- Client's MAR or computer printout
- Correct sterile medication
- Diluent for medication in powdered form (see manufacturer's instructions)
- Correct solution container, if a new one is to be attached
- Antiseptic swabs
- Sterile syringe of appropriate size (e.g., 5 or 10 mL) and a 1- to 1 1/2-inch, #20- or #21-gauge sterile safety needle if not using a needleless system
- IV additive label

introducing microorganisms into the container when the needle is inserted.

- Remove the needle cap from the syringe, insert the needle through the center of the injection port, and inject the medication into the bag. Activate the needle safety device. **2**
- Mix the medication and solution by gently rotating the bag or bottle. **Rationale:** *This should disperse the medication throughout the solution.* **3**

1 Cleanse the injection port with an alcohol swab.

2 Inserting a medication through the injection port of an infusing container.

Adding Medications to Intravenous Fluid Containers—continued

3 Rotating an IV bag to distribute a medication.

- Complete the IV additive label with name and dose of medication, date, time, and nurse's initials. Attach it on the bag or bottle. **Rationale:** This documents that medication has been added to the solution. The label should be easy to read when the bag is hanging. 4
- Clamp the IV tubing. Spike the bag or bottle with IV tubing and hang the IV. **Rationale:** Clamping prevents rapid infusion of the solution.
- Regulate infusion rate as ordered. Often a controller device such as an IV pump is used to ensure accurate rate of infusion.

To an Existing Infusion

- Determine that the IV solution in the container is sufficient for adding the medication. **Rationale:** Sufficient volume is necessary to dilute the medication adequately.
- Confirm the desired dilution of the medication, that is, the amount of medication per milliliter of solution.
- Close the infusion clamp. **Rationale:** This prevents the medication from infusing directly into the client as it is injected into the bag or bottle.
- Wipe the medication port with the alcohol or disinfectant swab. **Rationale:** This reduces the risk of introducing microorganisms into the container when the needle is inserted. Remove the needle cover from the medication syringe.
- While supporting and stabilizing the bag with your thumb and forefinger, carefully insert the syringe needle through the port and inject the medication. **Rationale:** The bag is

EVALUATION

- Conduct appropriate follow-up such as desired effect of medication, any adverse reactions or side effects, or change in vital signs.
- Reassess the status of IV site and patency of IV infusion.

4 Top, label indicating a medication added to an IV infusion; bottom, label for indicating when the IV tubing was changed.

supported during the injection of the medication to avoid punctures. If the bag is too high to reach easily, lower it from the IV pole. Activate the needle safety device.

- Remove the bag from the pole and gently rotate the bag. **Rationale:** This will mix the medication and solution.
 - Rehang the container and regulate the flow rate. **Rationale:** This establishes the correct flow rate.
 - Complete the medication label and apply to the IV container.
4. Dispose of the equipment and supplies according to agency practice. **Rationale:** This prevents inadvertent injury to others and the spread of microorganisms.
 5. Document the medication(s) on the appropriate form in the client's record.

- Relate to previous findings, if available.
- Report significant deviations from normal to the primary care provider.

INTERMITTENT INTRAVENOUS INFUSIONS

An intermittent infusion is a method of administering a medication mixed in a small amount of IV solution, such as 50 or 100 mL. It is important for the label on an IV intermittent medication to be designed to prevent medication errors. The ISMP (2010b) developed recommended principles for these medication labels. See Figure 35–44 ■

for a sample label. The drug is administered at regular intervals, such as every 4 hours, with the drug being infused for a short period of time such as 30 to 60 minutes. Two commonly used additive or secondary IV setups are the **tandem** and the **piggyback**.

In a tandem setup, a second container is attached to the line of the first container at the lower, secondary port (Figure 35–45A ■).

Janice James (client name) MR#6789101 (second identifier)	Room 267 (location)
cefotaxime (generic name) (CLAFORAN) (BRAND NAME)	1 g (client dose)
In D5W (diluent)	IVPB (route)
Total Volume 50 mL (total volume)	
	
(bar code)	
Exp: 5-26-2014 (expiration date) RPh Initials: <i>SJS</i> (Pharmacist initials)	
St. Rose Pharmacy (Pharmacy information, if required)	
Infuse medication over 20–30 minutes (comments)	

Figure 35–44 ■ Sample label for an IV piggyback medication using ISMP recommendations.

This permits medications to be administered intermittently or simultaneously with the primary solution.

In the piggyback alignment, a second set connects the second container to the tubing of the primary container at the upper port. This setup is used solely for intermittent drug administration. Various manufacturers describe these sets differently, so the nurse must check the manufacturer’s labeling and directions carefully. Traditionally the tubing of the secondary set has been attached to ports of the primary infusion by inserting a needle through the port and taping it in place. Needleless systems are now available. These needleless systems can use threaded-lock or lever-lock cannulas to connect the secondary set to the ports of the primary infusion. This design prevents needlestick injuries and also prevents touch contamination at the IV connection site.

Another method of intermittently administering an IV medication is by a syringe pump or mini-infuser. The medication is mixed in a syringe that is connected to the primary IV line via a mini-infuser (Figure 35–46 ■).

Figure 35–45 ■ Secondary intravenous lines: A, a tandem intravenous alignment; B, an intravenous piggyback (IVPB) alignment.

Figure 35-46 ■ Syringe pump or mini-infuser for administration of IV medications.

VOLUME-CONTROL INFUSIONS

Intermittent medications may also be administered by a **volume-control infusion set** such as Buretrol, Soluset, Volutrol, and Pediatrol (Figure 35-47 ■). Such sets are small fluid containers (100 to 150 mL in size) attached below the primary infusion container so that the medication is administered through the client's IV line. Volume-control sets are frequently used to infuse solutions into children and older clients when the volume administered is critical and must be carefully monitored. Box 35-9 provides additional information.

INTRAVENOUS PUSH

Intravenous push (IVP) or bolus is the intravenous administration of an undiluted drug directly into the systemic circulation. It is used when a medication cannot be diluted or in an emergency. An IV bolus can be introduced directly into a vein by venipuncture or into an existing IV line through an injection port or through an IV lock.

There are two major disadvantages to this method of drug administration: Any error in administration cannot be corrected after the drug has entered the client, and the drug may be irritating to the lining of the blood vessels. Before administering a bolus, the nurse should look up the maximum concentration

Figure 35-47 ■ A volume-control infusion set.

recommended for the particular drug and the rate of administration. The purpose is to achieve rapid serum concentrations (Phillips, 2010, p. 641). The administered medication takes effect immediately (Skill 35-9).

CLINICAL ALERT!

Never administer a medication IVP into an IV line that is infusing blood, blood products, or parenteral nutrition. Check the compatibility of the IV solution and what to do if it is incompatible with the IVP medication. Check if the IVP medication needs to be diluted before administration.

INTERMITTENT INFUSION DEVICES

Intermittent infusion devices (Figure 35-48 ■) may be attached to an intravenous catheter or needle to allow medications to be administered intravenously without requiring a continuous intravenous infusion. The device may also have a port at one end of the lock and a needleless injection cap at the other end with the extension tubing between the two ends (Figure 35-49 ■).

Intermittent injection ports have either a resealable latex injection site for needle access or a port that allows a syringe or a needleless adapter to be connected for administering medications. Needleless systems are preferred, because they significantly reduce the risk of needlestick injuries among health care workers. Skill 52-5 in Chapter 52 ∞ describes how to convert an intravenous infusion to an intermittent injection port. With the needleless system, the injection adapter may be attached at the time of

BOX 35–9 Adding a Medication to a Volume-Control Infusion Set

- Withdraw the required dose of the medication into a syringe.
- Ensure that there is sufficient fluid in the volume-control fluid chamber to dilute the medication. Generally, at least 50 mL of fluid is used. Check the directions from the drug manufacturer or consult the pharmacist.
- Close the inflow to the fluid chamber by adjusting the upper roller or slide clamp above the fluid chamber; also ensure that the clamp on the air vent of the chamber is open.
- Clean the medication port on the volume-control fluid chamber with an antiseptic swab.
- Inject the medication into the port of the partially filled volume-control set.
- Gently rotate the fluid chamber until the fluid is well mixed.
- Open the line's upper clamp, and regulate the flow by adjusting the lower roller or slide clamp below the fluid chamber.
- Attach a medication label to the volume-control fluid chamber.
- Document relevant data, and monitor the client and the infusion.

Figure 35–48 ■ Intermittent infusion device with an injection port.
R.A. Penne-Casanova/Science Source.

Figure 35–49 ■ Intermittent infusion device with injection port and extension tubing.

intravenous catheter placement, allowing a closed system to be maintained.

Intermittent injection ports may be flushed with sterile saline prior to and after medication administration. Most agencies use saline flushes with medication administration through peripheral IV lines. When administering a medication through a central venous access device (CVAD), some agencies use the SASH (saline–administer drug–saline–heparin) flushing procedure. Flushing the port maintains patency of the intravenous catheter and port, and reduces the risks of mixing incompatible medications within the system (see Skill 35–9).

Clients who require long-term venous access for administering medications (e.g., people receiving chemotherapy for cancer treatment) may have a specialized catheter or port to allow central venous access. The catheter may be tunneled subcutaneously and accessed through an intermittent injection port attached to the distal end of the venous catheter. Other devices have an implantable port or vascular access port surgically inserted under the skin so that no portion of the device exits the body. To administer medications, the port is accessed using a specialized needle through the skin. See Chapter 52 ∞ for more information about central venous lines.

Administering Intravenous Medications Using IV Push

PURPOSE

- To achieve immediate and maximum effects of a medication

ASSESSMENT

- Inspect and palpate the IV insertion site for signs of infection, infiltration, or a dislocated catheter.
- Inspect the surrounding skin for redness, pallor, or swelling.
- Palpate the surrounding tissues for coldness and the presence of edema, which could indicate leakage of the IV fluid into the tissues.
- Take vital signs for baseline data if the medication being administered is particularly potent.
- Determine if the client has allergies to the medication(s).
- Check the compatibility of the medication(s) and IV fluid.
- Determine specific drug action, side effects, normal dosage, recommended administration time, and peak action time.
- Check patency of IV.

Administering Intravenous Medications Using IV Push—continued

PLANNING

DELEGATION

The administration of intravenous medication via IV push involves the application of nursing knowledge and critical thinking. This procedure is not delegated to UAP. The nurse, however, can inform the UAP of the intended therapeutic effects and/or specific side effects of the medication and direct the UAP to report specific client observations to the nurse for follow-up. *Note:* Administration of IV push medications varies by state nurse practice acts. For example, some states may allow the RN to delegate certain medications to be given by an LPN/LVN, whereas other states may allow only the RN to administer IV push medications. The nurse needs to know his or her scope of practice according to the state's nurse practice act and agency policies.

Equipment

IV Push for an Existing Line

- Client's MAR
- Medication in a vial or ampule

- Sterile syringe (3 to 5 mL) (to prepare the medication)
- Sterile needles, #21 to #25 gauge, 2.5 cm (1 in.) (needle not needed if using a needleless system)
- Antiseptic swabs
- Watch with a digital readout or second hand
- Clean gloves

IV Push for an IV Lock

- Client's MAR
- Medication in a vial or ampule
- Sterile syringe (3 to 5 mL) (to prepare medication)
- Sterile syringe (3 mL) (for the saline or heparin flush)
- Vial of normal saline to flush the IV catheter or vial of heparin flush solution or both depending on agency practice.

Rationale: *These maintain the patency of the IV lock. Saline is commonly used for peripheral locks.*

- Antiseptic swabs
- Watch with a digital readout or second hand
- Clean gloves. **Rationale:** *OSHA recommends gloves be worn when performing vascular access procedures.*

IMPLEMENTATION

Preparation

1. Check the MAR.
 - Check the label on the medication carefully against the MAR to make sure that the correct medication is being prepared.
 - Follow the three checks for correct medication and dose. Read the label on the medication (1) when it is taken from the medication cart, (2) before withdrawing the medication, and (3) after withdrawing the medication.
 - Calculate medication dosage accurately.
 - Confirm that the route is correct.
2. Organize the equipment.

Performance

1. Perform hand hygiene and observe other appropriate infection prevention procedures.
2. Prepare the medication.

Existing Line

- Prepare the medication according to the manufacturer's direction. **Rationale:** *It is important to have the correct dose and the correct dilution.*

IV Lock

- a. Flushing with saline:
 - Prepare two syringes, each with 1 mL of sterile normal saline.
 - b. Flushing with heparin (if indicated by agency policy) and saline:
 - Prepare one syringe with 1 mL of heparin flush solution (if indicated by agency policy).
 - Prepare two syringes with 1 mL each of sterile, normal saline.
 - Draw up the medication into a syringe.
3. Put a small-gauge needle on the syringe if using a needleless system.
 4. Perform hand hygiene and apply clean gloves. **Rationale:** *This reduces the transmission of microorganisms and reduces the likelihood of the nurse's hands contacting the client's blood.*
 5. Provide for client privacy.
 6. Prepare the client.
 - Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. **Rationale:** *This ensures that the right client receives the right medication.*
 - If not previously assessed, take the appropriate assessment measures necessary for the medication. If any of the

findings are above or below the predetermined parameters, consult the primary care provider before administering the medication.

7. Explain the purpose of the medication and how it will help, using language that the client can understand. Include relevant information about the effects of the medication. **Rationale:** *Information can facilitate acceptance of and compliance with the therapy.*
8. Administer the medication by IV push.

IV Lock with Needle

- Clean the injection port with the antiseptic swab. **Rationale:** *This prevents microorganisms from entering the circulatory system during the needle insertion.*
- Insert the needle of the syringe containing normal saline through the injection port of an IV lock and aspirate for blood. **Rationale:** *The presence of blood confirms that the catheter or needle is in the vein. In some situations, blood will not return even though the lock is patent. 1*
- Flush the lock by injecting 1 mL of saline slowly. **Rationale:** *This removes blood and heparin (if present) from the needle and the lock.*
- Observe the area above the IV catheter for puffiness or swelling. This indicates infiltration into tissue, which would require removal of the IV catheter.

