portion of blood, in which blood cells and other particulates are suspended.

plasma cell An antibody-secreting cell that develops from a B cell; the effector cell of the humoral immune system.

plasma membrane The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a plasma membrane.

plasmid A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element; found in many bacteria. May replicate independently of the chromosome.

plasmodesma (plural: plasmodesmata) [Gk. *plassein*: to mold + *desmos*: band] A cytoplasmic strand connecting two adjacent plant cells.

plasmogamy The fusion of the cytoplasm of two cells. (Contrast with karyogamy.)

plastid A class of plant cell organelles that includes the chloroplast, which houses biochemical pathways for photosynthesis.

plate tectonics [Gk. *tekton*: builder] The scientific study of the structure and movements of Earth's lithospheric plates, which are the cause of continental drift.

platelet A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

pleural membrane [Gk. *pleuras*: rib, side] The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

pluripotent [L. *pluri*: many + *potens*: powerful] Having the ability to form all of the cells in the body. (Contrast with multipotent, totipotent.)

podocytes Cells of Bowman's capsule of the nephron that cover the capillaries of the glomerulus, forming filtration slits.

point mutation A mutation that results from the gain, loss, or substitution of a single nucleotide.

polar body A nonfunctional nucleus produced by meiosis during oogenesis.

polar covalent bond A covalent bond in which the electrons are drawn to one nucleus more than the other, resulting in an unequal distribution of charge.

polar Having separate and opposite electric charges at two ends, or poles. (Contrast with nonpolar.)

polar nuclei In angiosperms, the two nuclei in the central cell of the megagametophyte; following fertilization they give rise to the endosperm.

polarity (1) In chemistry, the property of unequal electron sharing in a covalent bond that defines a polar molecule. (2) In development, the difference between one end of an organism or structure and the other.

pollen [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male

gametophyte (microgametophyte) and gamete (microspore).

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

poly A tail A long sequence of adenine nucleotides (50–250) added after transcription to the 3' end of most eukaryotic mRNAs.

poly- [Gk. *poly*: many] A prefix denoting multiple entities.

polyandry Mating system in which one female mates with multiple males.

polygyny Mating system in which one male mates with multiple females.

polymer [Gk. *poly*: many + *meros*: unit] A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer.)

polymerase chain reaction (PCR) An enzymatic technique for the rapid production of millions of copies of a particular stretch of DNA where only a small amount of the parent molecule is available.

polymorphic (pol' lee mor' fik) [Gk. *poly*: many + *morphe*: form, shape] Coexistence in a population of two or more distinct traits.

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

polypeptide A large molecule made up of many amino acids joined by peptide linkages. Large polypeptides are called proteins.

polyphyletic (pol' lee fih leht' ik) [Gk. *poly*: many + *phylon*: tribe] Pertaining to a group that consists of multiple distantly related organisms, and does not include the common ancestor of the group. (Contrast with monophyletic, paraphyletic.)

polyploidy (pol' lee ploid ee) The possession of more than two entire sets of chromosomes.

polyribosome (polysome) A complex consisting of a threadlike molecule of messenger RNA and several (or many) ribosomes. The ribosomes move along the mRNA, synthesizing polypeptide chains as they proceed.

polysaccharide A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

pons [L. *pons*: bridge] Region of the brainstem anterior to the medulla.

pool The total amount of an element in a given compartment of the biosphere.

population Any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another.

population bottleneck A period during which only a few individuals of a normally large population survive.

population density The number of individuals in a population per unit of area or volume.

population dynamics The patterns and processes of change in populations.

population genetics The study of genetic variation and its causes within populations.

population size The total number of individuals in a population.

positional information In development, the basis of the spatial sense that induces cells to differentiate as appropriate for their location within the developing organism; often comes in the form of a morphogen gradient.

positive feedback In regulatory systems, information that amplifies a regulatory response, increasing the deviation of the system from the set point. (Contrast with negative feedback.)

positive regulation A form of gene regulation in which a regulatory macromolecule is needed to turn on the transcription of a structural gene; in its absence, transcription will not occur. (Contrast with negative regulation.)

post- [L. *postere*: behind, following after] Prefix denoting something that comes after.

postabsorptive state State in which no food remains in the gut and thus no nutrients are being absorbed. (Contrast with absorptive state.)

posterior pituitary A portion of the pituitary gland that is derived from neural tissue and is involved in the storage and release of antidiuretic hormone and oxytocin. (See also pituitary gland and anterior pituitary.)

posterior Toward or pertaining to the rear. (Contrast with anterior.)

postsynaptic cell See postsynaptic neuron.

postsynaptic neuron The cell that receives information from a neuron at a synapse. (Contrast with presynaptic neuron.)

postzygotic isolating mechanisms Barriers to the reproductive process that occur after the union of the nuclei of two gametes. (Contrast with prezygotic isolating mechanisms.)

potential energy Energy not doing work, such as the energy stored in chemical bonds. (Contrast with kinetic energy.)

P_r See phytochrome.

pre-mRNA (precursor mRNA) Initial gene transcript before it is modified to produce functional mRNA. Also known as the primary transcript.

Precambrian The first and longest period of geological time, during which life originated.

precapillary sphincter A cuff of smooth muscle that can shut off the blood flow to a capillary bed.

predator An organism that kills and eats other organisms.

pre-replication complex In eukaryotes, a complex of proteins that binds to DNA at the initiation of DNA replication.

pressure flow model An effective model for phloem transport in angiosperms. It holds that sieve element transport is driven by an osmotically generated pressure gradient between source and sink.

pressure potential (Ψ_p) The hydrostatic pressure of an enclosed solution in excess of the surrounding atmospheric pressure. (Contrast with solute potential, water potential.)

presynaptic neuron The neuron that transmits information to another cell at a synapse. (Contrast with postsynaptic cell.)

prey [L. *praeda*: booty] An organism consumed by a predator as an energy source.

prezygotic isolating mechanisms Barriers to the reproductive process that occur before the union of the nuclei of two gametes. (Contrast with postzygotic isolating mechanisms.)

primary active transport Active transport in which ATP is hydrolyzed, yielding the energy required to transport an ion or molecule against its concentration gradient. (Contrast with secondary active transport.)

primary cell wall In plant cells, a structure that forms at the middle lamella after cytokinesis, made up of cellulose microfibrils, hemicelluloses, and pectins. (Contrast with secondary cell wall.)

primary consumer An organism (herbivore) that eats plant tissues.

primary endosymbiosis The engulfment of a cyanobacterium by a larger eukaryotic cell that gave rise to the first photosynthetic eukaryotes with chloroplasts.

primary growth In plants, growth that is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. (Contrast with secondary growth.)

primary immune response The first response of the immune system to an antigen, involving recognition by lymphocytes and the production of effector cells and memory cells. (Contrast with secondary immune response.)

primary lysosome See lysosome.

primary meristem Meristem that produces the tissues of the primary plant body.

primary motor cortex An area of the frontal lobe that controls muscles; neurons in this area are arranged according to the parts of the body with which they communicate.

primary oocyte (oh' eh site) [Gk. *oon*: egg + *kytos*: container] The diploid progeny of an oogonium. In many species, a primary oocyte enters prophase of the first meiotic division, then remains in developmental arrest for a long time before resuming meiosis to form a secondary oocyte and a polar body.

primary plant body That part of a plant produced by primary growth. Consists of all the *nonwoody* parts of a plant; many herbaceous plants consist entirely of a primary plant body. (Contrast with secondary plant body.)

primary producer A photosynthetic or chemosynthetic organism that synthesizes complex organic molecules from simple inorganic ones.

primary somatosensory cortex An area of the parietal lobe that receives touch and pressure information from the body; neurons in this area are arranged according to the parts of the body with which they communicate.

primary spermatocyte The diploid progeny of a spermatogonium; undergoes the first meiotic division to form secondary spermatocytes.

primary structure The specific sequence of amino acids in a protein.

primase An enzyme that catalyzes the synthesis of a primer for DNA replication.

primer Strand of nucleic acid, usually RNA, that is the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

primordium (plural: primordia) [L. origin] The most rudimentary stage of an organ or other part.

principle of allocation The idea that a unit of some resource acquired by an organism can be used for only one function at a time, meaning that resources must be divided among competing functions.

pro- [L.: first, before, favoring] A prefix often used in biology to denote a developmental stage that comes first or an evolutionary form that appeared earlier than another. For example, prokaryote, prophase.

probe A segment of single-stranded nucleic acid used to identify DNA molecules containing the complementary sequence.

procambium Primary meristem that produces the vascular tissue.

procedural memory Memory of motor tasks. Cannot be consciously recalled and described. (Contrast with declarative memory.)

processive Pertaining to an enzyme that catalyzes many reactions each time it binds to a substrate, as DNA polymerase does during DNA replication.

products The molecules that result from the completion of a chemical reaction.

progesterone [L. *pro*: favoring + *gestare*: to bear] A female sex hormone that maintains pregnancy.

prokaryotes Unicellular organisms that do not have nuclei. (Contrast with eukaryotes.)

prolactin A hormone released by the anterior pituitary, one of whose functions is the stimulation of milk production in female mammals.

prometaphase The phase of nuclear division that begins with the disintegration of the nuclear envelope.

promoter A DNA sequence to which RNA polymerase binds to initiate transcription.

prop roots Adventitious roots in some monocots that function as supports for the shoot.

prophage (pro' fayj) The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

prophase (pro' phase) The first stage of nuclear division, during which chromosomes condense from diffuse, threadlike material to discrete, compact bodies.

prostaglandin Any one of a group of specialized lipids with hormone-like functions. It is not clear that they act at any considerable distance from the site of their production.

prostate gland In male humans, surrounds the urethra at its junction with the vas deferens; supplies an acid-neutralizing fluid to the semen.

prosthetic group Any nonprotein portion of an enzyme.

proteasome In the eukaryotic cytoplasm, a huge protein structure that binds to and digests cellular proteins that have been tagged by ubiquitin.