1 Inserting a needle through the injection port of an IV lock.

Administering Intravenous Medications Using IV Push—continued

2 Using a watch to time the rate of a medication injection.

4 Stopping the IV flow by pinching the tubing above the injection port.

3 A blunt plastic cannula replaces the sharp steel needle.

5 Injecting a medication by IV push to an existing IV using a needleless system.

- Remove the needle and syringe. Activate the needle safety device.
- Clean the lock's diaphragm with an antiseptic swab.
Rationale: *This prevents the transfer of microorganisms.*
- Insert the needle of the syringe containing the prepared medication through the center of the injection port.
- Inject the medication slowly at the recommended rate of infusion. Use a watch or digital readout to time the injection.
2 Rationale: *Injecting the drug too rapidly can have a serious untoward reaction.*
- Observe the client closely for adverse reactions. Remove the needle and syringe when all medication is administered.
- Activate the needle safety device.
- Clean the injection port of the lock.
- Attach the second saline syringe, and inject 1 mL of saline.
Rationale: *The saline injection flushes the medication through the catheter and prepares the lock for heparin if this medication is used. Heparin is incompatible with many medications.*
- If heparin is to be used, insert the heparin syringe and inject the heparin slowly into the lock.

IV Lock with Needleless System

- Clean the injection port of the lock.
- Insert syringe containing normal saline into the injection port.
- Flush the lock with 1 mL of sterile saline. **Rationale:** *This clears the lock of blood.*
- Remove the syringe.
- Insert the syringe containing the medication into the port. **3**
- Inject the medication following the precautions described previously.

- Withdraw the syringe.
- Repeat injection of 1 mL of saline.

Existing Line

- Identify the injection port closest to the client. Some ports have a circle indicating the site for the needle insertion.
Rationale: *An injection port must be used because it is self-sealing. Any puncture to the plastic tubing will leak.*
- Clean the port with an antiseptic swab.
- Stop the IV flow by closing the clamp or pinching the tubing above the injection port. **4**
- Connect the syringe to the IV system.
 - Needle system:
 - Hold the port steady.
 - Insert the needle of the syringe that contains the medication through the center of the port.
Rationale: *This prevents damage to the IV line and to the diaphragm of the port.*
 - Needleless system:
 - Remove the cap from the needleless injection port. Connect the tip of the syringe directly to the port. **5**
 - Inject the medication at the ordered rate. Use the watch or digital readout to time the medication administration. **Rationale:** *This ensures safe drug administration because a too rapid injection could be dangerous.*
 - Release the clamp or tubing.

Administering Intravenous Medications Using IV Push—continued

- After injecting the medication, withdraw the needle and activate the needle safety device. For a needleless system, detach the syringe and attach a new sterile cap to the port.
- 9. Dispose of equipment according to agency practice.

Rationale: *This reduces needlestick injuries and spread of microorganisms.*
- 10. Remove and discard gloves.
 - Perform hand hygiene.
- 11. Observe the client closely for adverse reactions.
- 12. Determine agency practice about recommended times for changing the IV lock. Some agencies advocate a change every 48 to 72 hours for peripheral IV devices.
- 13. Document all relevant information.
 - Record the date, time, drug, dose, and route; client response; and assessments of infusion or heparin lock site if appropriate.

EVALUATION

- Conduct appropriate follow-up such as desired effect of medication, any adverse reactions or side effects, or change in vital signs.
- Reassess status of IV lock site and patency of IV infusion, if running.
- Relate to previous findings, if available.
- Report significant deviations from normal to the primary care provider.
- Inspect appearance of medication and check expiration date.

Home Care Considerations Administering IV Push Antibiotics

PATIENT-CENTERED CARE

Shortened hospital stays and the need to cut costs have led to clients or their caregivers being taught to administer IV push antibiotics at home. The antibiotic is delivered IV push directly into a venous access device with pre- and post-administration flushing. The nurse must:

- Know which antibiotics are unsuitable for IV push administration.
- Know the adverse side effects:
 - Phlebitis (pain and tenderness over the vein, erythema, swelling, and warmth)
 - Speed shock (systemic reaction when a drug is given too rapidly)
 - Venous spasm (cramping and pain above infusion site)
 - Infiltration.
- Assess caregiver or client's eyesight and manual dexterity. Both are needed for safe administration of the antibiotic.
- Provide thorough teaching about:
 - Venous access device
 - Administration rate (minutes/dose)
 - Schedule for medication administration
 - Flushing technique
 - Adverse reactions
 - Signs that indicate an emergency and the need to call 911
 - Proper storage of medication.
- Inspect appearance of medication and check expiration date.

Topical Medications

A topical medication is applied locally to the skin or to mucous membranes in areas such as the eye, external ear canal, nose, vagina, and rectum. Most topical applications used therapeutically are not absorbed well, completely, or predictably when applied to intact skin because the skin's thick outer layer serves as a natural barrier to drug diffusion. This route of absorption through the skin, called **percutaneous**, can be increased if the skin is altered by a laceration, burn, or some other problem. However, if high concentrations or large amounts of a topical medication are applied to the skin, especially if it is done repeatedly, sufficient amounts of the drug can enter the bloodstream to cause systemic effects, usually undesirable ones.

A particular type of topical or dermatologic medication delivery system is the **transdermal patch**. This system administers sustained-action medications (e.g., nitroglycerin, estrogen, and nicotine) via multilayered films containing the drug and an adhesive layer. Technology is expanding the use of drug patches. For example, researchers are working on transdermal patches that will include ultrasound and electrical charges to force larger drug molecules through

the skin. One potential example of these "active patches" may permit the delivery of insulin to diabetics (MRIsafety.com, n.d., para 2).

The rate of delivery of the drug is controlled and varies with each product (e.g., from 12 hours to 1 week). Generally, the patch is applied to a hairless, clean area of skin that is not subject to excessive movement or wrinkling (i.e., the trunk or lower abdomen). It may also be applied on the side, lower back, or buttocks. Patches should not be applied to areas with cuts, burns, or abrasions, or on distal parts of extremities (e.g., the forearms). Women who use a patch containing estrogen or nicotine should not apply the patch to the breasts (Association of Reproductive Health Professionals, 2011). If hair is likely to interfere with patch adhesion or removal, clipping (not shaving) may be necessary before application (Figure 35-50 ■).

CLINICAL ALERT!

The nurse should wear gloves when applying a transdermal patch to avoid getting any of the medication on his or her skin, which can result in the nurse receiving the effect of the medication.

A

B

Figure 35-50 ■ Transdermal patch administration: A, protective coating removed from patch; B, patch immediately applied to clean, dry, hairless skin and labeled with date, time, and initials.

Reddening of the skin with or without mild local itching or burning, as well as allergic contact dermatitis, may occasionally occur. Upon removal of the patch, any slight reddening of the skin usually disappears within a few hours. All applications should be changed regularly to prevent local irritation, and each successive application should be placed on a different site. The transdermal patch should be dated, timed, and initialed by the nurse before it is applied to the client.

All clients need to be assessed for allergies to the drug and to materials in the patch before the patch is applied. If a client has a transdermal patch on and develops a fever, the medication may be absorbed and metabolize at a faster rate than normal. The client will need to be monitored for changes in effects of the medication.

When transdermal patches are removed, care needs to be taken as to how and where they are discarded. In the home environment, if they are simply discarded into a trash can, pets or children can be exposed to them, causing effects from any drug remaining on the patch. When removed, they should be folded with the medication

side to the inside, put into a closed container, and kept out of reach of children and pets.

CLINICAL ALERT!

It is important to keep track of the transdermal patches. Some patches are clear and may be difficult to see and, as a result, be overlooked. If the client is obese, patches may be difficult to find in the skinfolds. Duplication of patches may cause adverse reactions. Remove the old patch and clean the skin thoroughly before applying a new one.

SKIN APPLICATIONS

Topical skin or dermatologic preparations include ointments, pastes, creams, lotions, powders, sprays, and patches. See Table 35-1 earlier in this chapter. See Practice Guidelines for applying topical medications. Before applying a dermatologic preparation, thoroughly clean the area with soap and water and dry it with a patting motion. Skin encrustations harbor microorganisms and these as well as previously applied applications can prevent the medication from coming in

PRACTICE GUIDELINES

Applying Skin Preparations

POWDER

Make sure the skin surface is dry. Spread apart any skinfolds, and sprinkle the site until the area is covered with a fine thin layer of powder. Cover the site with a dressing if ordered.

SUSPENSION-BASED LOTION

Shake the container before use to distribute suspended particles. Put a little lotion on a small gauze dressing or pad, and apply the lotion to the skin by stroking it evenly in the direction of the hair growth.

CREAMS, OINTMENTS, PASTES, AND OIL-BASED LOTIONS

Warm and soften the preparation in gloved hands to make it easier to apply and to prevent chilling (if a large area is to be treated). Smear it evenly over the skin using long strokes that follow the direction of the hair growth. Explain that the skin may feel somewhat greasy after application. Apply a sterile dressing if ordered by the primary care provider.

AEROSOL SPRAY

Shake the container well to mix the contents. Hold the spray container at the recommended distance from the area (usually about 15 to 30 cm [6 to 12 in.] but check the label). Cover the client's face with a towel if the upper chest or neck is to be sprayed. Spray the medication over the specified area.

TRANSDERMAL PATCHES

Select a clean, dry area that is free of hair and matches the manufacturer's recommendations. Remove the patch from its protective covering, holding it without touching the adhesive edges, and apply it by pressing firmly with the palm of the hand for about 10 seconds. Advise the client to avoid using a heating pad over the area to prevent an increase in circulation and the rate of absorption. Remove the patch at the appropriate time, folding the medicated side to the inside so it is covered.

contact with the area to be treated. Nurses should wear gloves when administering skin applications and always use surgical asepsis when an open wound is present.

OPHTHALMIC MEDICATIONS

Medications may be administered to the eye using irrigations or instillations. An eye irrigation is administered to wash out the conjunctival sac to remove secretions or foreign bodies or to remove chemicals that

may injure the eye. Medications for the eyes, called **ophthalmic** medications, are instilled in the form of liquids or ointments. Eyedrops are packaged in monodrip plastic containers that are used to administer the preparation. Ointments are usually supplied in small tubes. All containers must state that the medication is for ophthalmic use. Sterile preparations and sterile technique are indicated. Prescribed liquids are usually dilute, for example, less than 1% strength.

Skill 35–10 illustrates how to administer ophthalmic instillations.

Administering Ophthalmic Instillations

PURPOSE

- To provide an eye medication the client requires (e.g., an antibiotic) to treat an infection or for other reasons (see specific drug action)

ASSESSMENT

In addition to the assessment performed by the nurse related to the administration of any medication, prior to applying ophthalmic medications, assess:

- Appearance of eye and surrounding structures for lesions, exudate, erythema, or swelling
- The location and nature of any discharge, lacrimation, and swelling of the eyelids or of the lacrimal gland
- Client complaints (e.g., itching, burning pain, blurred vision, and photophobia)

- Client behavior (e.g., squinting, blinking excessively, frowning, or rubbing the eyes).

Determine if assessment data influence administration of the medication (i.e., is it appropriate to administer the medication or does the medication need to be held and the primary care provider notified?).

PLANNING

DELEGATION

Due to the need for assessment, interpretation of client status, and use of sterile technique, ophthalmic medication administration is not delegated to UAP.

- Medication
 - Sterile eye dressing (pad) as needed and paper tape to secure it
- For irrigation, add:

- Irrigating solution (e.g., normal saline) and irrigating syringe or tubing
- Dry sterile absorbent sponges
- Moisture-resistant towel
- Basin (e.g., emesis basin)

Equipment

- Client's MAR or computer printout
- Clean gloves
- Sterile absorbent sponges soaked in sterile normal saline

IMPLEMENTATION

Preparation

- Check the MAR.
 - Check the MAR for the drug name, dose, and strength. Also confirm the prescribed frequency of the instillation and which eye is to be treated.
 - Check client allergy status.
 - If the MAR is unclear or pertinent information is missing, compare it with the most recent primary care provider's written order.
 - Report any discrepancies to the charge nurse or primary care provider, as agency policy dictates.
- Know the reason why the client is receiving the medication, the drug classification, contraindications, usual dose range, side effects, and nursing considerations for administering and evaluating the intended outcomes of the medication.

Performance

- Compare the label on the medication tube or bottle with the medication record and check the expiration date.
- If necessary, calculate the medication dosage.
- Introduce self and explain to the client what you are going to do, why it is necessary, and how he or she can participate. The administration of an ophthalmic medication is not usually

painful. Ointments are often soothing to the eye, but some liquid preparations may sting initially. Discuss how the results will be used in planning further care or treatments.

- Perform hand hygiene and observe other appropriate infection prevention procedures.
- Provide for client privacy.
- Prepare the client.
 - Prior to performing the procedure, verify the client's identity using agency protocol. **Rationale:** *This ensures that the right client receives the right medication.*
 - Assist the client to a comfortable position, usually lying.
- Clean the eyelid and the eyelashes.
 - Apply clean gloves.
 - Use sterile cotton balls moistened with sterile irrigating solution or sterile normal saline, and wipe from the inner canthus to the outer canthus. **Rationale:** *If not removed, material on the eyelid and lashes can be washed into the eye. Cleaning toward the outer canthus prevents contamination of the other eye and the lacrimal duct.*
- Administer the eye medication.
 - Check the ophthalmic preparation for the name, strength, and number of drops if a liquid is used. **Rationale:** *Checking medication data is essential to prevent a medication error.*

Administering Ophthalmic Instillations—continued

Draw the correct number of drops into the shaft of the dropper if a dropper is used. If ointment is used, discard the first bead. **Rationale:** *The first bead of ointment from a tube is considered to be contaminated.*

- Instruct the client to look up to the ceiling. Give the client a dry sterile absorbent sponge. **Rationale:** *The person is less likely to blink if looking up. While the client looks up, the cornea is partially protected by the upper eyelid. A sponge is needed to press on the nasolacrimal duct after a liquid instillation to prevent systemic absorption or to wipe excess ointment from the eyelashes after an ointment is instilled.*
- Expose the lower conjunctival sac by placing the thumb or fingers of your nondominant hand on the client's cheekbone just below the eye and gently drawing down the skin on the cheek. If the tissues are edematous, handle the tissues carefully to avoid damaging them. **Rationale:** *Placing the fingers on the cheekbone minimizes the possibility of touching the cornea, avoids putting any pressure on the eyeball, and prevents the person from blinking or squinting.*
- Holding the medication in the dominant hand, place hand on client's forehead to stabilize hand. Approach the eye from the side and instill the correct number of drops onto the outer third of the lower conjunctival sac. Hold the dropper 1 to 2 cm (0.4 to 0.8 in.) above the sac. **1 Rationale:** *The client is less likely to blink if a side approach is used. When instilled into the conjunctival sac, drops will not harm the cornea as they might if dropped directly on it. The dropper must not touch the sac or the cornea.*

or

- Holding the tube above the lower conjunctival sac, squeeze 2 cm (0.8 in.) of ointment from the tube into the lower conjunctival sac from the inner canthus outward. **2**
- Instruct the client to close the eyelids but not to squeeze them shut. **Rationale:** *Closing the eye spreads the medication over the eyeball. Squeezing can injure the eye and push out the medication.*
- For liquid medications, press firmly or have the client press firmly on the nasolacrimal duct for at least 30 seconds. **Rationale:** *Pressing on the nasolacrimal duct prevents the medication from running out of the eye and down the duct, preventing systemic absorption.* **3**

Variation: Irrigation

- Place absorbent pads under the head, neck, and shoulders. Place an emesis basin next to the eye to catch drainage. Some eye medications cause systemic reactions such as confusion or a decrease in heart rate and blood pressure if the eyedrops go down the nasolacrimal duct and get into the systemic circulation.
- Expose the lower conjunctival sac. Or, to irrigate in stages, first hold the lower lid down, then hold the upper lid up. Exert pressure on the bony prominences of the cheekbone and beneath the eyebrow when holding the eyelids. **Rationale:** *Separating the lids prevents reflex blinking. Exerting pressure on the bony prominences minimizes the possibility of pressing the eyeball and causing discomfort.*
- Fill and hold the eye irrigator about 2.5 cm (1 in.) above the eye. **Rationale:** *At this height the pressure of the solution will not damage the eye tissue, and the irrigator will not touch the eye.*
- Irrigate the eye, directing the solution onto the lower conjunctival sac and from the inner canthus to the outer canthus. **Rationale:** *Directing the solution in this way prevents possible injury to the cornea and prevents fluid and*

1 Instilling an eyedrop into the lower conjunctival sac.

2 Instilling an eye ointment into the lower conjunctival sac.

3 Pressing on the nasolacrimal duct.

Administering Ophthalmic Instillations—continued

contaminants from flowing down the nasolacrimal duct.

- Irrigate until the solution leaving the eye is clear (no discharge is present) or until all the solution has been used.
- Instruct the client to close and move the eye periodically.

Rationale: Eye closure and movement help to move secretions from the upper to the lower conjunctival sac.

9. Clean and dry the eyelids as needed. Wipe the eyelids gently from the inner to the outer canthus to collect excess medication.

10. Remove and discard gloves.
 - Perform hand hygiene.

11. Apply an eye pad if needed, and secure it with paper eye tape.

12. Assess the client's response immediately after the instillation or irrigation and again after the medication should have acted.

13. Document all relevant assessments and interventions. Include the name of the drug or irrigating solution, the strength, the number of drops if a liquid medication, the time, and the response of the client.

EVALUATION

- Perform follow-up based on findings of the effectiveness of the administration or outcomes that deviated from expected or normal for the client. Relate findings to previous data if available.
- Report significant deviations from normal to the primary care provider.

SKILL 35-10

LIFESPAN CONSIDERATIONS Administering Ophthalmic Medications

INFANTS/CHILDREN

- Explain the technique to the parents of an infant or child.
- For a young child or infant, obtain assistance to immobilize the arms and head. The parent may hold the infant or young child.

Rationale: This prevents accidental injury during medication administration.

- For a young child, use a doll to demonstrate the procedure.
- **Rationale:** This facilitates cooperation and decreases anxiety.
- Drops may be tolerated better by children than ointment since they are less likely to cause blurred vision.
- An IV bag and tubing may be used to deliver irrigating fluid to the eye

OTIC MEDICATIONS

Instillations or irrigations of the external auditory canal are referred to as **otic** and are generally carried out for cleaning purposes. Sometimes applications of heat and antiseptic solutions are prescribed. Irrigations performed in a hospital require aseptic technique so that microorganisms will not be introduced into the ear. Sterile technique

is used if the eardrum is perforated. The position of the external auditory canal varies with age. In the child under 3 years of age, it is directed upward. In the adult, the external auditory canal is an S-shaped structure about 2.5 cm (1 in.) long.

Skill 35-11 explains how to administer otic instillations.

Administering Otic Instillations

PURPOSE

- To soften earwax so that it can be readily removed at a later time
- To provide local therapy to reduce inflammation, destroy infective organisms in the external ear canal, or both
- To relieve pain

ASSESSMENT

In addition to the assessment performed by the nurse related to the administration of any medications, prior to applying otic medications, assess:

- Appearance of the pinna of the ear and meatus for signs of redness and abrasions

- Type and amount of any discharge.

Determine if assessment data influence administration of the medication (i.e., is it appropriate to administer the medication or does the medication need to be held and the primary care provider notified?).

PLANNING

DELEGATION

Due to the need for assessment, interpretation of client status, and use of sterile technique, otic medication administration is not delegated to UAP.

Equipment

- Client's MAR or computer printout
- Clean gloves
- Cotton-tipped applicator
- Correct medication bottle with a dropper

- Flexible rubber tip (optional) for the end of the dropper, which prevents injury from sudden motion, for example, by a disoriented client
- Cotton fluff

For irrigation, add:

- Moisture-resistant towel
- Basin (e.g., emesis basin)
- Irrigating solution at the appropriate temperature, about 500 mL (16 oz) or as ordered
- Container for the irrigating solution
- Syringe (rubber bulb or Asepto syringe is frequently used)

SKILL 35-11

Administering Otic Instillations—continued

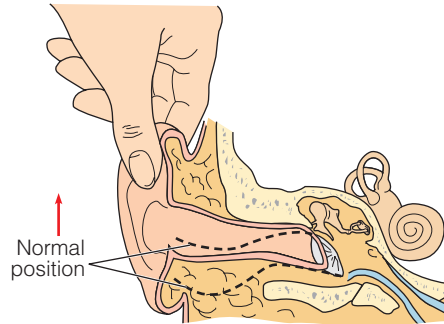

IMPLEMENTATION

Preparation

1. Check the MAR.
 - Check the MAR for the drug name, strength, number of drops, and prescribed frequency.
 - Check client allergy status.
 - If the MAR is unclear or pertinent information is missing, compare it with the most recent primary care provider's written order.
 - Report any discrepancies to the charge nurse or primary care provider, as agency policy dictates.
2. Know the reason why the client is receiving the medication, the drug classification, contraindications, usual dose range, side effects, and nursing considerations for administering and evaluating the intended outcomes of the medication.

Performance

1. Compare the label on the medication container with the medication record and check the expiration date.
2. If necessary, calculate the medication dosage.
3. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. The administration of an otic medication is not usually painful. Discuss how the results will be used in planning further care or treatments.
4. Perform hand hygiene and observe other appropriate infection prevention procedures.
5. Provide for client privacy.
6. Prepare the client.
 - Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. **Rationale:** *This ensures that the right client receives the right medication.*
 - Assist the client to a comfortable position for ear-drop administration, lying with the ear being treated uppermost.
7. Clean the pinna of the ear and the meatus of the ear canal.
 - Apply gloves if infection is suspected.
 - Use cotton-tipped applicators and solution to wipe the pinna and auditory meatus. **Rationale:** *This removes any discharge present before the instillation so that it will not be washed into the ear canal.* Ensure that applicator does not go into the ear canal. **Rationale:** *This avoids damage to tympanic membrane or wax becoming impacted within the canal.*
8. Administer the ear medication.
 - Warm the medication container in your hand, or place it in warm water for a short time. **Rationale:** *This promotes client comfort and prevents nerve stimulation and pain.*
 - Partially fill the ear dropper with medication.
 - Straighten the auditory canal. Pull the pinna upward and backward for clients over 3 years of age. **Rationale:** *The auditory canal is straightened so that the solution can flow the entire length of the canal.* ①
 - Instill the correct number of drops along the side of the ear canal. ②
 - Press gently but firmly a few times on the tragus of the ear (the cartilaginous projection in front of the exterior meatus of the ear). **Rationale:** *Pressing on the tragus assists the flow of medication into the ear canal.*
 - Ask the client to remain in the side-lying position for about 5 minutes. **Rationale:** *This prevents the drops from escaping and allows the medication to reach all sides of the canal cavity.*

- ① Straightening the adult ear canal by pulling the pinna upward and backward.

- ② Instilling eardrops.

- ③ Ear irrigation.

- Insert a small piece of cotton fluff loosely at the meatus of the auditory canal for 15 to 20 minutes. Do not press it into the canal. **Rationale:** *The cotton helps retain the medication when the client is up. If pressed tightly into the canal, the cotton would interfere with the action of the drug and the outward movement of normal secretions.*

Administering Otic Instillations—continued

Variation: Ear Irrigation

- Explain that the client may experience a feeling of fullness, warmth, and, occasionally, discomfort when the fluid comes in contact with the tympanic membrane.
- Assist the client to a sitting or lying position with head tilted toward the affected ear. **Rationale:** *The solution can then flow from the ear canal to a basin.* 3
- Place the moisture-resistant towel around the client's shoulder under the ear to be irrigated, and place the basin under the ear to be irrigated.
- Fill the syringe with solution.

or

- Hang up the irrigating container, and run solution through the tubing and the nozzle. **Rationale:** *Solution is run through the tubing/nozzle to remove air from the tubing and nozzle.*
- Straighten the ear canal.
- Insert the tip of the syringe into the auditory meatus, and direct the solution gently upward against the top of the canal. **Rationale:** *The solution will flow around the entire canal and out at the bottom. The solution is instilled gently*

because strong pressure from the fluid can cause discomfort and damage the tympanic membrane.

- Continue instilling the fluid until all the solution is used or until the canal is cleaned, depending on the purpose of the irrigation. Take care not to block the outward flow of the solution with the syringe.
 - Assist the client to a side-lying position on the affected side. **Rationale:** *Lying with the affected side down helps drain the excess fluid by gravity.*
 - Place a cotton fluff in the auditory meatus to absorb the excess fluid.
9. Remove and discard gloves.
 - Perform hand hygiene.
 10. Assess the client's response and the character and amount of discharge, appearance of the canal, discomfort, and so on, immediately after the instillation and again when the medication is expected to act. Inspect the cotton ball for any drainage.
 11. Document all nursing assessments and interventions relative to the procedure. Include the name of the drug or irrigating solution, the strength, the number of drops if a liquid medication, the time, and the response of the client.

EVALUATION

- Perform follow-up based on findings of the effectiveness of the administration or outcomes that deviated from expected or normal for the client. Relate findings to previous data if available.
- Report significant deviations from normal to the primary care provider.

LIFESPAN CONSIDERATIONS Administering Otic Medications

INFANTS/CHILDREN

- Obtain assistance to immobilize an infant or young child. This prevents accidental injury due to sudden movement during the procedure.
- Because in infants and children under 3 years of age, the ear canal is directed upward, to administer medication, gently pull the pinna down and back. For a child *older* than 3 years of age, pull the pinna upward and backward.

NASAL MEDICATIONS

Nasal instillations (nose drops and sprays) usually are instilled for their astringent effect (to shrink swollen mucous membranes), to loosen secretions and facilitate drainage, or to treat infections of the nasal cavity or sinuses. Nasal decongestants are the most common nasal instillations. Many of these products are available without a prescription. Clients need to be taught to use these agents with caution. Chronic use of nasal decongestants may lead to a rebound effect, that is, an increase in nasal congestion. If excess decongestant solution is swallowed, serious systemic effects may also develop, especially in children. Saline drops are safer as a decongestant for children.

Usually clients self-administer sprays. It is suggested that clients blow their noses prior to administration of nasal sprays unless contraindicated. In the seated position with the head tilted back, the client holds the tip of the container just inside the nares and inhales as the spray enters the nasal passages. For clients who use nasal sprays repeatedly, the nares need to be assessed for irritation. In children, nasal sprays are given with the head in an upright position to prevent excess spray from being swallowed.

Nasal drops may be used to treat sinus infections. Clients need to learn ways to position themselves to effectively treat the affected sinus:

- To treat the ethmoid and sphenoid sinuses, instruct the client to lie back with the head over the edge of the bed or a pillow under the shoulders so that the head is tipped backward (Figure 35-51 ■).
- To treat the maxillary and frontal sinuses, instruct the client to assume the same back-lying position, with the head turned toward the side to be treated (Figure 35-52 ■). The client should also be instructed to (a) breathe through the mouth to prevent aspiration of medication into the trachea and bronchi, (b) remain in a back-lying position for at least 1 minute so that the solution will come into contact with the entire nasal surface, and (c) avoid blowing the nose for several minutes.

VAGINAL MEDICATIONS

Vaginal medications, or instillations, are inserted as creams, jellies, foams, or suppositories to treat infection or to relieve vaginal

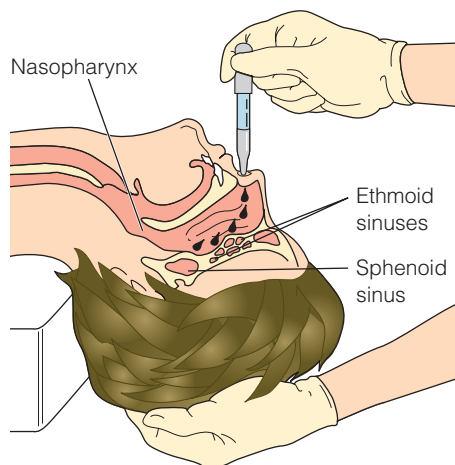

Figure 35-51 ■ Position of the head to instill drops into the ethmoid and sphenoid sinuses.

discomfort (e.g., itching or pain). Medical aseptic technique is usually used. Vaginal creams, jellies, and foams are applied by using a tubular applicator with a plunger. Suppositories are inserted with the index finger of a gloved hand. Suppositories are designed to melt at body temperature, so they are generally stored in the refrigerator to keep them firm for insertion. See Skill 35-12 for administering vaginal instillations.

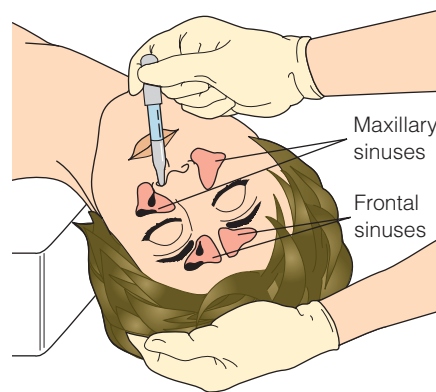

Figure 35-52 ■ Position of the head to instill drops into the maxillary and frontal sinuses.

A vaginal irrigation (douche) is the washing of the vagina by a liquid at a low pressure. Vaginal irrigations are not necessary for ordinary female hygiene but are used to prevent infection by applying an antimicrobial solution that discourages the growth of microorganisms, to remove an offensive or irritating discharge, and to reduce inflammation or prevent hemorrhage by the application of heat or cold. In hospitals, sterile supplies and equipment are used; in a home, sterility is not usually necessary because people are accustomed to the microorganisms in their environments. Sterile technique, however, is indicated if there is an open wound.