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins.

protein kinase (kye' nase) An enzyme that catalyzes the addition of a phosphate group from ATP to a target protein.

protein kinase cascade A series of reactions in response to a molecular signal, in which a series of protein kinases activate one another in sequence, amplifying the signal at each step.

proteoglycan A glycoprotein containing a protein core with attached long, linear carbohydrate chains.

proteolysis [protein + Gk. *lysis*: break apart] An enzymatic digestion of a protein or polypeptide.

proteome The set of proteins that can be made by an organism. Because of alternative splicing of pre-mRNA, the number of proteins that can be made is usually much larger than the number of protein-coding genes present in the organism's genome.

proteomics The study of the proteome—the complete complement of proteins produced by an organism.

prothrombin The inactive form of thrombin, an enzyme involved in blood clotting.

protoderm Primary meristem that gives rise to the plant epidermis.

proton (pro' ton) [Gk. *protos*: first, before] (1) A subatomic particle with a single positive charge. The number of protons in the nucleus of an atom determine its element. (2) A hydrogen ion, H⁺.

proton pump An active transport system that uses ATP energy to move hydrogen ions across a membrane, generating an electric potential.

proton-motive force Force generated across a membrane having two components: a chemical potential (difference in proton concentration) plus an electrical potential due to the electrostatic charge on the proton.

protoplast The living contents of a plant cell; the plasma membrane and everything contained within it.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

proximal convoluted tubule The initial segment of a renal tubule, closest to the glomerulus. (Compare with distal convoluted tubule.)

proximal Near the point of attachment or other reference point. (Contrast with distal.)

proximate cause The immediate genetic, physiological, neurological, and developmental mechanisms responsible for a behavior or morphology. (Contrast with ultimate cause.)

pseudocoelomate (soo' do see' low mate) [Gk. *pseudes*: false + *koiloma*: cavity] Having a body cavity, called a pseudocoel, consisting of a fluid-filled space in which many of the internal organs are suspended, but which is enclosed by mesoderm only on its outside.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

pseudopod (soo' do pod) [Gk. *pseudes*: false + *podos*: foot] A temporary, soft extension of the cell body that is used in location, attachment to surfaces, or engulfing particles.

puberty The process of sexual maturation in humans.

pulmonary [L. *pulmo*: lung] Pertaining to the lungs.

pulmonary circuit The portion of the circulatory system by which blood is pumped from the heart to the lungs or gills for oxygenation and back to the heart for distribution. (Contrast with systemic circuit.)

pulmonary valve A one-way valve between the right ventricle of the heart and the pulmonary artery that prevents

backflow of blood into the ventricle when it relaxes.

Punnett square Method of predicting the results of a genetic cross by arranging the gametes of each parent at the edges of a square.

pupa (pew' pa) [L. *pupa*: doll, puppet] In certain insects (the Holometabola), the encased developmental stage between the larva and the adult.

pupil The opening in the vertebrate eye through which light passes.

purine (pure' een) One of the two types of nitrogenous bases in nucleic acids. Each of the purines—adenine and guanine—pairs with a specific pyrimidine.

Purkinje fibers Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

pyrimidine (per im' a deen) One of the two types of nitrogenous bases in nucleic acids. Each of the pyrimidines—cytosine, thymine, and uracil—pairs with a specific purine.

pyruvate The ionized form of pyruvic acid, a three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

pyruvate oxidation Conversion of pyruvate to acetyl CoA and CO₂ that occurs in the mitochondrial matrix in the presence of O₂.

- Q -

Q₁₀ A value that compares the rate of a biochemical process or reaction over 10°C temperature ranges. A process that is not temperature-sensitive has a Q₁₀ of 1; values of 2 or 3 mean the reaction speeds up as temperature increases.

quantify To assign numerical values to observations through measurement.

quantitative trait loci A set of genes that determines a complex character that exhibits quantitative variation (*quantitative trait*).

quaternary structure The specific three-dimensional arrangement of protein subunits.

- R -

R group The distinguishing group of atoms of a particular amino acid; also known as a side chain.

radial symmetry The condition in which any two halves of a body are mirror images of each other, providing the cut passes through the center; a cylinder cut lengthwise down its center displays this form of symmetry.

radiation The transfer of heat from warmer objects to cooler ones via the exchange of infrared radiation. *See also* electromagnetic radiation; evolutionary radiation.

radicle An embryonic root.

radioisotope A radioactive isotope of an element. Examples are carbon-14 (¹⁴C) and hydrogen-3, or tritium (³H).

radiometric dating A method for determining the age of objects such as fossils and rocks based on the decay rates of radioactive isotopes.

rapid eye movement sleep See REM sleep.

reactant A chemical substance that enters into a chemical reaction with another substance.

reaction center A group of electron transfer proteins that receive energy from light-absorbing pigments and convert it to chemical energy by redox reactions.

receptive field The area of visual space that activates a particular cell in the visual system.

receptor potential The change in the resting potential of a sensory cell when it is stimulated.

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

receptor See receptor protein, sensory receptor cell.

receptor-mediated endocytosis Endocytosis initiated by macromolecular binding to a specific membrane receptor.

recessive In genetics, an allele that does not determine phenotype in the presence of a dominant allele. (Contrast with dominance.)

reciprocal adaptation Evolutionary processes in which an adaptation in one species leads to the evolution of an adaptation in a species with which it interacts; also known as coevolution.

reciprocal crosses A pair of matings in one of which a female of genotype A mates with a male of genotype B and in the other of which a female of genotype B mates with a male of genotype A.

recognition sequence See restriction site.

recombinant DNA A DNA molecule made in the laboratory that is derived from two or more genetic sources.

recombinant Pertaining to an individual, meiotic product, or chromosome in which genetic materials originally present in two individuals end up in the same haploid complement of genes.

recombination frequency The proportion of offspring of a genetic cross that have phenotypes different from the parental phenotypes due to crossing over between linked genes during gamete formation.

rectum The terminal portion of the gut, ending at the anus.

redox reaction A chemical reaction in which one reactant becomes oxidized and the other becomes reduced. Short for reduction-oxidation reaction.

reduction Gain of electrons by a chemical reactant; any reduction is accompanied by an oxidation. (Contrast with oxidation.)

refractory period The time interval after an action potential during which another action potential cannot be elicited from an excitable membrane.

regeneration The development of a complete individual from a fragment of an organism.

regulative development A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

regulatory gene A gene that codes for a protein (or RNA) that in turn controls the expression of another gene.

regulatory sequence A DNA sequence to which the protein product of a regulatory gene binds.

regulatory system A system that uses feedback information to maintain a physiological function or parameter at an optimal level. (Contrast with controlled system.)

regulatory T cells (T_{reg}) The class of T cells that mediates tolerance to self antigens.

reinforcement The evolution of enhanced reproductive isolation between populations due to natural selection for greater isolation.

Reissner's membrane One of two membranes (the other is the basilar membrane) that extend along the length of the cochlea in the human ear.

releaser Sensory stimulus that triggers performance of a stereotyped behavior pattern.

REM (rapid-eye-movement) sleep A sleep state characterized by vivid dreams, skeletal muscle relaxation, and rapid eye movements. (Contrast with non-REM sleep.)

renal [*L. renes*: kidneys] Relating to the kidneys.

renal tubule A structural unit of the kidney that collects filtrate from the blood, reabsorbs specific ions, nutrients, and water and returns them to the blood, and concentrates excess ions and waste products such as urea for excretion from the body.

renin An enzyme released from the kidneys in response to a drop in the glomerular filtration rate. Together with angiotensin converting enzyme, converts an inactive protein in the blood into angiotensin.

replication complex The close association of several proteins operating in the replication of DNA.

replication fork A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

replication The duplication of genetic material.

replicon A region of DNA replicated from a single origin of replication.

reporter gene A genetic marker included in recombinant DNA to indicate the presence of the recombinant DNA in a host cell.

repressor A protein encoded by a regulatory gene that can bind to a promoter and

prevent transcription of the associated gene. (Contrast with activator.)

reproductive isolation Condition in which two divergent populations are no longer exchanging genes. Can lead to speciation.

residual volume (RV) In tidal ventilation, the dead space that remains in the lungs at the end of exhalation.

resistance (R) genes Plant genes that confer resistance to specific strains of pathogens.

resource partitioning A situation in which selection pressures resulting from interspecific competition cause changes in the ways in which the competing species use the limiting resource, thereby allowing them to coexist.

resource Something in the environment required by an organism for its maintenance and growth that is consumed in the process of being used.

respiration (*res pi ra' shun*) [*L. spirare*: to breathe] (1) Cellular respiration. (2) Breathing.

respiratory chain The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

respiratory gases Oxygen (O_2) and carbon dioxide (CO_2); the gases that an animal must exchange between its internal body fluids and the outside medium (air or water).

resting potential The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential.)

restoration ecology The science and practice of restoring damaged or degraded ecosystems.

restriction enzyme Any of a type of enzyme that cleaves double-stranded DNA at specific sites; extensively used in recombinant DNA technology. Also called a restriction endonuclease.

restriction fragment length polymorphism See RFLP.

restriction point (R) The specific time during G1 of the cell cycle at which the cell becomes committed to undergo the rest of the cell cycle.

restriction site A specific DNA base sequence that is recognized and acted on by a restriction endonuclease.

reticular system A central region of the vertebrate brainstem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

reticulum One of the four chambers of the ruminant stomach. Along with the rumen,

where food is partially digested with the assistance of gut bacteria.

retina (rett' in uh) [L. *rete*: net] The light-sensitive layer of cells in the vertebrate or cephalopod eye.

11-cis-retinal The nonprotein, light-absorbing component of the visual system pigment rhodopsin; associated with the protein opsin. (*See* rhodopsin.)

retinoblastoma protein A protein that inhibits an animal cell from passing through the restriction point; inactivation of this protein is necessary for the cell cycle to proceed.

retrotransposons Mobile genetic elements that are reverse transcribed into RNA as part of their transfer mechanism. (Contrast with DNA transposons.)

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

RFLP Restriction fragment length polymorphism, the coexistence of two or more patterns of restriction fragments resulting from underlying differences in DNA sequence.

rhizoids (rye' zoids) [Gk. *root*] Hairlike extensions of cells in mosses, liverworts, and a few vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

rhizome (rye' zome) An underground stem (as opposed to a root) that runs horizontally beneath the ground.

rhodopsin A photopigment used in the visual process of transducing photons of light into changes in the membrane potential of photoreceptor cells.

ribonucleic acid *See* RNA.

ribose A five-carbon sugar in nucleotides and RNA.

ribosomal RNA (rRNA) Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

ribosome A small particle in the cell that is the site of protein synthesis.

ribozyme An RNA molecule with catalytic activity.

ribulose biphosphate carboxylase/oxygenase *See* rubisco.

risk cost The increased chance of being injured or killed as a result of performing a behavior, compared to resting.

RNA (ribonucleic acid) An often single-stranded nucleic acid whose nucleotides use ribose rather than deoxyribose and in which the base uracil replaces thymine found in DNA. Serves as genome for some viruses. (*See* ribosomal RNA, transfer RNA, messenger RNA, and ribozyme.)

RNA interference (RNAi) A mechanism for reducing mRNA translation whereby a double-stranded RNA, made by the cell or synthetically, is processed into a small, single-stranded RNA, whose binding to a target mRNA results in the latter's breakdown.

RNA polymerase An enzyme that catalyzes the formation of RNA from a DNA template.

RNA splicing The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

rod cells Light-sensitive cell in the vertebrate retina; these sensory receptor cells are sensitive in extremely dim light and are responsible for dim light, black and white vision.

root apical meristem Undifferentiated tissue at the apex of the root that gives rise to the organs of the root.

root cap A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem; the organ that perceives the gravitational stimulus in root gravitropism.

root hair A long, thin process from a root epidermal cell that absorbs water and minerals from the soil solution.

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

root The organ responsible for anchoring the plant in the soil, absorbing water and minerals, and producing certain hormones. Some roots are storage organs.

rough endoplasmic reticulum (RER) The portion of the endoplasmic reticulum whose outer surface has attached ribosomes. (Contrast with smooth endoplasmic reticulum.)

round window A flexible membrane at the end of the lower canal of the cochlea in the human ear. (*See also* oval window.)

rRNA *See* ribosomal RNA.

rubisco Contraction of ribulose biphosphate carboxylase/oxygenase, the enzyme that combines carbon dioxide or oxygen with ribulose biphosphate to catalyze the first step of photosynthetic carbon fixation or photorespiration, respectively.

rumen One of the four chambers of the ruminant stomach. Along with the reticulum, where food is partially digested with the assistance of gut bacteria.

ruminant Herbivorous, cud-chewing mammals such as cows or sheep, characterized by a stomach that consists of four compartments: the rumen, reticulum, omasum, and abomasum.

- S -

S phase In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G1 phase, G2 phase, M phase.)

salt glands Glands on the leaves of some halophytic plants that secrete salt, thereby ridding the plants of excess salt.

saltatory conduction [L. *saltare*: to jump] The rapid conduction of action potentials in myelinated axons; so called because action potentials appear to "jump" between nodes of Ranvier along the axon.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter.

sarcomere (sark' o meer) [Gk. *sark*: flesh + *meros*: unit] The contractile unit of a skeletal muscle.

sarcoplasm The cytoplasm of a muscle cell.

sarcoplasmic reticulum The endoplasmic reticulum of a muscle cell.

saturated fatty acid A fatty acid in which all the bonds between carbon atoms in the hydrocarbon chain are single bonds—that is, all the bonds are saturated with hydrogen atoms. (Contrast with unsaturated fatty acid.)

Schwann cell A type of glial cell that myelinates axons in the peripheral nervous system.

scientific method A means of gaining knowledge about the natural world by making observations, posing hypotheses, and conducting experiments to test those hypotheses.

scion In horticulture, the bud or stem from one plant that is grafted to a root or root-bearing stem of another plant (the stock).

sclereid One of the principle types of cells in sclerenchyma.

sclerenchyma (skler eng' kyma) [Gk. *skleros*: hard + *kymus*: juice] A plant tissue composed of cells with heavily thickened cell walls. The cells are dead at functional maturity. The principal types of sclerenchyma cells are fibers and sclereids.

scrotum In most mammals, a pouch outside the body cavity that contains the testes.

seasonality A aspect of climate characterized by fluctuations in temperature over the course of a year.

second filial generation *See* F₂.

second law of thermodynamics The principle that when energy is converted from one form to another, some of that energy becomes unavailable for doing work.

second messenger A compound, such as cAMP, that is released within a target cell after a hormone (the first messenger) has bound to a surface receptor on a cell; the second messenger triggers further reactions within the cell.

second polar body In oogenesis, the daughter cell of the second meiotic division that subsequently degenerates. (*See also* ootid.)

secondary active transport A form of active transport that does not use ATP as an

energy source; rather, transport is coupled to ion diffusion down a concentration gradient established by primary active transport.

secondary cell wall A thick, cellulose structure internal to the primary cell wall formed in some plant cells after cell expansion stops (Contrast with primary cell wall.)

secondary consumer An organism that eats primary consumers.

secondary endosymbiosis The engulfment of a photosynthetic eukaryote by another eukaryotic cell that gave rise to certain groups of photosynthetic eukaryotes (e.g., euglenids).

secondary growth In plants, growth that contributes to an increase in girth. (Contrast with primary growth.)

secondary immune response A rapid and intense response to a second or subsequent exposure to an antigen, initiated by memory cells. (Contrast with primary immune response.)

secondary lysosome Membrane-enclosed organelle formed by the fusion of a primary lysosome with a phagosome, in which macromolecules taken up by phagocytosis are hydrolyzed into their monomers. (Contrast with lysosome.)

secondary metabolite A compound synthesized by a plant that is not needed for basic cellular metabolism. Typically has an antiherbivore or antiparasite function.

secondary oocyte In oogenesis, the daughter cell of the first meiotic division that receives almost all the cytoplasm. (See also first polar body.)

secondary plant body That part of a plant produced by secondary growth; consists of woody tissues. (Contrast with primary plant body.)

secondary spermatocyte One of the products of the first meiotic division of a primary spermatocyte.

secondary structure Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet.

secretin (si kreef' in) A peptide hormone secreted by the upper region of the small intestine when acidic chyme is present. Stimulates the pancreatic duct to secrete bicarbonate ions.

sedimentary rock Rock formed by the accumulation of sediment grains on the bottom of a body of water.

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

seedling A plant that has just completed the process of germination.

segment polarity genes In *Drosophila* (fruit fly) development, segmentation genes that determine the boundaries and anterior-posterior organization of individual segments. Part of a developmental cascade that includes maternal effect genes, gap genes, pair rule genes, and Hox genes.

segmentation Division of an animal body into segments.

segmentation genes Genes that determine the number and polarity of body segments.

segregation In genetics, the separation of alleles, or of homologous chromosomes, from each other during meiosis so that each of the haploid daughter nuclei produced contains one or the other member of the pair found in the diploid parent cell, but never both. This principle was articulated by Mendel as his first law.

selectable marker A gene, such as one encoding resistance to an antibiotic, that can be used to identify (select) cells that contain recombinant DNA from among a large population of untransformed cells.

selective permeability Allowing certain substances to pass through while other substances are excluded; a characteristic of membranes.

self-incompatibility In plants, the possession of mechanisms that prevent self-fertilization.

semen (see' men) [L. *semin*: seed] The thick, whitish liquid produced by the male reproductive system in mammals, containing the sperm.

semicircular canals Three canals in the human inner ear that form part of the vestibular system. (See vestibular system.)

semiconservative replication The way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

semiferous tubules The tubules within the testes within which sperm production occurs.

senescence [L. *senescere*: to grow old] Aging; deteriorative changes with aging; the increased probability of dying with increasing age.

sensitive period The life stage during which some particular type of learning must take place, or during which it occurs much more easily than at other times. Typical of song learning among birds.

sensor See sensory receptor cell.

sensory neuron A specialized neuron that transduces a particular type of sensory stimulus into action potentials.

sensory receptor cell Cell that is responsive to a particular type of physical or chemical stimulation.

sensory system A set of organs and tissues for detecting a stimulus; consists of sensory cells, the associated structures, and the neural networks that process the information.

sensory transduction The transformation of environmental stimuli or information into neural signals.

sepal (see' pul) [L. *sepalum*: covering] One of the outermost structures of the flower,

usually protective in function and enclosing the rest of the flower in the bud stage.

sepsis Generalized inflammation caused by bacterial infection. Can cause a dangerous drop in blood pressure.

septum (plural: septa) [L. wall] (1) A partition or cross-wall appearing in the hyphae of some fungi. (2) The bony structure dividing the nasal passages.