Administering Vaginal Instillations

PURPOSES

- To treat or prevent infection
- To reduce inflammation
- To relieve vaginal discomfort

ASSESSMENT

In addition to the assessment performed by the nurse related to the administration of any medications, prior to applying vaginal medications, assess:

- The vaginal orifice for inflammation; amount, character, and odor of vaginal discharge
- For complaints of vaginal discomfort (e.g., burning or itching).

PLANNING

DELEGATION

Due to the need for assessments and interpretation of client status, vaginal medication administration is not delegated to UAP.

Equipment

- Client's MAR or computer printout
- Drape
- Correct vaginal suppository or cream

IMPLEMENTATION

Preparation

1. Check the MAR.
 - Check the MAR for the drug name, strength, and prescribed frequency.
 - Check client allergy status.

Determine if assessment data influence administration of the medication (i.e., is it appropriate to administer the medication or does the medication need to be held and the primary care provider notified?).

- Applicator for vaginal cream
- Clean gloves
- Lubricant for a suppository
- Disposable towel
- Clean perineal pad

For an irrigation, add:

- Moisture-proof pad
- Vaginal irrigation set (these are often disposable) containing a nozzle, tubing and a clamp, and a container for the solution
- Irrigating solution

- If the MAR is unclear or pertinent information is missing, compare it with the most recent primary care provider's written order.
- Report any discrepancies to the charge nurse or primary care provider, as agency policy dictates.

Administering Vaginal Instillations—continued

2. Know the reason why the client is receiving the medication, the drug classification, contraindications, usual dose range, side effects, and nursing considerations for administering and evaluating the intended outcomes of the medication.

Performance

1. Compare the label on the medication container with the medication record and check the expiration date.
2. If necessary, calculate the medication dosage.
3. Explain to the client what you are going to do, why it is necessary, and how she can participate. Explain to the client that a vaginal instillation is normally a painless procedure, and in fact may bring relief from itching and burning if an infection is present. Many people feel embarrassed about this procedure, and some may prefer to perform the procedure themselves if instruction is provided. Discuss how the results will be used in planning further care or treatments.
4. Perform hand hygiene and observe other appropriate infection prevention procedures.
5. Provide for client privacy.
6. Prepare the client.
 - Prior to performing the procedure, introduce self and verify the client's identity using agency protocol.
Rationale: *This ensures that the right client receives the right medication.*
 - Ask the client to void. **Rationale:** *If the bladder is empty, the client will have less discomfort during the treatment, and the possibility of injuring the vaginal lining is decreased.*
 - Assist the client to a back-lying position with the knees flexed and the hips rotated laterally.
 - Drape the client appropriately so that only the perineal area is exposed.
7. Prepare the equipment.
 - Unwrap the suppository, and place it on the opened wrapper.
or
 - Fill the applicator with the prescribed cream, jelly, or foam. Directions are provided with the manufacturer's applicator.
8. Assess and clean the perineal area.
 - Apply gloves. **Rationale:** *Gloves prevent contamination of the nurse's hands from vaginal and perineal microorganisms.*
 - Inspect the vaginal orifice, note any odor of discharge from the vagina, and ask about any vaginal discomfort.
 - Provide perineal care to remove microorganisms. **Rationale:** *This decreases the chance of moving microorganisms into the vagina.*
9. Administer the vaginal suppository, cream, foam, jelly, or irrigation.

Suppository

- Lubricate the rounded (smooth) end of the suppository, which is inserted first. **Rationale:** *Lubrication facilitates insertion.*
- Lubricate your gloved index finger.
- Expose the vaginal orifice by separating the labia with your nondominant hand.
- Insert the suppository about 8 to 10 cm (3 to 4 in.) along the posterior wall of the vagina, or as far as it will go. **Rationale:** *The posterior wall of the vagina is about 2.5 cm (1 in.) longer than the anterior wall because the cervix protrudes into the uppermost portion of the anterior wall.* ①
- Ask the client to remain lying in the supine position for 5 to 10 minutes following insertion. The hips may also be elevated on a pillow. **Rationale:** *This position allows the medication to flow into the posterior fornix after it has melted.*

① Instilling a vaginal suppository.

② Using an applicator to instill a vaginal cream.

Vaginal Cream, Jelly, or Foam

- Gently insert the applicator about 5 cm (2 in.).
- Slowly push the plunger until the applicator is empty. ②
- Remove the applicator and place it on the towel. **Rationale:** *The applicator is placed on the towel to prevent the spread of microorganisms.*
- Discard the applicator if disposable or clean it according to the manufacturer's directions.
- Ask the client to remain lying in the supine position for 5 to 10 minutes following the insertion.

Irrigation

- Place the client on a bedpan.
- Clamp the tubing. Hold the irrigating container about 30 cm (12 in.) above the vagina. **Rationale:** *At this height, the pressure of the solution should not be great enough to injure the vaginal lining.*
- Run fluid through the tubing and nozzle into the bedpan. **Rationale:** *Fluid is run through the tubing/nozzle to remove air and to moisten the nozzle.*
- Insert the nozzle carefully into the vagina. Direct the nozzle toward the sacrum, following the direction of the vagina.
- Insert the nozzle about 7 to 10 cm (3 to 4 in.), start the flow, and rotate the nozzle several times. **Rationale:** *Rotating the nozzle irrigates all parts of the vagina.*
- Use all of the irrigating solution, permitting it to flow out freely into the bedpan.

Administering Vaginal Instillations—continued

- Remove the nozzle from the vagina.
- Assist the client to a sitting position on the bedpan.
Rationale: *Sitting on the bedpan will help drain the remaining fluid by gravity.*

10. Ensure client comfort.
- Dry the perineum with tissues as required.
 - Apply a clean perineal pad if there is excessive drainage.

11. Remove and discard gloves.

- Perform hand hygiene.

12. Document all nursing assessments and interventions relative to the skill. Include the name of the drug or irrigating solution, the strength, the time, and the response of the client.

EVALUATION

- Perform follow-up based on findings of the effectiveness of the administration or outcomes that deviated from expected or normal for the client. Relate findings to previous data if available.
- Report significant deviations from normal to the primary care provider.

LIFESPAN CONSIDERATIONS Administering Rectal Medications

INFANTS/CHILDREN

- Obtain assistance to immobilize an infant or young child. This prevents accidental injury due to sudden movement during the procedure.
- For a child under 3 years of age, the nurse should use the gloved fifth finger for insertion. After this age, the index finger can usually be used.
- For a child or infant, insert a suppository 5 cm (2 in.) or less.

RECTAL MEDICATIONS

Insertion of medications into the rectum in the form of suppositories is a frequent practice. Rectal administration is a convenient and safe method of giving certain medications. Advantages include the following:

- It avoids irritation of the upper GI tract in clients who encounter this problem (e.g., in clients who are nauseated or vomiting).
- It is advantageous when the medication has an objectionable taste or odor.
- The drug is released at a slow but steady rate.
- Rectal suppositories are thought to provide higher bloodstream levels (titers) of medication because the venous blood from the lower rectum is not transported through the liver.

To insert a rectal suppository:

- Assist the client to a left lateral or left Sims' position, with the upper leg flexed.
- Fold back the top bedclothes to expose the buttocks.
- Put a glove on the hand used to insert the suppository.
- Unwrap the suppository and lubricate the smooth rounded end, or see the manufacturer's instructions. The rounded end is usually inserted first and lubricant reduces irritation of the mucosa.
- Lubricate the gloved index finger.
- Encourage the client to relax by breathing through the mouth. This usually relaxes the external anal sphincter.
- Insert the suppository gently into the anal canal, rounded end first (or according to manufacturer's instructions), along the rectal wall using the gloved index finger. For an adult, insert the suppository beyond the internal sphincter (i.e., 10 cm [4 in.]) (Figure 35-53 ■).
- Avoid embedding the suppository in feces in order for the suppository to be absorbed effectively.
- Press the client's buttocks together for a few minutes.
- Ask the client to remain in the left lateral or supine position for at least 5 minutes to help retain the suppository. The suppository

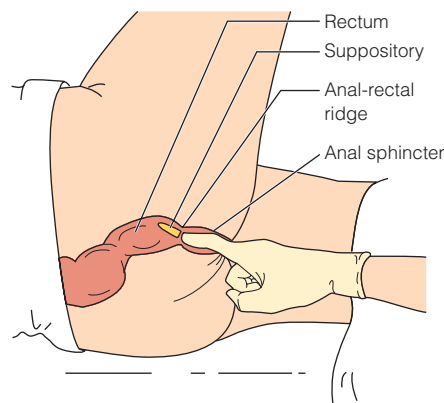

Figure 35-53 ■ Inserting a rectal suppository beyond the internal sphincter and along the rectal wall.

should be retained for varying lengths of time according to the manufacturer's instructions.

INHALED MEDICATIONS

Nebulizers deliver most medications administered through the inhaled route. A nebulizer is used to deliver a fine spray (fog or mist) of medication or moisture to a client. There are two kinds of nebulization: *atomization* and *aerosolization*. In atomization, a device called an *atomizer* produces rather large droplets for inhalation. In aerosolization, the droplets are suspended in a gas, such as oxygen. The smaller the droplets, the further they can be inhaled into the respiratory tract. When a medication is intended for the nasal mucosa, it is inhaled through the nose; when it is intended for the trachea, bronchi, and/or lungs, it is inhaled through the mouth.

A large-volume nebulizer can provide a heated or cool mist. It is used for long-term therapy, such as that following a tracheostomy. The ultrasonic nebulizer provides 100% humidity and can provide particles small enough to be inhaled deeply into the respiratory tract.

A

B

Figure 35-54 ■ A, Metered-dose inhaler; B, metered-dose inhaler with spacer.

The **metered-dose inhaler (MDI)**, a handheld nebulizer (Figure 35-54 ■), is a pressurized container of medication that can be used by the client to release the medication through a mouthpiece. The force with which the air moves through the nebulizer causes the large particles of medicated solution to break up into finer particles, forming a mist or fine spray. The use of MDIs can

Figure 35-55 ■ Delivery of medication to the lungs using a metered-dose inhaler extender.

deliver accurate doses, provide for target action at the needed sites, and sustain less systemic effects than medication delivered by other routes.

To ensure correct delivery of the prescribed medication by MDIs, nurses need to instruct clients to use aerosol inhalers correctly. The client compresses the medication canister by hand to release medication through a mouthpiece. An extender or spacer may be attached to the mouthpiece to facilitate medication absorption for better results (Figure 35-55 ■). Spacers are holding chambers into which the medication is fired and from which the client inhales, so that the dose is not lost by exhalation. Breath-activated MDIs are being produced in which inhalation triggers the release of a premeasured dose of medication. The main advantage is that it decreases the problem that some clients have in coordinating the actuating (releasing) of the medication and the inhaling of the medication. Dry powder inhalers (DPIs) are also used. A capsule is inserted into the center of the chamber of the inhalation device. A piercing device punctures the capsule which allows the medication to be released upon inhalation by the client. Client Teaching provides instructions for clients about using an MDI.

CLINICAL ALERT!

It is important for the nurse to assess if the client is using an MDI correctly. A client's ability to use an MDI correctly can decrease over time.

LIFESPAN CONSIDERATIONS Administering Metered-Dose Inhalers and Nebulizers

CHILDREN

- Spacers hold a medication in suspension and provide the child an opportunity to take several deep breaths in order to inhale all of the medication.
- A mask used for nebulizer treatments allows the child to breathe naturally. Some infants and children may be frightened

or uncomfortable with the mask and become resistant. Use a doll or stuffed animal to demonstrate its use, and allow them to play with the equipment before putting it in place. Having the child sit in the parent's lap during the procedure can help the child relax and be more cooperative.

Home Care Considerations Metered-Dose Inhalers

PATIENT-CENTERED CARE

- Disinfect the metered-dose inhaler mouthpieces weekly by soaking for 20 minutes in 1 pint of water with 2 ounces of vinegar added.
- Teach clients how to determine the amount of medication remaining in a metered-dose inhaler canister:
 - Calculate the number of days' doses in a canister. Divide the number of doses (puffs) in the canister (on the label) by the number of puffs taken per day. The previous method of floating the canister in water is not considered accurate because some of the propellant may remain (even after the medication is gone), which leads the client to incorrectly believe he or she is receiving medication.
- Review instructions and periodically assess the client's techniques for using an inhaler spacer or chamber correctly. Research shows that these devices assist in delivering the medication deeply into the lungs rather than only to the oropharynx.

CLIENT TEACHING

Using a Metered-Dose Inhaler

- Ensure that the canister is firmly and fully inserted into the inhaler.
- Remove the mouthpiece cap. Holding the inhaler upright, shake the inhaler vigorously for 3 to 5 seconds to mix the medication evenly.
- Exhale comfortably (as in a normal full breath).
- Hold the canister upside down.
 - Hold the MDI 2 to 4 cm (1 to 2 in.) from the open mouth (Figure 35-56 ■).
 - Put the mouthpiece far enough into the mouth with its opening toward the throat such that the lips can tightly close around the mouthpiece (Figure 35-57 ■). An MDI with a spacer or extender is always placed in the mouth (Figure 35-58 ■).

ADMINISTERING THE MEDICATION

- Press down *once* on the MDI canister (which releases the dose) and inhale slowly (for 3 to 5 seconds) and deeply through the mouth.
- Hold your breath for 10 seconds or as long as possible.
- Rationale:** *This allows the aerosol to reach deeper airways.*
- Remove the inhaler from or away from the mouth.
- Exhale slowly through *pursed* lips. **Rationale:** *Controlled exhalation keeps the small airways open during exhalation.*
- Repeat the inhalation if ordered. Wait 20 to 30 seconds between inhalations of bronchodilator medications.
- Rationale:** *The first inhalation has a chance to work and the subsequent dose reaches deeper into the lungs.*

Figure 35-56 ■ Inhaler positioned 2 to 4 cm (1 to 2 in.) away from the open mouth.

Figure 35-57 ■ Placing MDI in mouth with lips sealed around the mouthpiece.

Figure 35-58 ■ An extender spacer attached to a mouthpiece placed in the mouth.

- Report adverse reactions such as restlessness, palpitations, nervousness, or rash to the primary care provider.
- Many MDIs contain steroids for an anti-inflammatory effect. Prolonged use increases the risk of fungal infections in the mouth, indicating a need for attentive mouth care.

If two inhalers are to be used, the bronchodilator medication (which opens the airways) should be given prior to other medications.

A mnemonic to help remember this is *B before C* (i.e., bronchodilator before corticosteroid).