Sertoli cells Cells in the seminiferous tubules that nurture the developing sperm.

sessile (sess' ul) [L. *sedere*: to sit] Permanently attached; not able to move from one place to another. (Contrast with motile.)

set point In a regulatory system, the threshold sensitivity to the feedback stimulus.

sex chromosome In organisms with a chromosomal mechanism of sex determination, one of the chromosomes involved in sex determination.

sex linkage The pattern of inheritance characteristic of genes located on the sex chromosomes of organisms having a chromosomal mechanism for sex determination. Also called *sex-linked inheritance*.

sex pilus A thin connection between two bacteria through which genetic material passes during conjugation.

sex-linked inheritance Inheritance of a gene that is carried on a sex chromosome. Also called *sex linkage*.

sexual reproduction Reproduction involving the union of gametes.

sexual selection Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in one sex as a result of competition among individuals of that sex for mates.

shared derived trait See synapomorphy.

shoot apical meristem Undifferentiated tissue at the apex of the shoot that gives rise to the organs of the shoot.

shoot system In plants, the organ system consisting of the leaves, stem(s), and flowers.

short-day plant (SDP) A plant that flowers when nights are longer than a critical length specific for that plant's species. (Compare to long-day plant.)

short tandem repeat (STR) A short (1–5 base pairs), moderately repetitive sequence of DNA. The number of copies of an STR at a particular location varies between individuals and is inherited.

side chain See R group.

sieve tube element The characteristic cell of the phloem in angiosperms, which contains cytoplasm but relatively few organelles, and whose end walls (*sieve plates*) contain pores that form connections with neighboring cells.

sigma factor In prokaryotes, a protein that binds to RNA polymerase, allowing the complex to bind to and stimulate the

transcription of a specific class of genes (e.g., those involved in sporulation).

signal sequence The sequence within a protein that directs the protein to a particular organelle.

signal transduction pathway The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

silent mutation A change in a gene's sequence that has no effect on the amino acid sequence of a protein because it occurs in noncoding DNA or because it does not change the amino acid specified by the corresponding codon. (Contrast with frameshift mutation, missense mutation, nonsense mutation.)

simple diffusion Diffusion that doesn't involve a direct input of energy or assistance by carrier proteins.

single nucleotide polymorphisms (SNPs) Inherited variations in a single nucleotide base in DNA that differ between individuals.

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

sinoatrial node (sigh' no ay' tree al) [L. *sinus*: curve + *atrium*: chamber] The pace-maker of the mammalian heart.

siRNAs (small interfering RNAs) Short, double-stranded RNA molecules used in RNA interference.

sister chromatid Each of a pair of newly replicated chromatids.

sister clades Two phylogenetic groups that are each other's closest relatives.

sister species Two species that are each other's closest relatives.

skeletal muscle A type of muscle tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also called striated muscle. (Contrast with cardiac muscle, smooth muscle.)

skeletal systems Organ systems that provide rigid supports against which muscles can pull to create directed movements.

sliding filament theory Mechanism of muscle contraction based on the formation and breaking of crossbridges between actin and myosin filaments, causing the filaments to slide together.

slow-twitch fibers Skeletal muscle fibers specialized for sustained aerobic work; contain myoglobin and abundant mitochondria, and are well-supplied with blood vessels. Also called oxidative or red muscle fibers. (Compare to fast-twitch fibers.)

slow-wave sleep See non-REM sleep.

small intestine The portion of the gut between the stomach and the colon; consists of the duodenum, the jejunum, and the ileum.

small nuclear ribonucleoprotein particle (snRNP) A complex of an enzyme and a small nuclear RNA molecule, functioning in RNA splicing.

smooth endoplasmic reticulum (SER) Portion of the endoplasmic reticulum that lacks ribosomes and has a tubular appearance. (Contrast with rough endoplasmic reticulum.)

smooth muscle Muscle tissue consisting of sheets of mononucleated cells innervated by the autonomic nervous system. (Contrast with cardiac muscle, skeletal muscle.)

sodium-potassium (Na⁺-K⁺) pump Anti-porter responsible for primary active transport; it pumps sodium ions out of the cell and potassium ions into the cell, both against their concentration gradients. Also called a sodium-potassium ATPase.

soil horizon See horizons.

soil solution The aqueous portion of soil, from which plants take up dissolved mineral nutrients.

solute A substance that is dissolved in a liquid (solvent) to form a solution.

solute potential (Ψ_s) A property of any solution, resulting from its solute contents; it may be zero or have a negative value. The more negative the solute potential, the greater the tendency of the solution to take up water through a differentially permeable membrane. (Contrast with pressure potential, water potential.)

solution A liquid (the solvent) and its dissolved solutes.

solvent Liquid in which a substance (solute) is dissolved to form a solution.

somatic cell [Gk. *soma*: body] All the cells of the body that are not specialized for reproduction. (Contrast with germ cell.)

somatic mutation Permanent genetic change in a somatic cell. These mutations affect the individual only; they are not passed on to offspring. (Contrast with germ line mutation.)

somatosensory cortex The region of the cerebral cortex that receives input from mechanosensors distributed throughout the body.

somatostatin Peptide hormone made in the hypothalamus that inhibits the release of other hormones from the pituitary and intestine.

somite (so' might) One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

spatial summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations and hyperpolarizations produced at differ-

ent sites on the postsynaptic cell. (Contrast with temporal summation.)

spawning See external fertilization.

speciation (spee' see ay' shun) The process of splitting one population into two populations that are reproductively isolated from one another.

species (spee' sees) [L. *kind*] The base unit of taxonomic classification, consisting of an ancestor-descendant group of populations of evolutionarily closely related, similar organisms. The more narrowly defined "biological species" consists of individuals capable of interbreeding with each other but not with members of other species.

species composition The particular mix of species a community contains and the abundances of those species.

species evenness A measure of species diversity that reflects the distribution of the species' abundances in a community.

species richness The total number of species living in a region.

specific heat The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

sperm [Gk. *sperma*: seed] The male gamete.

spermatid One of the products of the second meiotic division of a primary spermatocyte; four haploid spermatids, which remain connected by cytoplasmic bridges, are produced for each primary spermatocyte that enters meiosis.

spermatogenesis (spur mat' oh jen' e sis) [Gk. *sperma*: seed + *genesis*: source] Gametogenesis leading to the production of sperm.

spermatogonia In animals, the diploid progeny of a germ cell in males.

spherical symmetry The simplest form of symmetry, in which body parts radiate out from a central point such that an infinite number of planes passing through that central point can divide the organism into similar halves.

sphincter (slink' ter) [Gk. *sphinkter*: something that binds tightly] A ring of muscle that can close an orifice, for example, at the anus.

spicule [L. arrowhead] A hard, calcareous skeletal element typical of sponges.

spinal cord Along with the brain, part of the central nervous system; transmits information between the body and the brain and mediates simple reflexes.

spinal reflex The conversion of afferent to efferent information in the spinal cord without participation of the brain.

spindle Array of microtubules emanating from both poles of a dividing cell during mitosis and playing a role in the movement of chromosomes at nuclear division. Named for its shape.

spleen Organ that serves as a reservoir for venous blood and eliminates old, damaged red blood cells from the circulation.

spliceosome RNA–protein complex that splices out introns from eukaryotic pre-mRNAs.

splicing See RNA splicing.

spontaneous mutation A genetic change caused by internal cellular mechanisms, such as an error in DNA replication. (Contrast with induced mutation.)

sporangiophore A stalked reproductive structure produced by zygosporic fungi that extends from a hypha and bears one or many sporangia.

sporangium (spor an' gee um) (plural: sporangia) [Gk. *spora*: seed + *angeion*: vessel or reservoir] In plants and fungi, any specialized structure within which one or more spores are formed.

spore [Gk. *spora*: seed] (1) Any asexual reproductive cell capable of developing into an adult organism without gametic fusion. In plants, haploid spores develop into gametophytes, diploid spores into sporophytes. (2) In prokaryotes, a resistant cell capable of surviving unfavorable periods.

sporocyte Specialized cells of the diploid sporophyte that will divide by meiosis to produce four haploid spores. Germination of these spores produces the haploid gametophyte.

sporophyte (spor' o fyte) [Gk. *spora*: seed + *phyton*: plant] In plants and protists with alternation of generations, the diploid phase that produces the spores. (Contrast with gametophyte.)

stabilizing selection Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with disruptive selection.)

stamen (stay' men) [L. *stamen*: thread] A male (pollen-producing) unit of a flower, usually composed of an anther, which bears the pollen, and a filament, which is a stalk supporting the anther.

starch [O.E. *stearc*: stiff] A polymer of glucose; used by plants to store energy.

Starling's forces The two opposing forces responsible for water movement across capillary walls: blood pressure, which squeezes water and small solutes out of the capillaries, and osmotic pressure, which pulls water back into the capillaries.

start codon The mRNA triplet (AUG) that acts as a signal for the beginning of translation at the ribosome. (Contrast with stop codon.)

stele (steel) [Gk. *stylos*: pillar] The central cylinder of vascular tissue in a plant stem.

stem In plants, the organ that holds leaves and/or flowers and transports and distributes materials among the other organs of the plant.

stem cell In animals, an undifferentiated cell that is capable of continuous proliferation. A stem cell generates more stem cells

and a large clone of differentiated progeny cells. (See also embryonic stem cell.)

stereocilia Fingerlike extensions of hair cell membranes whose bending initiates mechanosensation. (See hair cell.)

steroid Any of a family of lipids whose multiple rings share carbons. The steroid cholesterol is an important constituent of membranes; other steroids function as hormones.

sticky ends On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends facilitate the joining of segments of DNA from different sources.

stigma [L. *stigma*: mark, brand] The part of the pistil at the apex of the style that is receptive to pollen, and on which pollen germinates.

stimulus [L. *stimulare*: to goad] Something causing a response; something in the environment detected by a receptor.

stock In horticulture, the root or root-bearing stem to which a bud or piece of stem from another plant (the scion) is grafted.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

stomach An organ that physically (and sometimes enzymatically) breaks down food, preparing it for digestion in the midgut.

stomatal crypt In plants, a sunken cavity below the leaf surface in which a stoma is sheltered from the drying effects of air currents.

stop codon Any of the three mRNA codons that signal the end of protein translation at the ribosome: UAG, UGA, UAA.

stratosphere The upper part of Earth's atmosphere, above the troposphere; extends from approximately 18 kilometers upward to approximately 50 kilometers above Earth's surface.

stratum (plural strata) [L. *stratos*: layer] A layer of sedimentary rock laid down at a particular time in the past.

stretch receptor A modified muscle cell embedded in the connective tissue of a muscle that acts as a mechanoreceptor in response to stretching of that muscle.

striated muscle See skeletal muscle.

strigolactones Signaling molecules produced by plant roots that attract the hyphae of mycorrhizal fungi.

strobilus (plural: strobili) One of several conelike structures in various groups of plants (including club mosses, horsetails, and conifers) associated with the production and dispersal of reproductive products.

stroma The fluid contents of an organelle such as a chloroplast or mitochondrion.

structural gene A gene that encodes the primary structure of a protein not involved in the regulation of gene expression.

structural motif A three-dimensional structural element that is part of a larger molecule. For example, there are four common motifs in DNA-binding proteins: helix-turn-helix, zinc finger, leucine zipper, and helix-loop-helix.

style [Gk. *stylos*: pillar or column] In the angiosperm flower, a column of tissue extending from the tip of the ovary, and bearing the stigma or receptive surface for pollen at its apex.

sub- [L. under] A prefix used to designate a structure that lies beneath another or is less than another. For example, subcutaneous (beneath the skin); subspecies.

suberin A waxlike lipid that is a barrier to water and solute movement across the Casparian strip of the endodermis.

submucosa (sub mew koe' sah) The tissue layer just under the epithelial lining of the lumen of the digestive tract.

subsoil The soil horizon lying below the topsoil and above the parent rock (bedrock); the zone of infiltration and accumulation of materials leached from the topsoil. Also called the B horizon.

substrate (sub' strayte) (1) The molecule or molecules on which an enzyme exerts catalytic action. (2) The base material on which a sessile organism lives.

succession The gradual, sequential series of changes in the species composition of a community following a disturbance.

succulence In plants, possession of fleshy, water-storing leaves or stems; an adaptation to dry environments.

superficial cleavage A variation of incomplete cleavage in which cycles of mitosis occur without cell division, producing a syncytium (a single cell with many nuclei).

suprachiasmatic nuclei (SCN) In mammals, two clusters of neurons just above the optic chiasm that act as the master circadian clock.

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

surface tension The attractive intermolecular forces at the surface of liquid; an especially important property of water.

surfactant A substance that decreases the surface tension of a liquid. Lung surfactant, secreted by cells of the alveoli, is mostly phospholipid and decreases the amount of work necessary to inflate the lungs.

survivorship (l_x) In life tables, the proportion of individuals in a cohort that are alive at age x . A graph of this data is a survivorship curve.

suspensor In the embryos of seed plants, the stalk of cells that pushes the embryo into

the endosperm and is a source of nutrient transport to the embryo.

symbiosis (sim' bee oh' sis) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

symmetry Pertaining to an attribute of an animal body in which at least one plane can divide the body into similar, mirror-image halves. (See bilateral symmetry, radial symmetry.)

sympathetic nervous system The division of the autonomic nervous system that works in opposition to the parasympathetic nervous system. (Contrast with parasympathetic nervous system.)

sympatric speciation (sim pat' rik) [Gk. *sym*: same + *patria*: homeland] Speciation due to reproductive isolation without any physical separation of the subpopulation. (Contrast with allopatric speciation.)

symplast The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

symporter A membrane transport protein that carries two substances in the same direction. (Contrast with antiporter, uniporter.)

synapomorphy A trait that arose in the ancestor of a phylogenetic group and is present (sometimes in modified form) in all of its members, thus helping to delimit and identify that group. Also called a shared derived trait.

synapse (sin' aps) [Gk. *syn*: together + *haptein*: to fasten] A specialized type of junction where a neuron meets its target cell (which can be another neuron or some other type of cell) and information in the form of neurotransmitter molecules is exchanged across a synaptic cleft.

synapsis (sin ap' sis) The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

synaptic cleft The space between the presynaptic cell and the postsynaptic cell in a chemical synapse.

synergids [Gk. *syn*: together + *ergos*: work] In angiosperms, the two cells accompanying the egg cell at one end of the megagametophyte.

syngamy See fertilization.

synonymous (silent) substitution A change of one nucleotide in a sequence to another when that change does not affect the amino acid specified (i.e., UUA → UUG, both specifying leucine). (Contrast with non-synonymous substitution, missense mutation, nonsense mutation.)

systematics The scientific study of the diversity and relationships among organisms.

systemic acquired resistance A general resistance to many plant pathogens following infection by a single agent.

systemic circuit Portion of the circulatory system by which oxygenated blood from the lungs or gills is distributed throughout the rest of the body and returned to the heart. (Contrast with pulmonary circuit.)

systems biology The scientific study of an organism as an integrated and interacting system of genes, proteins, and biochemical reactions.

systole (sis' tuh lee) [Gk. *systole*: contraction] Contraction of a chamber of the heart, driving blood forward in the circulatory system. (Contrast with diastole.)

- T -

T cell A type of lymphocyte involved in the cellular immune response. The final stages of its development occur in the thymus gland. (Contrast with B cell; see also cytotoxic T cell, T-helper cell.)

T cell receptor A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

T tubules A system of tubules that runs throughout the cytoplasm of a muscle fiber, through which action potentials spread.

T-helper (T_H) cell Type of T cell that stimulates events in both the cellular and humoral immune responses by binding to the antigen on an antigen-presenting cell; target of the HIV-I virus, the agent of AIDS. (Contrast with cytotoxic T cells.)

taproot system A root system typical of eudicots consisting of a primary root (*taproot*) that extends downward by tip growth and outward by initiating lateral roots. (Contrast with fibrous root system.)

target cell A cell with the appropriate receptors to bind and respond to a particular hormone or other chemical mediator.

taste bud A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

TATA box An eight-base-pair sequence, found about 25 base pairs before the starting point for transcription in many eukaryotic promoters, that binds a transcription factor and thus helps initiate transcription.

taxon (plural: taxa) [Gk. *taxis*: arrange, put in order] A biological group (typically a species or a clade) that is given a name.

teeth Parts of the jaw in mammals that are variously adapted for grinding, stabbing, or cutting food.

telencephalon The outer, surrounding structure of the embryonic vertebrate forebrain, which develops into the cerebrum.

telomerase An enzyme that catalyzes the addition of telomeric sequences lost from chromosomes during DNA replication.

telomeres (tee' lo merz) [Gk. *telos*: end + *meros*: units, segments] Repeated DNA sequences at the ends of eukaryotic chromosomes.

telophase (tee' lo phase) [Gk. *telos*: end] The final phase of mitosis or meiosis during which chromosomes became diffuse, nucle-

ar envelopes re-form, and nucleoli begin to reappear in the daughter nuclei.

template A molecule or surface on which another molecule is synthesized in complementary fashion, as in the replication of DNA.

template strand In double-stranded DNA, the strand that is transcribed to create an RNA transcript that will be processed into a protein. Also refers to a strand of RNA that is used to create a complementary RNA.

temporal lobe One of the four lobes of the cerebral hemisphere; receives and processes auditory and visual information; involved in recognizing, identifying, and naming objects.

temporal summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations or hyperpolarizations produced by rapidly repeated stimulation of a single point on the postsynaptic cell. (Contrast with spatial summation.)

tendon A collagen-containing band of tissue that connects a muscle with a bone.

tepal A sterile, modified, nonphotosynthetic leaf of an angiosperm flower that cannot be distinguished as a petal or a sepal.

termination In molecular biology, the end of transcription or translation.

terminator A sequence at the 3' end of mRNA that causes the RNA strand to be released from the transcription complex.

terrestrial (ter res' tree al) [L. *terra*: earth] Pertaining to or living on land. (Contrast with aquatic, marine.)

territorial behavior Aggressive actions engaged in to defend a habitat or resource such that other animals are denied access.