Inhaled steroids may not be correctly used by clients because they do not associate these medications with immediate symptom relief. The bronchodilators act to open the airways in the short term. However, it is the inhaled steroids that keep airway inflammation under control.

IRRIGATIONS

An **irrigation (lavage)** is the washing out of a body cavity by a stream of water or other fluid that may or may not be medicated. Irrigation is performed for one or more of the following reasons:

- To clean the area, that is, to remove a foreign object or excessive secretions or discharge
- To apply heat or cold
- To apply a medication, such as an antiseptic
- To reduce inflammation
- To relieve discomfort.

Surgical asepsis is required when there is a break in the skin (e.g., in a wound irrigation) or whenever a sterile body cavity (e.g., the bladder) is entered. Some irrigations (e.g., a vaginal, rectal, or gastric irrigation) are often safely conducted using medical asepsis.

Different kinds of syringes are used for irrigations. The most common are the Asepto and the rubber bulb (Figure 35–59 ■). The syringes are often calibrated, permitting the nurse to determine the amount of irrigant being delivered at any given time.

The Asepto syringe is a plastic (or glass) syringe with a rubber bulb. Squeezing the air out of the bulb produces negative

pressure, and fluid can be sucked into the syringe. When the bulb is squeezed again, the fluid is ejected from the syringe. Asepto syringes come in several sizes ranging from 30 mL (1 oz) to 120 mL (4 oz).

The rubber bulb syringe is often used for irrigating the ears. Like the Asepto syringe, the rubber bulb syringe comes in a range of sizes.

Other syringes that can be used are the piston syringe, which has a tip to which a catheter can be attached, and the Pomeroy syringe. Catheters may be used for deep-wound irrigations and for some types of bladder irrigations. The Pomeroy syringe is a metal syringe commonly used for ear irrigations. A shield near the tip prevents the solution from spraying outward. Plastic squeezable bottles are also available for irrigations. These are commonly used for perineal irrigations and some wound irrigations.

The type, amount, temperature, and strength of the solution and the frequency of the irrigation are ordered by the primary care provider. Generally, normal saline at body temperature (37°C [98.6°F]) is used unless specified otherwise. The amount of solution used varies with the site and purpose of the irrigation. Guidelines for administering eye and ear irrigations are given in Skills 35-10 and 35-11, respectively.

Critical Thinking Checkpoint

Mr. Ketron is a 20-year-old client who just returned to the nursing unit from surgery after undergoing an emergency appendectomy. He is awake and complaining of mild incisional pain. His dressing is dry and intact, and he has an intravenous infusion of lactated Ringer's solution running at 125 mL/h. He is to receive Ancef (a cephalosporin antibiotic) 1 g intravenously every 4 hours until he is able to tolerate fluids, at which time he will be placed on oral Suprax (cefixime) 200 mg twice daily until discharged and for 1 week after returning home. He also has an order for morphine sulfate 2.5 mg to be given every 4 hours IVP as necessary for pain.

1. It is always possible that a person receiving antibiotic drugs may experience side effects or an allergic reaction. How does an allergic reaction differ from a drug side effect?

2. Predict the possible consequences of not obtaining a medication history from Mr. Ketron despite the fact that he will be receiving antibiotics and pain medication.
3. Mr. Ketron is complaining of pain and you have prepared his IVP morphine. What assessments will you make before giving the morphine?
4. What precautions should you take, if any, prior to administering Mr. Ketron's intravenous antibiotic medication?
5. Mr. Ketron will be placed on the oral antibiotic when he can tolerate food and oral fluids. What difference, if any, does it make if this drug is given before or after meals?

See Critical Thinking Possibilities on student resource website.

Chapter 35 Review

CHAPTER HIGHLIGHTS

- Medications have several names. Nurses need to know the generic and trade names of a medication and be aware of both its therapeutic and side effects.
- Federal drug legislation regulates the production, prescription, distribution, and administration of drugs.
- Nurse practice acts define limits on the nurse's responsibilities regarding medications.
- Adverse effects of medications include drug toxicity, drug allergy, drug tolerance, idiosyncratic effect, and drug interactions.
- Several factors other than the drug itself can affect its action. These include pregnancy; age; gender; cultural, ethnic, and genetic factors; diet; client environment; psychological factors; illness and disease; and time of administration.
- Various routes are used to administer medications: oral, sublingual, buccal, parenteral, topical, or via a nasogastric or gastrostomy tube. When administering a medication, the nurse must ensure that it is appropriate for the route specified.
- Medication orders must include the client name; date and time the order is written; name of the medication; dosage, frequency, and route of administration; and signature of the ordering primary care provider or nurse. Nurses must question any unclear orders before implementing the order.
- Telephone or verbal orders must be cosigned by the primary care provider within a time specified by agency policy (usually 24 to 48 hours).
- Three systems of measurement are used in North America: the metric system, the apothecaries' system, and the household system. Weights and measures may need to be converted by the nurse within these three systems.
- Several formulas can be used to calculate dosages: basic formula, ratio and proportion, fractional equation, and dimensional analysis. Pediatric dosages are calculated by the child's weight or body surface area.
- Nurses must always assess a client's physical status before giving any medication and obtain a medication history.
- A significant number of clients die annually due to medication errors. Most medication errors occur during the administration stage. Research shows that interruptions during medication administration create a greater risk for and severity of errors.
- Medication reconciliation is another method that the nurse uses to ensure that clients receive the appropriate medications and dosages. Three important areas for medication reconciliation to occur are (a) on admission, (b) during transfers, and (c) at discharge.
- When administering medications the nurse observes specified "rights" to ensure accurate administration. When preparing medications, the nurse checks the medication container label against the MAR three times.
- The nurse always identifies the client appropriately before administering a medication and stays with the client until the medication is taken.
- Medications, once given, are documented as soon as possible after administration.
- Medications given parenterally act more quickly than those given orally or topically and must be prepared using aseptic technique.
- When preparing two insulins to be mixed in the same syringe, a vial of unmodified insulin should never be contaminated with modified insulin.
- Proper site selection is essential for an intramuscular injection to prevent tissue, bone, and nerve damage. The nurse should always palpate anatomic landmarks when selecting a site.
 - The ventrogluteal site is the safest site of choice because it provides the greatest thickness of gluteal muscle and is free of penetrating nerves.
 - The dorsogluteal site should *not* be used for injection because it poses unnecessary and unacceptable risk for clients.
- The Z-track method for intramuscular injection is recommended because it is less painful than the traditional injection technique and decreases leakage of irritating or staining medication into subcutaneous tissues.

- Clients receiving a series of injections (e.g., insulin, low molecular weight heparin) should have injection sites rotated or alternated.
- After use, needles should *not* be recapped and must be placed in puncture-resistant containers.
- Intravenous medications can be administered by various methods: in a large-volume infusion of intravenous fluid, by intermittent intravenous infusion, by volume-controlled infusion, by intravenous push (IVP) or bolus, or by intermittent injection ports. In all of these methods the client has an existing IV line or an IV access site such as a saline lock.
- Topical medications are applied to the skin or mucous membranes in areas such as the eye, external ear canal, nose, vagina, and rectum.
- A metered-dose inhaler (MDI) is a handheld nebulizer that can be used by clients to self-administer measured doses of an aerosol medication. To ensure correct delivery of the prescribed medication by MDIs, nurses need to instruct clients to use aerosol inhalers correctly.
- Irrigations of body cavities may be performed (a) to remove a foreign object or excessive secretions or discharge, (b) to apply heat or cold, (c) to apply a medication, such as an antiseptic, (d) to reduce inflammation, or (e) to relieve discomfort.
- Surgical asepsis for an irrigation is required when there is a break in the skin (e.g., in a wound irrigation) or whenever a sterile body cavity (e.g., the bladder) is entered.

TEST YOUR KNOWLEDGE

1. A client tells the nurse, "This pill is a different color than the one that I usually take at home." Which is the best response by the nurse?
 1. "Go ahead and take your medicine."
 2. "I will recheck your medication orders."
 3. "Maybe the doctor ordered a different medication."
 4. "I'll leave the pill here while I check with the doctor."
2. The following medications are listed on a client's medication administration record (MAR). Which medication order should the nurse question?
 1. Lasix 40 mg, po, STAT
 2. Ampicillin 500 mg, q6h, IVPB
 3. Humulin L (Lente) insulin 36 units, subcutaneously, every morning before breakfast
 4. Codeine q4–6h, po, prn for pain
3. The primary care provider prescribed 5 mL of a medication to be given deep intramuscular for a 40-year-old female who is 5'7" tall and weighs 135 pounds. Which is the most appropriate equipment for the nurse to use? Select all that apply.
 1. Two 3-mL syringes
 2. One 5-mL syringe
 3. A #20–#23 gauge needle
 4. A 1-inch needle
 5. A 1 1/2-inch needle
4. The nurse is to administer 0.75 mL of medication subcutaneously in the upper arm to a 300-pound adult client. The nurse can grasp approximately 2 inches of the client's tissue at the upper arm. Which is the most appropriate for the nurse to use?
 1. A tuberculin syringe, #25–#27 gauge, 1/4- to 5/8-inch needle
 2. Two 3-mL syringes, #20–#23 gauge, 1 1/2-inch needle
 3. 2-mL syringe, #25 gauge, 5/8-inch needle
 4. 2-mL syringe, #20–#23 gauge, 1-inch needle
5. The nurse is to administer a tuberculin test to a client who is 6 feet tall and weighs 180 pounds. Which is the most appropriate for the nurse to use?
 1. A tuberculin syringe, #25–#27 gauge, 1/4- to 5/8-inch needle
 2. Two 3-mL syringes, #20–#23 gauge, 1 1/2-inch needle
 3. 2-mL syringe, #25 gauge, 5/8-inch needle
 4. 2-mL syringe, #20–#23 gauge, 1-inch needle
6. The nurse is to administer 0.5 mL of a medication by intramuscular injection to an older emaciated client. Which is the most appropriate for the nurse to use?
 1. A tuberculin syringe, #25–#27 gauge, 1/4- to 5/8-inch needle
 2. Two 3-mL syringes, #20–#23 gauge, 1 1/2-inch needle
 3. 2-mL syringe, #25 gauge, 5/8-inch needle
 4. 2-mL syringe, #20–#23 gauge, 1-inch needle
7. An older client with renal insufficiency is to receive a cardiac medication. Which is the nurse most likely to administer?
 1. A decreased dosage
 2. The standard dosage
 3. An increased dosage
 4. Divided dosages
8. Proper administration of an otic medication to a 2-year-old client includes which of the following?
 1. Pull the ear straight back.
 2. Pull the ear down and back.
 3. Pull the ear up and back.
 4. Pull the ear straight upward.
9. A primary care provider writes a prescription for 0.15 milligram of digoxin intravenously every day. The medication is available in a concentration of 400 micrograms per mL. How many mL will the nurse administer?
 1. 0.000375 mL
 2. 0.00375 mL
 3. 0.0375 mL
 4. 0.375 mL
10. A nursing student is preparing to administer insulin to a client with diabetes. Indicate the correct order for the administration of this medication:
 1. Cleanse the site with alcohol.
 2. Insert the needle quickly into the subcutaneous tissue.
 3. Mix the insulins.
 4. Assess the skin for the injection.
 5. Pinch the skin lightly.
 6. Inject the medication.
 7. Count to five.
 8. Remove the syringe.

Correct sequence: _____

See Answers to Test Your Knowledge in Appendix A.

36 Skin Integrity and Wound Care

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe factors affecting skin integrity.
2. Identify clients at risk for pressure ulcers.
3. Describe the four stages of pressure ulcer development.
4. Differentiate primary and secondary wound healing.
5. Describe the three phases of wound healing.
6. Identify three major types of wound exudate.
7. Identify the main complications of and factors that affect wound healing.
8. Identify assessment data pertinent to skin integrity, pressure sites, and wounds.
9. Identify nursing diagnoses associated with impaired skin integrity.
10. Identify essential aspects of planning care to maintain skin integrity and promote wound healing.
11. Describe nursing strategies to treat pressure ulcers, promote wound healing, and prevent complications of wound healing.
12. Identify purposes of commonly used wound dressing materials and binders.
13. Verbalize the steps used in:
 - a. Obtaining wound specimens.
 - b. Irrigating a wound.
 - c. Applying dressings.
 - d. Applying dry and moist heat and cold.
14. Identify physiological responses to and the purposes of heat and cold.
15. Recognize when it is appropriate to delegate aspects of skin and wound care to unlicensed assistive personnel.
16. Demonstrate appropriate documentation and reporting of skin integrity and wound care.

INTRODUCTION

The skin is the largest organ in the body and serves a variety of important functions in maintaining health and protecting the individual from injury. Important nursing functions are maintaining skin integrity and promoting wound healing. Impaired skin integrity is not a frequent problem for most healthy people but is a threat to older adults; to clients with restricted mobility, chronic illnesses, or trauma; and to those undergoing invasive health care procedures. To protect the skin and manage wounds effectively, the nurse must understand the factors affecting skin integrity, the physiology of wound healing, and specific measures that promote optimal skin conditions.

SKIN INTEGRITY

Intact skin refers to the presence of normal skin and skin layers uninterrupted by wounds. Chapter 30  provides details regarding physical examination of the integumentary system. The appearance of the skin and skin integrity are influenced by internal factors such

as genetics, age, and the underlying health of the individual as well as external factors such as activity.

Genetics and heredity determine many aspects of a person's skin, including skin color, sensitivity to sunlight, and allergies. Age influences skin integrity in that the skin of both the very young and the very old is more fragile and susceptible to injury than that of most adults. Wounds tend to heal more rapidly in infants and children, however.

Many chronic illnesses and their treatments affect skin integrity. People with impaired peripheral arterial circulation may have skin on the legs that damages easily. Some medications, corticosteroids for example, cause thinning of the skin and allow it to be much more readily harmed. Many medications increase sensitivity to sunlight and can predispose one to severe sunburns. Some of the most common medications that cause this damage are certain antibiotics (e.g., tetracycline and doxycycline), chemotherapy drugs for cancer (e.g., methotrexate), and some psychotherapeutic drugs (e.g., tricyclic antidepressants). Poor nutrition alone can interfere with the appearance and function of normal skin.

TYPES OF WOUNDS

Body wounds are either intentional or unintentional. *Intentional* trauma occurs during therapy. Examples are operations or venipunctures. Although removing a tumor, for example, is therapeutic, the surgeon must cut into body tissues, thus traumatizing them. *Unintentional* wounds are accidental; for example, a person may fracture an arm in an automobile collision. If the tissues are traumatized without a break in the skin, the wound is closed. The wound is open when the skin or mucous membrane surface is broken.