tertiary consumers Carnivores that consume primary carnivores (secondary consumers).

tertiary endosymbiosis The mechanism by which some eukaryotes acquired the capacity for photosynthesis; for example, a dinoflagellate that apparently lost its chloroplast became photosynthetic by engulfing another protist that had acquired a chloroplast through secondary endosymbiosis.

tertiary structure In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, secondary, and quaternary structures.)

test cross Mating of a dominant-phenotype individual (who may be either heterozygous or homozygous) with a homozygous-recessive individual.

testis (tes' tis) (plural: testes) [L. *testis*: witness] The male gonad; the organ that produces the male gametes.

tetanus [Gk. *tetanos*: stretched] (1) A state of sustained maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often fatal disease

("lockjaw") caused by the bacterium *Clostridium tetani*.

tetrad [Gk. *tettares*: four] During prophase I of meiosis, the association of a pair of homologous chromosomes or four chromatids.

thalamus [Gk. *thalamos*: chamber] A region of the vertebrate forebrain; involved in integration of sensory input.

theory [Gk. *theoria*: analysis of facts] A far-reaching explanation of observed facts that is supported by such a wide body of evidence, with no significant contradictory evidence, that it is scientifically accepted as a factual framework. Examples are Newton's theory of gravity and Darwin's theory of evolution. (Contrast with hypothesis.)

thermoneutral zone (TNZ) [Gk. *thermos*: temperature] The range of temperatures over which an endotherm does not have to expend extra energy to thermoregulate.

thermophile (ther' muh fyle) [Gk. *thermos*: temperature + *philos*: loving] An organism that lives exclusively in hot environments.

thoracic cavity [Gk. *thorax*: breastplate] The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

thoracic duct The connection between the lymphatic system and the circulatory system.

threshold The level of depolarization that causes an electrically excitable membrane to fire an action potential.

thrombin An enzyme involved in blood clotting; cleaves fibrinogen to form fibrin.

thrombus (throm' bus) [Gk. *thrombos*: clot] A blood clot that forms within a blood vessel and remains attached to the wall of the vessel.

thylakoid (thigh la koid) [Gk. *thylakos*: sack or pouch] A flattened sac within a chloroplast. Thylakoid membranes contain all of the chlorophyll in a plant, in addition to the electron carriers of photophosphorylation. Thylakoids stack to form grana.

thymine (T) Nitrogen-containing base found in DNA.

thymus [Gk. *thymos*: warty] A ductless, glandular lymphoid tissue, involved in development of the immune system of vertebrates. In humans, the thymus degenerates during puberty.

thyroid gland [Gk. *thyreos*: door-shaped] A two-lobed gland in vertebrates. Produces the hormone thyroxine.

thyrotropin Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyroid-stimulating hormone (TSH).

thyrotropin-releasing hormone (TRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to release thyrotropin.

thyroxine Hormone produced by the thyroid gland; controls many metabolic processes.

tidal The bidirectional form of ventilation used by all vertebrates except birds; air enters and leaves the lungs by the same route.

tidal volume (TV) The amount of air that is exchanged during each breath when a person is at rest.

tight junction A junction between epithelial cells in which there is no gap between adjacent cells.

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

tissue system In plants, any of three organized groups of tissues—dermal tissue, vascular tissue, and ground tissue—that are established during embryogenesis and have distinct functions.

titin A protein that holds bundles of myosin filaments in a centered position within the sarcomeres of muscle cells. The largest protein in the human body.

TNZ See thermoneutral zone.

tonoplast The membrane of the plant central vacuole.

topography The variations in the elevation of Earth's surface that form, for example, mountains and valleys.

topsoil The uppermost soil horizon; contains most of the organic matter of soil, but may be depleted of most mineral nutrients by leaching. Also called the A horizon.

totipotent [L. *toto*: whole, entire + *potens*: powerful] Possessing all the genetic information and other capacities necessary to form an entire individual. (Contrast with multipotent, pluripotent.)

toxigenicity The ability of some pathogenic bacteria to produce chemical substances that harm the host.

trachea (tray' kee ah) [Gk. *trakhoia*: tube] A tube that carries air to the bronchi of the lungs of vertebrates. When plural (*tracheae*), refers to the major airways of insects.

tracheary element Either of two types of xylem cells—tracheids and vessel elements—that undergo apoptosis before assuming their transport function.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

trade-off The relationship between the fitness benefits conferred by an adaptation and the fitness costs it imposes. For an adaptation to be favored by natural selection, the benefits must exceed the costs.

trait In genetics, a specific form of a character: eye color is a character; brown eyes and blue eyes are traits. (Contrast with character.)

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

transcription initiation site The part of a gene's promoter where synthesis of the gene's RNA transcript begins.

transcription The synthesis of RNA using one strand of DNA as a template.

transduction (1) Transfer of genes from one bacterium to another by a bacteriophage. (2) In sensory cells, the transformation of a stimulus (e.g., light energy, sound pressure waves, chemical or electrical stimulants) into action potentials.

transfection Insertion of recombinant DNA into animal cells.

transfer RNA (tRNA) A family of folded RNA molecules. Each tRNA carries a specific amino acid and anticodon that will pair with the complementary codon in mRNA during translation.

transformation (1) A mechanism for transfer of genetic information in bacteria in which pure DNA from a bacterium of one genotype is taken in through the cell surface of a bacterium of a different genotype and incorporated into the chromosome of the recipient cell. (2) Insertion of recombinant DNA into a host cell.

transgenic Containing recombinant DNA incorporated into the genetic material.

transition state In an enzyme-catalyzed reaction, the reactive condition of the substrate after there has been sufficient input of energy (activation energy) to initiate the reaction.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

translational repressor A protein that blocks translation by binding to mRNAs and preventing their attachment to the ribosome. In mammals, the production of ferritin protein is regulated by a translational repressor.

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

transmembrane protein An integral membrane protein that spans the phospholipid bilayer.

transpiration [L. *spirare*: to breathe] The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus mineral nutrients) from the roots.

transpiration-cohesion-tension mechanism Theoretical basis for water movement in plants: evaporation of water from cells within leaves (transpiration) causes an increase in surface tension, pulling water

up through the xylem. Cohesion of water occurs because of hydrogen bonding.

transposable element A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

transposon Mobile DNA segment that can insert into a chromosome and cause genetic change.

triglyceride A simple lipid in which three fatty acids are combined with one molecule of glycerol.

triploblastic Having three cell layers.

trisomic Containing three rather than two members of a chromosome pair.

tRNA See transfer RNA.

trochophore (troke' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

trophic cascade The progression over successively lower trophic levels of the indirect effects of a predator.

trophic interactions The consumer-resource relationships among species in a community.

trophic level [Gk *trophes*: nourishment] A group of organisms united by obtaining their energy from the same part of the food web of a biological community.

trophoblast [Gk *trophes*: nourishment + *blastos*: sprout] At the 32-cell stage of mammalian development, the outer group of cells that will become part of the placenta and thus nourish the growing embryo. (Contrast with inner cell mass.)

tropic hormones Hormones produced by the anterior pituitary that control the secretion of hormones by other endocrine glands.

tropomyosin [troe' poe my' oh sin] One of the three protein components of an actin filament; controls the interactions of actin and myosin necessary for muscle contraction.

troponin One of the three components of an actin filament; binds to actin, tropomyosin, and Ca²⁺.

true-breeding A genetic cross in which the same result occurs every time with respect to the trait(s) under consideration, due to homozygous parents.

trypsin A protein-digesting enzyme. Secreted by the pancreas in its inactive form (trypsinogen), it becomes active in the duodenum of the small intestine.

tube feet A unique feature of echinoderms; extensions of the water vascular system, which functions in gas exchange, locomotion, and feeding.

tubulin A protein that polymerizes to form microtubules.

tumor [L. *tumor*: a swollen mass] A disorganized mass of cells. Malignant tumors spread to other parts of the body.

tumor necrosis factor A family of cytokines (growth factors) that causes cell death and is involved in inflammation.

tumor suppressor A gene that codes for a protein product that inhibits cell proliferation; inactive in cancer cells. (Contrast with oncogene.)

turgor pressure [L. *turgidus*: swollen] See pressure potential.

twitch A muscle fiber's minimum unit of contraction, stimulated by a single action potential.

tympenic membrane [Gk. *tympanum*: drum] The eardrum.

- U -

ubiquitin A small protein that is covalently linked to other cellular proteins identified for breakdown by the proteasome.

ultimate cause In ethology, the evolutionary processes that produced an animal's capacity and tendency to behave in particular ways. (Contrast with proximate cause.)

uniporter [L. *unus*: one + *portal*: doorway] A membrane transport protein that carries a single substance in one direction. (Contrast with antiporter, symporter.)

unsaturated fatty acid A fatty acid whose hydrocarbon chain contains one or more double bonds. (Contrast with saturated fatty acid.)

upregulation A process by which the abundance of receptors for a hormone increases when hormone secretion is suppressed. (Contrast with downregulation.)

upwelling zones Areas of the ocean where cool, nutrient-rich water from deeper layers rises to the surface.

uracil (U) A pyrimidine base found in nucleotides of RNA.

urea A compound that is the main form of nitrogen excreted by many animals, including mammals.

ureotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is urea. (Contrast with ammonotelic, uricotelic.)

ureter (your' uh tur) Long duct leading from the vertebrate kidney to the urinary bladder or the cloaca.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

uric acid A compound that serves as the main excreted form of nitrogen in some animals, particularly those which must conserve water, such as birds, insects, and reptiles.

uricotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is uric acid. (Contrast with ammonotelic, ureotelic.)

urinary bladder A structure in which urine is stored until it can be excreted to the outside of the body.

urine (you' rin) In vertebrates, the fluid waste product containing the toxic nitrogenous by-products of protein and nucleic acid metabolism.

uterine cycle In human females, the monthly cycle of events by which the endometrium is prepared for the arrival of a blastocyst. (Contrast with ovarian cycle.)