Wounds may be described according to how they are acquired (Table 36–1). They also can be described according to the likelihood and degree of wound contamination:

- *Clean wounds* are uninfected wounds in which there is minimal inflammation and the respiratory, gastrointestinal, genital, and urinary tracts are not entered. Clean wounds are primarily closed wounds.
- *Clean-contaminated wounds* are surgical wounds in which the respiratory, gastrointestinal, genital, or urinary tract has been entered. Such wounds show no evidence of infection.
- *Contaminated wounds* include open, fresh, accidental wounds and surgical wounds involving a major break in sterile technique or a large amount of spillage from the gastrointestinal tract. Contaminated wounds show evidence of inflammation.
- *Dirty or infected wounds* include wounds containing dead tissue and wounds with evidence of a clinical infection, such as purulent drainage.

Wounds, excluding pressure ulcers and burns, are classified by depth, that is, the tissue layers involved in the wound (Box 36–1).

PRESSURE ULCERS

Pressure ulcers consist of injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of force alone or in combination with movement. Pressure ulcers were previously called *decubitus ulcers*, *pressure sores*, or *bedsores*. Pressure ulcers are a problem in both acute care settings and long-term care settings, including homes. A *Healthy People 2020* proposed objective is to reduce the rate of pressure ulcer–related hospitalizations among older adults (U.S. Department of Health and Human Services, 2013). One of the national patient safety goals for long-term care settings is prevention of health care–associated pressure ulcers (The Joint Commission, 2013).

BOX 36–1 Classifying Wounds by Depth

- *Partial thickness*: confined to the skin, that is, the dermis and epidermis; heal by regeneration
- *Full thickness*: involving the dermis, epidermis, subcutaneous tissue, and possibly muscle and bone; require connective tissue repair

Because pressure ulcers are preventable, public health insurance—and increasing numbers of private health insurance companies—will no longer reimburse health care agencies for the cost of treating health care–associated pressure ulcers. In addition, development of a stage III or IV or unstageable pressure ulcer (see later in this chapter) is considered a serious reportable event (National Quality Forum, 2013).

SAFETY ALERT!

SAFETY

2014 The Joint Commission National Patient Safety Goals (2013)

GOAL 14: PREVENT HEALTH CARE–ASSOCIATED PRESSURE ULCERS (DECUBITUS ULCERS).

- Assess and periodically reassess each resident’s risk for developing a pressure ulcer and take action to address any identified risks.
Rationale: *Pressure ulcers (decubiti) continue to be problematic in all health care settings. Most pressure ulcers can be prevented, and deterioration at stage 1 can be halted. The use of clinical practice guidelines can effectively identify residents and define early intervention for prevention of pressure ulcers.*

Etiology of Pressure Ulcers

Pressure ulcers are due to localized **ischemia**, a deficiency in the blood supply to the tissue. The tissue is compressed between two surfaces, usually the surface of furniture such as the bed or chair and the bony skeleton. When blood cannot reach the tissue, the cells are deprived of oxygen and nutrients, the waste products of metabolism accumulate in the cells, and the tissue consequently dies. Prolonged, unrelieved pressure also damages the small blood vessels.

After the skin has been compressed, it appears pale, as if the blood had been squeezed out of it. When pressure is relieved, the skin

TABLE 36–1 Types of Wounds

Type	Cause	Description and Characteristics
Incision	Sharp instrument (e.g., knife or scalpel)	Open wound; deep or shallow; once the edges have been sealed together as a part of treatment or healing, the incision becomes a closed wound.
Contusion	Blow from a blunt instrument	Closed wound, skin appears ecchymotic (bruised) because of damaged blood vessels.
Abrasion	Surface scrape, either unintentional (e.g., scraped knee from a fall) or intentional (e.g., dermal abrasion to remove pockmarks)	Open wound involving the skin
Puncture	Penetration of the skin and often the underlying tissues by a sharp instrument, either intentional or unintentional	Open wound
Laceration	Tissues torn apart, often from accidents (e.g., with machinery)	Open wound; edges are often jagged
Penetrating wound	Penetration of the skin and the underlying tissues, usually unintentional (e.g., from a bullet or metal fragments)	Open wound

takes on a bright red flush, called **reactive hyperemia**. The flush is due to **vasodilation**, a process in which extra blood floods to the area to compensate for the preceding period of impeded blood flow. Reactive hyperemia usually lasts one half to three quarters as long as the duration of impeded blood flow to the area. If the redness disappears in that time, no tissue damage is anticipated. If, however, the redness does not disappear, then tissue damage has occurred.

Risk Factors

Several factors contribute to the formation of pressure ulcers: friction and shearing, immobility, inadequate nutrition, fecal and urinary incontinence, decreased mental status, diminished sensation, excessive body heat, advanced age, and the presence of certain chronic conditions.

FRICITION AND SHEARING

Friction is a force acting parallel to the skin surface. For example, sheets rubbing against skin create friction. Friction can abrade the skin, that is, remove the superficial layers, making it more prone to breakdown.

Shearing force is a combination of friction and pressure. It occurs commonly when a client assumes a sitting position in bed. In this position, the body tends to slide downward toward the foot of the bed. This downward movement is transmitted to the sacral bone and the deep tissues. At the same time, the skin over the sacrum tends not to move because of the adherence between the skin and the bed linens. The skin and superficial tissues are thus relatively unmoving in relation to the bed surface, whereas the deeper tissues are firmly attached to the skeleton and move downward. This causes a shearing force in the area where the deeper tissues and the superficial tissues meet. The force damages the blood vessels and tissues in this area.

IMMOBILITY

Immobility refers to a reduction in the amount and control of movement a person has. Normally people move when they experience discomfort due to pressure on an area of the body. Healthy people rarely exceed their tolerance to pressure. However, paralysis, extreme weakness, pain, or any cause of decreased activity can hinder a person's ability to change positions independently and relieve the pressure, even if the person can perceive the pressure.

INADEQUATE NUTRITION

Prolonged inadequate nutrition causes weight loss, muscle atrophy, and the loss of subcutaneous tissue. These three conditions reduce the amount of padding between the skin and the bones, thus increasing the risk of pressure ulcer development. More specifically, inadequate intake of protein, carbohydrates, fluids, zinc, and vitamin C contributes to pressure ulcer formation.

Hypoproteinemia (abnormally low protein content in the blood), due either to inadequate intake or abnormal loss, predisposes the client to dependent edema. Edema (the presence of excess interstitial fluid) makes skin more prone to injury by decreasing its elasticity, resilience, and vitality. Edema increases the distance between the capillaries and the cells, thereby slowing the diffusion of oxygen to the tissue cells and of metabolites away from the cells.

FECAL AND URINARY INCONTINENCE

Moisture from incontinence promotes skin **maceration** (tissue softened by prolonged wetting or soaking) and makes the epidermis

more easily eroded and susceptible to injury. Digestive enzymes in feces, urea in urine, and gastric tube drainage also contribute to skin **excoriation** (area of loss of the superficial layers of the skin; also known as *denuded* area). Any accumulation of secretions or excretions is irritating to the skin, harbors microorganisms, and makes an individual prone to skin breakdown and infection.

DECREASED MENTAL STATUS

Individuals with a reduced level of awareness, for example, those who are unconscious, heavily sedated, or have dementia, are at risk for pressure ulcers because they are less able to recognize and respond to pain associated with prolonged pressure.

DIMINISHED SENSATION

Paralysis, stroke, or other neurologic disease may cause loss of sensation in a body area. Loss of sensation reduces a person's ability to respond to trauma, to injurious heat and cold, and to the tingling ("pins and needles") that signals loss of circulation. Sensory loss also impairs the body's ability to recognize and provide healing mechanisms for a wound.

EXCESSIVE BODY HEAT

Body heat is another factor in the development of pressure ulcers. An elevated body temperature increases the metabolic rate, thus increasing the cells' need for oxygen. This increased need is particularly severe in the cells of an area under pressure, which are already oxygen deficient. Severe infections with accompanying elevated body temperatures may affect the body's ability to deal with the effects of tissue compression.

ADVANCED AGE

The aging process brings about several changes in the skin and its supporting structures, making the older person more prone to impaired skin integrity. These changes include the following:

- Loss of lean body mass
- Generalized thinning of the epidermis
- Decreased strength and elasticity of the skin due to changes in the collagen fibers of the dermis
- Increased dryness due to a decrease in the amount of oil produced by the sebaceous glands
- Diminished pain perception due to a reduction in the number of cutaneous end organs responsible for the sensation of pressure and light touch
- Diminished venous and arterial flow due to aging vascular walls.

CHRONIC MEDICAL CONDITIONS

Certain chronic conditions such as diabetes and cardiovascular disease are risk factors for skin breakdown and delayed healing. These conditions compromise oxygen delivery to tissues by poor perfusion and thus cause poor and delayed healing and increase risk of pressure sores.

OTHER FACTORS

Other factors contributing to the formation of pressure ulcers are poor lifting and transferring techniques, incorrect positioning, hard support surfaces, and incorrect application of pressure-relieving devices.

Stages of Pressure Ulcers

The recognized stages of pressure ulcers related to observable tissue damage are shown in Figure 36-1 ■.

Figure 36-1 ■ Stages of pressure ulcers: *A*, Stage I: nonblanchable erythema signaling potential ulceration. *B*, Stage II: partial-thickness skin loss (abrasion, blister, or shallow crater) involving the epidermis and possibly the dermis. *C*, Stage III: full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue. *D*, Stage IV: full-thickness skin loss with tissue necrosis or damage to muscle, bone, or supporting structures, such as a tendon or joint capsule. Undermining and sinus tracts may also be present. *E*, Unstageable/unclassified: full-thickness skin or tissue loss—depth unknown: Actual depth of the ulcer is completely obscured by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. *F*, Suspected deep tissue injury—depth unknown: purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Figure 36-1 ■ *Continued***RISK ASSESSMENT TOOLS**

Although clients may be at risk for developing a number of different alterations in skin integrity, the most common and most preventable are pressure ulcers. Several risk assessment tools are available that provide the nurse with systematic means of identifying clients at high risk for pressure ulcer development. The tool chosen for use should include data collection in the areas of immobility, incontinence, nutrition, and level of consciousness.

The Braden Scale for Predicting Pressure Sore Risk consists of six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction and shear (Figure 36-2 ■). A total of 23 points is possible and an adult who scores below 18 points is considered at risk (Braden & Blanchard, 2007). For best results, nurses should be trained in proper use of the scale.

Another tool, shown in Table 36-2, is Norton's Pressure Area Risk Assessment Scoring System (Norton, McLaren, & Exton-Smith, 1975). It includes the categories of general physical condition, mental state, activity, mobility, and incontinence. A category of medications is added by some users, resulting in a possible score of 24. Scores of 15 or 16 should be viewed as indicators, not predictors, of risk.

The Braden and Norton tools should be used when the client first enters the health care agency and whenever the client's condition changes. In some long-term care facilities, a risk assessment using the Braden or Norton scale is conducted on admission and then on a regular basis, usually weekly. This increases awareness of specific risk factors and serves as assessment data from which to plan goals and interventions to either maintain or improve skin integrity.

The accompanying Practice Guidelines describe the principles of assessing common pressure sites.

WOUND HEALING

Healing is a quality of living tissue; it is also referred to as **regeneration** (renewal) of tissues. Healing can be considered in terms of *types of healing*, having to do with the primary care provider's decision on whether to allow the wound to seal itself or to purposefully close the wound, and *phases of healing*, which refer to the steps in the body's natural processes of tissue repair. The phases are the same for all wounds, but the rate and extent of healing depends on factors such as the type of healing, the location and size of the wound, and the health of the client.

BRADEN SCALE FOR PREDICTING PRESSURE SORE RISK

Patient's Name _____ Evaluator's Name _____

Date of Assessment

<p>SENSORY PERCEPTION</p> <p>Ability to respond meaningfully to pressure-related discomfort</p>	<p>1. Completely Limited: Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation, OR limited ability to feel pain over most of body surface.</p>	<p>2. Very Limited: Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness, OR has a sensory impairment which limits the ability to feel pain or discomfort over 1/2 of body.</p>	<p>3. Slightly Limited: Responds to verbal commands but cannot always communicate discomfort or need to be turned, OR has some sensory impairment which limits ability to feel pain or discomfort in 1 or 2 extremities.</p>	<p>4. No Impairment: Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.</p>
<p>MOISTURE</p> <p>Degree to which skin is exposed to moisture</p>	<p>1. Constantly Moist: Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.</p>	<p>2. Moist: Skin is often but not always moist. Linen must be changed at least once a shift.</p>	<p>3. Occasionally Moist: Skin is occasionally moist, requiring an extra linen change approximately once a day.</p>	<p>4. Rarely Moist: Skin is usually dry; linen requires changing only at routine intervals.</p>
<p>ACTIVITY</p> <p>Degree of physical activity</p>	<p>1. Bedfast: Confined to bed.</p>	<p>2. Chairfast: Ability to walk severely limited or nonexistent. Cannot bear own weight and/or must be assisted into chair or wheelchair.</p>	<p>3. Walks Occasionally: Walks occasionally during day but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.</p>	<p>4. Walks Frequently: Walks outside the room at least twice a day and inside room at least once every 2 hours during waking hours.</p>
<p>MOBILITY</p> <p>Ability to change and control body position</p>	<p>1. Completely Immobile: Does not make even slight changes in body or extremity position without assistance.</p>	<p>2. Very Limited: Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.</p>	<p>3. Slightly Limited: Makes frequent though slight changes in body or extremity position independently.</p>	<p>4. No Limitations: Makes major and frequent changes in position without assistance.</p>
<p>NUTRITION</p> <p>Usual food intake pattern</p>	<p>1. Very Poor: Never eats a complete meal. Rarely eats more than 1/3 of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement, OR is NPO and/or maintained on clear liquids or IV's for more than 5 days.</p>	<p>2. Probably Inadequate: Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement, OR receives less than optimum amount of liquid diet or tube feeding.</p>	<p>3. Adequate: Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally will refuse a meal, but will usually take a supplement if offered, OR is on a tube feeding or TPN regimen, which probably meets most of nutritional needs.</p>	<p>4. Excellent: Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.</p>
<p>FRICTION AND SHEAR</p>	<p>1. Problem: Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.</p>	<p>2. Potential Problem: Moves feebly or requires minimum assistance. During a move skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.</p>	<p>3. No Apparent Problem: Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times.</p>

PRACTICE GUIDELINES

Assessing Common Pressure Sites

- Ensure the lighting is good, preferably natural or fluorescent, because incandescent lights can create a transilluminating effect.
- Regulate the environment before beginning the assessment so that the room is neither too hot nor too cold. Heat can cause the skin to flush; cold can cause the skin to blanch or become cyanotic.
- Inspect pressure areas (Figure 36-3 ■) for discoloration. This can be caused by impaired blood circulation to the area. The pressure areas should have brisk capillary refill when gently pressed with a finger or thumb.