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

- V -

vaccination Injection of virus or bacteria or their proteins into the body, to induce immunity. The injected material is usually attenuated (weakened) before injection and is called a *vaccine*.

vacuole (vac' yew ole) Membrane-enclosed organelle in plant cells that can function for storage, water concentration for turgor, or hydrolysis of stored macromolecules.

vagina (vuh jine' uh) [L. sheath] In female animals, the entry to the reproductive tract.

van der Waals forces Weak attractions between atoms resulting from the interaction of the electrons of one atom with the nucleus of another. This type of attraction is about one-fourth as strong as a hydrogen bond.

variable In a controlled experiment, a factor that is manipulated to test its effect on a phenomenon.

variable region The portion of an immunoglobulin molecule or T cell receptor that includes the antigen-binding site and is responsible for its specificity. (Contrast with constant region.)

vas deferens (plural: vasa deferentia) Duct that transfers sperm from the epididymis to the urethra.

vasa recta Blood vessels that parallel the loops of Henle and the collecting ducts in the renal medulla of the kidney.

vascular (vas' kew lar) [L. *vasculum*: a small vessel] Pertaining to organs and tissues that conduct fluid, such as blood vessels in animals and xylem and phloem in plants.

vascular bundle In vascular plants, a strand of vascular tissue, including xylem and phloem as well as thick-walled fibers.

vascular cambium (kam' bee um) [L. *cambiare*: to exchange] In plants, a lateral meristem that gives rise to secondary xylem and phloem.

vascular tissue system The transport system of a vascular plant, consisting primarily of xylem and phloem.

vasopressin See antidiuretic hormone.

vector (1) An agent, such as an insect, that carries a pathogen affecting another species. (2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

vegetal hemisphere The lower portion of some animal eggs, zygotes, and embryos, in which the dense nutrient yolk settles. The *vegetal pole* is to the very bottom of the egg or embryo. (Contrast with animal hemisphere.)

vegetative cells In filamentous colonies of cyanobacteria the cells that perform photosynthesis. (Contrast with spores and heterocysts.)

vegetative meristem An apical meristem that produces leaves.

vegetative Nonreproductive, nonflowering, or asexual.

vegetative reproduction Asexual reproduction through the modification of stems, leaves, or roots.

vein [L. *vena*: channel] A blood vessel that returns blood to the heart. (Contrast with artery.)

vena cavae In the circulatory systems of crocodilians, birds, and mammals, large veins that empty into the right atrium of the heart.

ventral [L. *venter*: belly, womb] Toward or pertaining to the belly or lower side. (Contrast with dorsal.)

ventricle A muscular heart chamber that pumps blood through the lungs or through the body.

venule A small blood vessel draining a capillary bed that joins others of its kind to form a vein. (Contrast with arteriole.)

vernalization [L. *vernal*: spring] Events occurring during a required chilling period, leading eventually to flowering.

vertebral column [L. *vertere*: to turn] The jointed, dorsal column that is the primary support structure of vertebrates.

very low-density lipoproteins (VLDLs) Lipoproteins that consist mainly of triglyceride fats, which they transport to fat cells in adipose tissues throughout the body; associated with excessive fat deposition and high risk for cardiovascular disease.

vesicle Within the cytoplasm, a membrane-enclosed compartment that is associated with other organelles; the Golgi complex is one example.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

vestibular system (ves tib' yew lar) [L. *vestibulum*: an enclosed passage] Structures within the inner ear that sense changes in position or momentum of the head, affecting balance and motor skills.

villus (vil' lus) (plural: villi) [L. *villus*: shaggy hair or beard] A hairlike projection from a membrane; for example, from many gut walls.

virion (veer' e on) The virus particle, the minimum unit capable of infecting a cell.

virulence [L. *virus*: poison, slimy liquid] The ability of a pathogen to cause disease and death.

virus Any of a group of ultramicroscopic particles constructed of nucleic acid and protein (and, sometimes, lipid) that require living cells in order to reproduce. Viruses evolved multiple times from different cellular species.

vital capacity (VC) The maximum capacity for air exchange in one breath; the sum of the tidal volume and the inspiratory and expiratory reserve volumes.

vitamin [L. *vita*: life] An organic compound that an organism cannot synthesize, but nevertheless requires in small quantities for normal growth and metabolism.

vitelline envelope The inner, proteinaceous protective layer of a sea urchin egg.

viviparity (vye vi par' uh tee) Reproduction in which fertilization of the egg and development of the embryo occur inside the mother's body. (Contrast with oviparity.)

vivipary Premature germination in plants.

voltage A measure of the difference in electrical charge between two points.

voltage-gated channel A type of gated channel that opens or closes when a certain voltage exists across the membrane in which it is inserted.

vomer nasal organ (VNO) Chemosensory structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals. Often specialized for detecting pheromones.

- W -

water potential (ψ , Ψ) In osmosis, the tendency for a system (a cell or solution) to take up water from pure water through a differentially permeable membrane. Water flows toward the system with a more negative water potential. (Contrast with solute potential, pressure potential.)

water vascular system In echinoderms, a network of water-filled canals that functions in gas exchange, locomotion, and feeding.

wavelength The distance between successive peaks of a wave train, such as electromagnetic radiation.

weather The state of atmospheric conditions in a particular place at a particular time. (Contrast with climate.)

weathering The mechanical and chemical processes by which rocks are broken down into soil particles.

Wernicke's area A region in the temporal lobe of the human brain that is involved with the sensory aspects of language.

white blood cells Cells in the blood plasma that play defensive roles in the immune system. Also called leukocytes.

white matter In the central nervous system, tissue that is rich in axons. (Contrast with gray matter.)

wild type Geneticists' term for standard or reference type. Deviants from this standard, even if the deviants are found in the wild, are usually referred to as mutant. (Note that this terminology is not usually applied to human genes.)

wood Secondary xylem tissue.

- X -

xerophyte (zee' row fyte) [Gk. *xerox*: dry + *phyton*: plant] A plant adapted to an environment with limited water supply.

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

- Y -

yolk [M.E. *yolke*: yellow] The stored food material in animal eggs, rich in protein and lipids.

yolk sac In reptiles, birds, and mammals, the extraembryonic membrane that forms from the endoderm of the hypoblast; it encloses and digests the yolk.

- Z -

zeaxanthin A blue-light receptor involved in the opening of plant stomata.

zona pellucida A jellylike substance that surrounds the mammalian ovum when it is released from the ovary.

zone of cell division The apical and primary meristems of a plant root; the source of all cells of the root's primary tissues.

zone of cell elongation The part of a plant root, generally above the zone of cell division, where cells are expanding (growing), primarily in the longitudinal direction.

zone of cell maturation The part of a plant root, generally above the zone of cell elongation, where cells are differentiating.

zoospore (zoe' o spore) [Gk. *zoom*: animal + *spora*: seed] In algae and fungi, any swimming spore. May be diploid or haploid.

zygospore Multinucleate, diploid cell that is a resting stage in the life cycle of zygo-spore fungi.

zygote (zye' gote) [Gk. *zygotos*: yoked] The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

zymogen The inactive precursor of a digestive enzyme; secreted into the lumen of the gut, where a protease cleaves it to form the active enzyme.

LIFE WORKS FOR YOU

INVESTIGATION

FIGURE 5.5 Aquaporin Increases Membrane Permeability to Water A protein was isolated from the membranes of cells in which water diffuses rapidly across the membranes. When the protein was inserted into oocytes, which do not normally have it, the water permeability of the oocytes was greatly increased.

HYPOTHESIS

Aquaporin increases membrane permeability to water.

METHOD

RESULTS

CONCLUSION

Aquaporin increases the rate of water diffusion across the cell membrane.

ANALYZE THE DATA

Oocytes were injected with aquaporin mRNA (red circles) or a solution without mRNA (blue circles). Water permeability was tested by incubating the oocytes in hypotonic solution and measuring cell volume. After time X in the upper curve, intact oocytes were not visible:

- Why did the cells increase in volume?
- What happened at time X?
- Calculate the relative rates (volume increase per minute) of swelling in the control and experimental curves. What does this show about the effectiveness of mRNA injection?

For more, go to Working with Data 5.1 at yourBioPortal.com.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATION figures.

FRONTIERS As an animal embryo develops, cells detach from one region, move, and then reattach at another region. This requires that cell membrane glycoproteins with binding specificities for adjacent cells are replaced by new ones with different specificities, so the cells can bind to their new neighbors. To investigate embryonic development, scientists are making genetically modified organisms whose embryonic cell membranes lack one or another surface binding component.

RESEARCH TOOLS

FIGURE 4.4 Centrifugation Structures within cells can be separated from one another on the basis of size and density, and the isolated structures can then be analyzed chemically.

LINK Review the discussion of phagocytosis in Concept 4.3

FIGURE 26.8 Gibberellins and Auxin Have Similar Signal Transduction Pathways Both hormones act to stimulate gene transcription by inactivating a repressor protein.