- Inspect pressure areas for abrasions and excoriations. Abrasions can occur when skin rubs against a sheet. Excoriations can occur when the skin has prolonged contact with body secretions or excretions or with dampness in skinfolds.
- Palpate the surface temperature of the skin over the pressure areas (warm your hands first). Normally, the temperature is the same as that of the surrounding skin. Increased temperature is abnormal and may be due to inflammation.
- Palpate over bony prominences and dependent body areas for the presence of edema, which feels spongy or boggy.

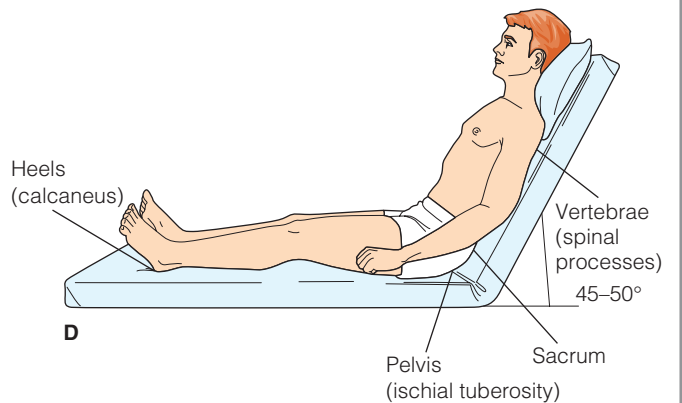

Figure 36-3 ■ Body pressure areas: A, supine position; B, lateral position; C, prone position; D, Fowler's position.

Types of Wound Healing

The types of healing are influenced by the amount of tissue loss. **Primary intention healing** occurs where the tissue surfaces have been **approximated** (closed) and there is minimal or no tissue loss; it is characterized by the formation of minimal granulation tissue and scarring. It is also called *primary union* or *first intention healing*. An example of wound healing by primary intention is a closed surgical incision. Another example would be the use of tissue adhesive, a liquid glue that can be used to

seal clean lacerations or incisions and may result in less noticeable scars.

A wound that is extensive and involves considerable tissue loss, and in which the edges cannot or should not be approximated, heals by **secondary intention healing**. An example of wound healing by secondary intention is a pressure ulcer. Secondary intention healing differs from primary intention healing in three ways: (1) The repair time is longer, (2) the scarring is greater, and (3) the susceptibility to infection is greater.

Evidence-Based Practice Does a Systematic Review of Research Studies Indicate Risk Factors That Can Predict Pressure Ulcers?

EVIDENCE-BASED PRACTICE

The purpose of the study by Coleman et al. (2013) was to identify risk factors independently predictive of pressure ulcer development in adult populations through a systematic review of existing primary research studies. The authors searched 14 electronic databases from their inception until March 2010. Studies were classified as high, moderate, low, and very low quality. Fifty-four reports fulfilled the eligibility criteria, and included 34,449 individuals in acute care and community settings. Only 17 of the 54 studies were classified as high or moderate quality. Risk factors emerging most frequently as independent predictors of pressure ulcer development included mobility/activity, perfusion (including diabetes), and skin/pressure ulcer status.

IMPLICATIONS

This study, which aims to provide guidance for evidence-based practice, demonstrates that, overall, no single factor can explain pressure ulcer risk. Instead, there is a complex interplay of factors that increases the probability of pressure ulcer development. The review highlights the limitations of overinterpretation of results from individual studies and the benefits of reviewing results from a number of studies to develop a more reliable overall assessment of factors that are important in affecting susceptibility to develop pressure ulcers. Nurses must be current in their knowledge of research findings but use caution in implementing changes in practice based on any one, or even a few, published results.

Wounds that are left open for 3 to 5 days to allow edema or infection to resolve or exudate to drain and are then closed with sutures, staples, or adhesive skin closures heal by **tertiary intention**. This is also called *delayed primary intention*.

Phases of Wound Healing

Wound healing can be broken down into three phases: inflammatory, proliferative, and maturation or remodeling.

INFLAMMATORY PHASE

The *inflammatory phase* begins immediately after injury and lasts 3 to 6 days. Two major processes occur during this phase: hemostasis and phagocytosis.

Hemostasis (the cessation of bleeding) results from vasoconstriction of the larger blood vessels in the affected area, retraction (drawing back) of injured blood vessels, the deposition of **fibrin** (connective tissue), and the formation of blood clots in the area. The blood clots provide a matrix of fibrin that becomes the framework for cell repair. A scab may also form on the surface of the wound. Consisting of clots and dead and dying tissue, this scab serves to aid hemostasis and inhibit contamination of the wound by microorganisms. Below the scab, epithelial cells migrate into the wound from the edges. The epithelial cells serve as a barrier between the body and the environment, preventing the entry of microorganisms.

The inflammatory phase also involves vascular and cellular responses intended to remove any foreign substances and dead and dying tissues. The blood supply to the wound increases, bringing with it oxygen and nutrients needed in the healing process. The area appears reddened and edematous as a result. Exudate of fluid and cell debris is a normal accumulation and helps cleanse the wound. Overproduction of this exudate and other factors can impair wound healing, especially in chronic wounds.

During cell migration, leukocytes (specifically, neutrophils) move into the interstitial space. These are replaced about 24 hours after injury by macrophages. These macrophages engulf microorganisms and cellular debris by a process known as **phagocytosis**. The macrophages also secrete an angiogenesis factor, which stimulates the formation of epithelial buds at the end of injured blood vessels. The microcirculatory network that results sustains the healing process and the wound during its life. This inflammatory response is essential to healing. Measures that impair inflammation, such as steroid medications, can place the healing process at risk.

PROLIFERATIVE PHASE

The *proliferative phase*, the second phase in healing, extends from day 3 or 4 to about day 21 postinjury. Fibroblasts (connective tissue cells), which migrate into the wound starting about 24 hours after injury, begin to synthesize collagen. **Collagen** is a whitish protein substance that adds tensile strength to the wound. As the amount of collagen increases, so does the strength of the wound; thus the chance that the wound will remain closed progressively increases. If the wound is sutured, a raised “healing ridge” appears under the intact suture line. In a wound that is not sutured, the new collagen is often visible.

Capillaries grow across the wound, increasing the blood supply. Fibroblasts move from the bloodstream into the wound, depositing fibrin. As the capillary network develops, the tissue becomes a translucent red color. This tissue, called **granulation tissue**, is fragile and bleeds easily.

When the skin edges of a wound are not sutured, the area must be filled in with granulation tissue. When the granulation tissue matures, marginal epithelial cells migrate to it, proliferating over this connective tissue base to fill the wound. If the wound does not close by epithelialization, the area becomes covered with dried plasma proteins and dead cells. This is called **eschar**. Initially, wounds healing by secondary intention seep blood-tinged (**serosanguineous**) drainage. Later, if they are not covered by epithelial cells, they become covered with thick, gray, fibrinous tissue that is eventually converted into dense scar tissue.

MATURATION PHASE

The *maturation phase* begins on about day 21 and can extend 1 or 2 years after the injury. Fibroblasts continue to synthesize collagen. The collagen fibers themselves, which were initially laid in a haphazard fashion, reorganize into a more orderly structure. During maturation, the wound is remodeled and contracted. The scar becomes stronger but the repaired area is never as strong as the original tissue. In some individuals, particularly dark-skinned individuals, an abnormal amount of collagen is laid down. This can result in a hypertrophic scar, or **keloid**.

One method of documenting the progress of healing in pressure ulcers is to use the Pressure Ulcer Scale for Healing (PUSH) tool (National Pressure Ulcer Advisory Panel [NPUAP], 2003). This well-validated tool assigns scores to the ulcer length, width, amount of exudate, and tissue type. The change in the total score over time can be used as an indication of healing.

Types of Wound Exudate

Exudate is material, such as fluid and cells, that has escaped from blood vessels during the inflammatory process and is deposited in tissue or on tissue surfaces. The nature and amount of exudate vary according to the tissue involved, the intensity and duration of the inflammation, and the presence of microorganisms.

The three major types of exudate are serous, purulent, and sanguineous. A **serous exudate** consists chiefly of serum (the clear portion of the blood) derived from blood and the serous membranes of the body, such as the peritoneum. It looks watery and has few cells. An example is the fluid in a blister from a burn.

A **purulent exudate** is thicker than serous exudate because of the presence of **pus**, which consists of leukocytes, liquefied dead tissue debris, and dead and living bacteria. The process of pus formation is referred to as **suppuration**. Purulent exudates vary in color, some acquiring tinges of blue, green, or yellow. The color may depend on the causative organism.

A **sanguineous exudate** consists of large amounts of red blood cells, indicating damage to capillaries that is severe enough to allow the escape of red blood cells from plasma. This type of exudate is frequently seen in open wounds.

Mixed types of exudates are often observed. A serosanguineous exudate consisting of both clear and blood-tinged drainage, is commonly seen in surgical incisions. A *purrosanguineous* discharge, consisting of pus and blood, is often seen in a new wound that is infected.

CLINICAL ALERT!

A bright sanguineous exudate indicates fresh bleeding, whereas dark sanguineous exudate denotes older bleeding.

Complications of Wound Healing

Several untoward events can interfere with the healing of a wound. These include hemorrhage, infection, and dehiscence and evisceration.

HEMORRHAGE

Some escape of blood from a wound is normal. **Hemorrhage** (massive bleeding), however, is abnormal. A dislodged clot, a slipped stitch, or erosion of a blood vessel may cause severe bleeding.

Internal hemorrhaging may be detected by swelling or distention in the area of the wound and, possibly, by sanguineous drainage from a surgical drain. Some clients will have a **hematoma**, a localized collection of blood underneath the skin that may appear as a reddish blue swelling (bruise). A large hematoma may be dangerous in that it places pressure on blood vessels and other structures and can thus obstruct flow.

The risk of hemorrhage is greatest during the first 48 hours after surgery. Hemorrhage is an emergency; the nurse should apply pressure dressings to the wound and monitor the client's vital signs. In many instances, the client must be taken to the operating room for surgical intervention.

INFECTION

Contamination of a wound surface with microorganisms (colonization) is an inevitable result because the surface cannot be permanently protected from contact with unsterile objects. Because the colonizing organisms compete with new cells for oxygen and nutrition, and

because their by-products can interfere with a healthy surface condition, the presence of contamination can impair wound healing and lead to infection. When the microorganisms colonizing the wound multiply excessively or invade tissues, infection occurs. Infection suggested by a change in wound color, pain, odor, or drainage is confirmed by performing a culture of the wound (see Chapter 34 ∞). Severe infection causes fever and an elevated white blood cell count. Clients who are immunosuppressed, such as those with HIV or receiving myelosuppressive treatment for cancer, are especially susceptible to wound infections.

A wound can be infected with microorganisms at the time of injury, during surgery, or postoperatively. Wounds that occur as a result of injury (e.g., motor vehicle crash, bullet or knife wound) are most likely to be contaminated at the time of injury. Surgery involving the intestines can also result in infection from the microorganisms inside the intestine. Surgical infection is most likely to become apparent 2 to 11 days postoperatively.

DEHISCENCE WITH POSSIBLE EVISCERATION

Dehiscence is the partial or total rupturing of a sutured wound. Dehiscence usually involves an abdominal wound in which the layers below the skin also separate. **Evisceration** is the protrusion of the internal viscera through an incision. A number of factors, including obesity, poor nutrition, multiple trauma, failure of suturing, excessive coughing, vomiting, and dehydration, heighten a client's risk of wound dehiscence. Wound dehiscence is more likely to occur 4 to 5 days postoperatively before extensive collagen is deposited in the wound.

Sudden straining, such as coughing or sneezing, may precede dehiscence. It is not unusual for a client to feel that "something has given way." When dehiscence or evisceration occurs, the wound should be quickly supported by large sterile dressings soaked in sterile normal saline. Place the client in bed with knees bent to decrease pull on the incision. The surgeon must be notified immediately because surgical repair of the area may be necessary.

Factors Affecting Wound Healing

Characteristics of the individual such as age, nutritional status, lifestyle, and medications influence the speed of wound healing.

DEVELOPMENTAL CONSIDERATIONS

Healthy children and adults often heal more quickly than older adults, who are more likely to have chronic diseases that hinder healing. For example, reduced liver function can impair the synthesis of blood clotting factors. Box 36-2 lists factors inhibiting wound healing in older adults.

NUTRITION

Wound healing places additional demands on the body. Clients require a diet rich in protein, carbohydrates, lipids, vitamins A and C, and minerals, such as iron, zinc, and copper. Malnourished clients may require time to improve their nutritional status before surgery, if this is possible. Obese clients are at increased risk of wound infection and slower healing because adipose tissue usually has a minimal blood supply.

LIFESTYLE

People who exercise regularly tend to have good circulation and because blood brings oxygen and nourishment to the wound, they are more likely to heal quickly. Smoking reduces the amount of functional

BOX 36-2 Factors Inhibiting Wound Healing in Older Adults

- Vascular changes associated with aging, such as atherosclerosis and atrophy of capillaries in the skin, can impair blood flow to the wound.
- Collagen tissue is less flexible, which increases the risk of damage from pressure, friction, and shearing.
- Scar tissue is less elastic.
- Changes in the immune system may reduce the formation of the antibodies and monocytes necessary for wound healing.
- Nutritional deficiencies may reduce the numbers of red blood cells and leukocytes, thus impeding the delivery of oxygen and the inflammatory response essential for wound healing. Oxygen is needed for the synthesis of collagen and the formation of new epithelial cells.
- Having diabetes or cardiovascular disease increases the risk of delayed healing due to impaired oxygen delivery to these tissues.
- Cell renewal is slower, leading to delayed healing.

hemoglobin in the blood, thus limiting the oxygen-carrying capacity of the blood, and constricts arterioles.

MEDICATIONS

Anti-inflammatory drugs (e.g., steroids and aspirin) and antineoplastic agents interfere with healing. Prolonged use of antibiotics may make a person susceptible to wound infection by resistant organisms.

●○○ NURSING MANAGEMENT

Assessing

Assessment of Skin Integrity

The nurse conducts an examination of the integument as part of a routine assessment and during regular care. Removing barriers to assessment is very important. Antiembolic stockings, braces, or devices must be removed to assess the skin condition underneath.