RESEARCH TOOLS

Throughout *Principles of Life*, this feature shows you how professional biologists go about their work, focusing on techniques and quantitative methods used to investigate biological systems.

INVESTIGATION

- Investigation** figures describe a key experiment's hypothesis, methods, results, and conclusion.
- Analyze the Data** exercises ask you to analyze a subset of data from the published experiment so you can see the connections between observations, analyses, hypotheses, and conclusions.
- For many Investigations, there are also online **Working with Data** problems, which give you an opportunity to work with the original published data in greater depth.

LINKS

These cross-references connect you to a more thorough discussion of a key term or concept elsewhere in the book.

HELPFUL ART

The numbered **Balloon Captions** allow you to easily follow the important steps as key processes unfold in the figures.

FRONTIERS

In each chapter, **Frontiers** introduces you to ongoing or possible future avenues of research and their importance to society.

featuring **PrepU** and the Interactive eBook
Smarter than the average quiz

BioPortal is your gateway to an extensive set of easy-to-use resources that can have a direct and immediate positive impact on your grade for the course.

Note: The activation card inserted into this textbook shows you how to get started with **BioPortal**. If your copy of the textbook does not include access to **BioPortal**, you can purchase it at **yourBioPortal.com**. The stand-alone eBook can be purchased at **ebooks.bfwpub.com/hillis1e**.

For more about **BioPortal** and its features, and to find out about additional student resources to accompany Principles of Life, see the Preface.

BIOPORTAL features include:

Prep-U—A powerful quizzing engine that bridges the gap between what you know and what you need to learn, with **personalized, adaptive quizzes** that are proven to lead to better grades. Here's how it works: You take a quiz. Prep-U grades it and then creates follow-up quizzes based on how you did. The system adapts to provide questions at the right level and on the right topics for you, so that you improve your mastery of the material as efficiently as possible.

Diagnostic Quizzing and Personalized Study Plans—The Diagnostic Quiz checks your understanding of the full range of concepts presented in each chapter, and then provides you with a **Personalized Study Plan** that helps you focus your study time on the areas that need your attention the most.

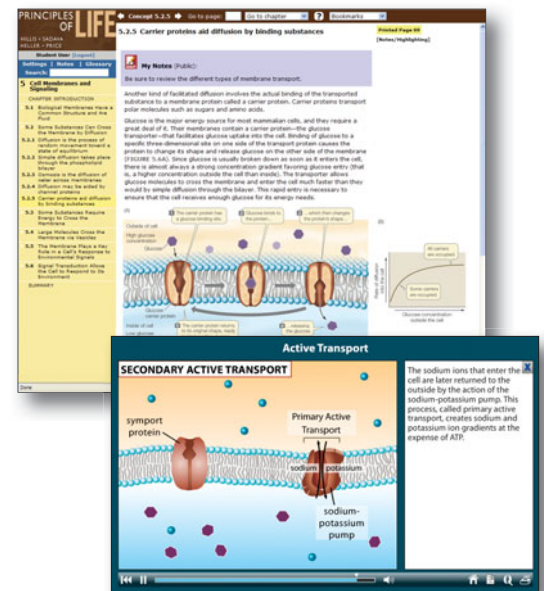

A Powerful Interactive eBook—A complete online version of the textbook and all of its media resources, fully integrated with links to animations, activities, and more, right where you need them. You can even personalize the eBook just like you would a printed textbook, with highlighting, bookmarks, and a flexible notes features.

Extraordinary media resources and study tools including **Animated Tutorials, Activities, Flashcards & Key Terms, the Lecture Notebook, BioNews** from *Scientific American*, and a lot more.

Available to all students

Free Companion Website at www.whfreeman.com/hillis1e

All students, including those NOT using BioPortal, have open access to the free *Principles of Life* Companion Website. Chapter by chapter, you'll find animations, flashcards, activities, study ideas, help with math, and more.

HOW PRINCIPLES OF

Each chapter of *Principles of Life* focuses on a series of essential biological concepts and the research that led to our understanding of them. Chapters are designed to help you focus on what's important and offer a number of ways to analyze and review what you've read, as you prepare for classtime or exams.

OPENING STORY

How do kangaroo rats, rattlesnakes, owls, bats, and moths "see in the dark"? Each chapter of *Principles of Life* begins with a **Question** like this, giving you a real-world starting point for what comes next.

Question & Answer at the end of the chapter revisits the opening question, explaining the answer by drawing on the material you've just read.

Sensors **35**

On moonless, pitch-black nights in the desert, kangaroo rats move silently about to forage and to seek mates. When two kangaroo rats meet, they immediately identify each other's gender and behave accordingly—males fight with other males and try to court females. We may not be able to observe their behavior in total darkness, but they can easily identify each other, interact, and also gather food. However, other denizens of the desert can observe the kangaroo rats and attempt to capture them for food.

If a kangaroo rat chances to hop near a coiled rattlesnake, the snake can detect the rat, accurately fix its location, and with a lightning fast strike attempt to nail the rat. But even as the strike of the rattlesnake is in process, the kangaroo rat senses it.

QA QUESTION How do kangaroo rats, rattlesnakes, owls, bats, and moths "see in the dark"?

ANSWER Kangaroo rats have large eyes that give them maximal visual sensitivity even in very dim light, but that is not the only sense that enables them to function on moonless nights. Their long whiskers enable them to use tactile information to explore their environments. Their olfactory sensitivity enables them to locate and identify other kangaroo rats, both as to the identity of familiar individuals and the gender of unfamiliar ones. The acute auditory sensitivity of the kangaroo rat enables it to hear the air disturbance caused by the strike of the rattlesnake and to jump reflexively.

KEY CONCEPTS

This list outlines the key ideas covered in the chapter ahead.

KEY CONCEPTS

- 16.1** All of Life Is Connected through Its Evolutionary History
- 16.2** Phylogeny Can Be Reconstructed from Traits of Organisms
- 16.3** Phylogeny Makes Biology Comparative and Predictive

Do You Understand Concept 16.1?

- What biological processes are represented in a phylogenetic tree?
- Why is it important to consider only homologous characters in reconstructing phylogenetic trees?
- What are some reasons that similar traits might arise independently in species that are only distantly related? Can you think of examples among familiar organisms?

DO YOU UNDERSTAND THE CONCEPT?

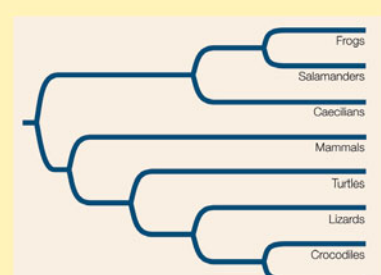

After each section in the chapter, a series of questions helps you check your understanding of the section's central ideas.

APPLY THE CONCEPT

These exercises give you the opportunity to work with a concept in a natural world setting by interpreting actual research data and drawing your own conclusions.

APPLY THE CONCEPT

Phylogeny is the basis of biological classification

Classification One:	
Named group	Included taxa
Amphibia	Frogs, salamanders, and
Mammalia	Mammals
Reptilia	Turtles, lizards, and croc-
Aves	Birds

Classification Two:	
Named group	Included taxa
Amphibia	Frogs, salamanders, and
Mammalia	Mammals
Reptilia	Turtles, lizards, croc-

Classification Three:	
Named group	Included taxa
Amphibia	Frogs, salamanders, and
Homothermia	Mammals and birds
Reptilia	Turtles, lizards, and croc-

- Consider the above phylogeny and three possible classifications of the taxa.
- Which of these classifications contains a paraphyletic group?
 - Which of these classifications contains a monophyletic group?
 - Which of these classifications is consistent with including only monophyletic groups?
 - Starting with the classification you named in question 3, how many additional group names would you need to add to make it a valid classification?

5 SUMMARY

concept 5.1 **Biological Membranes Have a Common Structure and Are Fluid**

- Biological membranes consist of lipids, proteins, and carbohydrates. The **fluid mosaic model** of membrane structure describes a phospholipid bilayer in which proteins can move about within the plane of the membrane.
- The two layers of a membrane may have different properties because of their different phospholipid compositions, exposed domains of **integral membrane proteins**, and **peripheral membrane proteins**. **Transmembrane proteins** span the membrane. **Review Figure 5.1, WEB ACTIVITY 5.1, and INTERACTIVE TUTORIAL 5.1**

concept 5.2 **Some Substances Can Cross the Membrane by Diffusion**

- Membranes exhibit **selective permeability**, regulating which substances pass through them.
- A substance can diffuse passively across a membrane by one of two processes: **simple diffusion** through the phospholipid bilayer or **facilitated diffusion**, either through a channel created by a **channel protein** or by means of a **carrier protein**. In both cases, molecules diffuse down their concentration gradients.
- In **osmosis**, water diffuses from a region of higher water concentration to a region of lower water concentration through membrane channels called **aquaporins**. Ions diffuse across membranes through ion channels. **Review Figures 5.3 and 5.4, ANIMATED TUTORIAL 5.1, and WORKING WITH DATA 5.1**
- **Carrier proteins** bind to polar molecules such as sugars and amino acids and transport them across the membrane. **Review Figure 5.6**

SUMMARY

The **Summary** reviews chapter content, including key figures, and directs you to supporting online resources, including:

- Interactive Tutorials
- Animated Tutorials
- Web Activities
- Working with Data problems