Nursing History and Physical Assessment

During the review of systems as part of the nursing history, the nurse gathers information regarding skin diseases, previous bruising, general skin condition, skin lesions, and usual healing of sores. Inspection and palpation of the skin focus on determination of skin color

distribution, skin turgor, presence of edema, and characteristics of any lesions that are present. Particular attention is paid to skin condition in areas most likely to break down: in skinfolds such as under the breasts, in areas that are frequently moist such as the perineum, and in areas that receive extensive pressure such as the bony prominences. Refer to Chapter 30 ∞ for further detail regarding skin assessment.

Assessment of Wounds

Nurses commonly assess both untreated and treated wounds. Assessment for these wounds is shown in the accompanying Practice Guidelines. Although a pressure ulcer can be categorized as an untreated or treated wound, the specific assessment of pressure ulcers is discussed separately in this chapter.

Untreated Wounds

Untreated wounds usually are seen shortly after an injury (e.g., at the scene of an accident or in an emergency center).

Treated Wounds

Treated wounds, or sutured wounds, are usually assessed to determine the progress of healing. These wounds may be inspected during changing of a dressing. If the wound itself cannot be directly inspected, the dressing is inspected and other data regarding the wound (e.g., the presence of pain) are assessed. Details about assessments and signs of healing for a surgical incision are discussed with surgical wounds in Chapter 37 ∞.

Estimating the amount of wound drainage can be difficult. One recommendation is to describe the degree to which the dressing is saturated. Minimal drainage only stains the dressing, moderate drainage saturates the dressing without leakage prior to scheduled dressing changes, and heavy drainage overflows the dressing prior to scheduled changes. These terms, plus the description of the drainage and the amount and type of dressing material used, should be well understood by all care providers.

Sometimes, the wound reaches under the skin surface (called undermining). The edges of the wound around an open center may be raw or appear healed, but the undermining can result in a sinus tract or tunnel that extends the wound many centimeters beyond the main wound surface. To fully assess the size of the wound, the nurse gently explores the undermined area with a sterile swab. One way to

PRACTICE GUIDELINES

Assessing Wounds

- Assess the location and extent of tissue damage (e.g., partial thickness or full thickness). Measure the wound length, width, and depth.
- Inspect the wound for bleeding. The amount of bleeding varies according to the type of wound and location. Penetrating wounds may cause internal bleeding.
- Control severe bleeding by (a) applying direct pressure over the wound and (b) elevating the involved extremity.
- Inspect the wound for foreign bodies (soil, broken glass, shreds of cloth, or other foreign substances).
- Assess associated injuries such as fractures, internal bleeding, spinal cord injuries, or head trauma.
- If the wound is contaminated with foreign material, determine when the client last had a tetanus toxoid injection. A tetanus immunization or booster may be necessary.
- Prevent infection by (a) cleaning or flushing abrasions or lacerations with normal saline, and (b) covering the wound with a clean dressing, if possible. A sterile dressing is preferred. When applying a dressing, wrap the wound tightly enough to apply pressure and approximate the wound edges, if you are able. If the first layer of dressing becomes saturated with blood, apply a second layer. Do so without removing the first layer of dressing, because blood clots might be disturbed, resulting in more bleeding.
- Control swelling and pain by applying ice over the wound and surrounding tissues.
- If bleeding is severe or if internal bleeding is suspected, assess the client for signs of shock (rapid thready pulse, cold clammy skin, pallor, lowered blood pressure).

Figure 36-4 ■ Parallel swabs used to measure wound depth.
Courtesy of Cory Patrick Hartley, RN.

measure depth is to place a second swab parallel to the first and measure the distance from the edge of the wound to the tip of the exposed swab (Figure 36-4 ■). Sinus tracts are often caused by infection and have significant drainage. They may be treated using antibiotics, irrigation, surgical incision to open and drain the tract, or negative pressure therapy for large tracts.

Pressure Ulcers

When a pressure ulcer is present, the nurse notes the following:

- Location of the ulcer, related to a bony prominence.
- Size of ulcer in centimeters. Measure greatest length, width, and depth. To measure depth, insert a sterile applicator swab at the deepest part of the wound, and then measure it against a measuring guide.
- Presence of undermining or sinus tracts, location described by position on the face of a clock, 12 o'clock as the client's head.
- Stage of the ulcer (see Figure 36-1).
- Color of the wound bed and location of necrosis (dead tissue) or eschar.
- Condition of the wound margins.
- Integrity of surrounding skin.
- Clinical signs of infection, such as redness, warmth, swelling, pain, odor, and exudate (note color of exudate).

The easiest and most accurate method of documenting wound size and shape is with disposable wound-measuring guides (for example, see Figure 36-5A ■). For irregularly shaped wounds, the nurse can use two layers of transparent film, trace the wound margins on the top layer, and then discard the bottom layer that came in contact with the wound. To measure an area located on a curved portion of the body, use a flexible measure (Figure 36-5B). New electronic devices allow tracings to be digitized for improved determination of the total wound area (Hammond & Nixon, 2011).

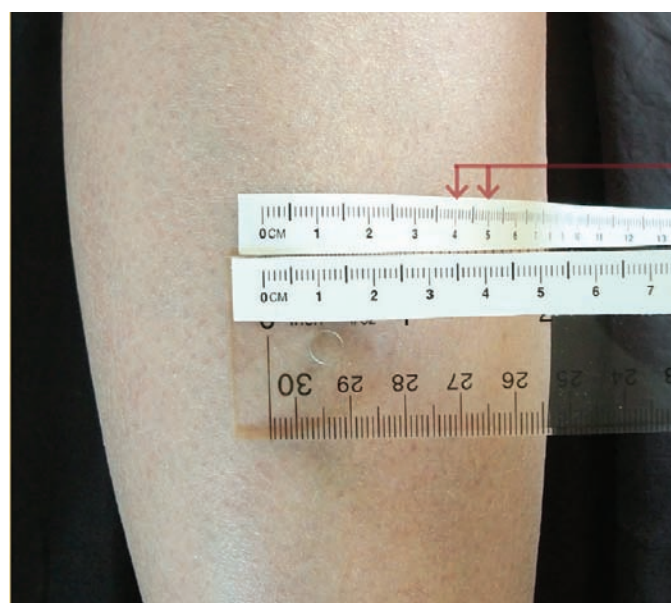

Document the status of the client's skin and wounds on a skin/wound documentation form (see Figure 36-6 ■ for an example). It is important to be able to determine how these change over time.

Laboratory Data

Laboratory data can often support the nurse's clinical assessment of the wound's progress in healing. A decreased leukocyte count can

A

B

Figure 36-5 ■ Use of photo wound-measuring guides provide documentation of scale and alignment with the body. A, This guide provides the diameter of the wound irrespective of camera distance. B, A flexible ruler (upper) is needed to prevent measurement error when assessing a wound on a curved part of the body. The red arrows indicate a difference of more than 0.5 cm between the two rulers.

delay healing and increase the possibility of infection. A hemoglobin level below the normal range indicates poor oxygen delivery to the tissues. Blood coagulation studies are also significant. Prolonged coagulation times can result in excessive blood loss and prolonged clot absorption. Hypercoagulability can lead to intravascular clotting, and result in a deficient blood supply to the wound area. Serum protein analysis provides an indication of the body's nutritional reserves for rebuilding cells. Albumin is an important indicator of nutritional status. A value below 3.5 g/dL indicates poor nutrition and may increase the risk of poor healing and infection. Wound cultures can either confirm or rule out the presence of infection. Sensitivity studies are helpful in the selection of appropriate antibiotic therapy. The nurse obtains a wound culture whenever an infection is suspected.

Skill 36-1 provides guidelines to obtain a specimen of wound drainage.

Figure 36–6 ■ Pressure ulcer documentation.

Obtaining a Wound Drainage Specimen for Culture

PURPOSES

- To identify the microorganisms potentially causing an infection and the antibiotics to which they are sensitive
- To evaluate the effectiveness of antibiotic therapy

ASSESSMENT

Assess

- Appearance of the wound and surrounding tissue. Check the character and amount of wound drainage
- Client complaints of pain or discomfort at the wound site
- Signs of infection such as fever, chills, or elevated white blood cell (WBC) count

Obtaining a Wound Drainage Specimen for Culture—continued

PLANNING

Before obtaining a specimen of wound drainage, determine (a) whether the wound should be cleaned prior to obtaining the specimen and (b) whether the site from which to take the specimen has been specified.

DELEGATION

Obtaining a wound culture is an invasive procedure that requires the application of sterile technique, knowledge of wound healing, and potential problem solving to ensure client safety; therefore, the nurse needs to perform this skill and does not delegate it to unlicensed assistive personnel (UAP).

INTERPROFESSIONAL PRACTICE

Obtaining a wound specimen may be within the scope of practice for other health care providers such as physical therapists and occupational therapists. Health care systems frequently employ an infection preventionist (other titles may be infection control coordinator/manager), who may be a nurse but could also be a non-nurse with related health care background and certification. Although these providers may verbally communicate their findings and plan to the health care team members, the nurse must also know where to locate the providers' documentation in the client's health record.

IMPLEMENTATION

Preparation

Check the medical orders to determine if the specimen is to be collected for an **aerobic** (growing only in the presence of oxygen) or **anaerobic** (growing only in the absence of oxygen) culture. Aerobic organisms are generally found on the surface of the wound, whereas anaerobic organisms would be found in deep wounds, tunnels, and cavities. Administer an analgesic 30 minutes before the procedure if the client is complaining of pain at the wound site.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss how the results will be used in planning further care or treatments.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Remove any moist outer dressings that cover the wound.
 - Apply clean gloves.
 - Remove the outer dressing, and observe any drainage on the dressing. Hold the dressing so that the client does not see the drainage. **Rationale:** *The appearance of the drainage could upset the client.*
 - Determine the amount, color, consistency, and odor of the drainage, for example, "one 4×4 gauze saturated with pale yellow, thick, malodorous drainage."
 - Discard the dressing in the moisture-proof bag. Handle it carefully so that the dressing does not touch the outside of the bag. **Rationale:** *Touching the outside of the bag will contaminate it.*
 - Remove and discard gloves.
 - Perform hand hygiene.
5. Open the sterile dressing set using sterile technique (see Skill 31-3).
6. Assess the wound.
 - Apply sterile gloves (see Skill 31-4).

Equipment

- Personal protective equipment, goggles, and gown if appropriate
- Clean gloves
- Sterile gloves
- Moisture-proof bag
- Sterile dressing set
- Normal saline and irrigating syringe
- Culture tube with swab and transport medium (aerobic and anaerobic tubes are available) or sterile syringe with needle for anaerobic culture
- Completed labels for each container
- Completed requisition to accompany the specimens to the laboratory

- Assess the appearance of the tissues in and around the wound and the drainage. Infection can cause reddened tissues with a thick discharge, which may be foul smelling, whitish, or colored.

7. Cleanse the wound.

- If a topical antimicrobial ointment or cream is being used to treat the wound, wipe or irrigate (see Skill 36-2 later in this chapter) to remove it. **Rationale:** *Residual antiseptic must be removed prior to culture.*
- Cleanse the wound with normal saline until all exudate has been removed.
- After cleansing, apply a sterile gauze pad to the wound. **Rationale:** *This absorbs excess cleansing solution.*
- Remove and discard sterile gloves.
- Perform hand hygiene.

8. Obtain the aerobic culture.

- Apply clean gloves.
- Open a specimen tube and place the cap upside down on a firm, dry surface so that the inside will not become contaminated, or if the swab is attached to the lid, twist the cap to loosen the swab. Hold the tube in one hand and take out the swab in the other.
- Rotate the swab back and forth over clean areas of granulation tissue from the sides or base of the wound. **Rationale:** *Microorganisms most likely to be responsible for a wound infection reside in viable tissue. ①*
- Do not use pus or pooled exudates to culture. **Rationale:** *These secretions contain a mixture of contaminants that are not the same as those causing the infection.*
- Avoid touching the swab to intact skin at the wound edges. **Rationale:** *This prevents the introduction of superficial skin organisms into the culture.*
- Return the swab to the culture tube, taking care not to touch the top or the outside of the tube. Secure the swab or lid firmly. **Rationale:** *The outside of the container must remain free of pathogenic microorganisms to prevent their spread to others. ②*

Obtaining a Wound Drainage Specimen for Culture—*continued*

1 Obtaining a culture specimen from the base of the wound.

- Crush the barrier to the inner compartment containing the transport medium at the bottom of the tube. **Rationale:** *This ensures that the swab with the specimen is surrounded by medium, which prevents the specimen from drying out or any microorganisms from continuing to multiply.* 3
- If a specimen is required from another site, repeat the steps. Specify the exact site (e.g., inferior drain site or lower aspect of incision) on the label of each container. Be sure to put each swab in the appropriately labeled tube.

9. Dress the wound.

- Apply any ordered medication to the wound.
- Cover the wound with a sterile wound dressing. See Table 36-5 later in this chapter for selecting a wound dressing.
- Remove and discard gloves.
- Perform hand hygiene.

2 Return the swab to the culturette tube.

EVALUATION

- Compare findings of wound assessment and drainage to previous assessments to determine any changes.
- Report the culture results to the primary care provider.

3 Break the ampule containing the transport medium.

10. Arrange for the specimen to be transported to the laboratory immediately. Be sure to include the completed requisition.

11. Document all relevant information.

- Record on the client's chart the taking of the specimen and source.
- Include the date and time; the appearance of the wound; the color, consistency, amount, and odor of any drainage; the type of culture collected; and any discomfort experienced by the client.

SAMPLE DOCUMENTATION

5/27/15 1000 Specimen from @ hip to lab for anaerobic culture. Pressure ulcer 3x3 cm, 6-mm deep, minimal amt. thick yellow drainage. No odor. Skin around wound erythematous. Pain 0 on 0-10 scale. _____ N. Jamaghani, RN

Variation: Obtaining a Specimen for Anaerobic Culture

- Apply clean gloves.
- Insert a sterile 10-mL syringe (without needle) into the wound, and aspirate 1 to 5 mL of drainage into the syringe.
- Attach the needle to the syringe, and expel all air from the syringe and needle.
- Immediately inject the drainage into the anaerobic culture tube and cap the tube tightly.

or

- Use an anaerobic culture swab system in which the swab is immediately placed into a tube filled with an oxygen-free gas or gel environment.
- Label the tube or syringe appropriately.
- Remove and discard gloves.
- Perform hand hygiene.
- Send the tube or syringe of drainage to the laboratory immediately. Do not refrigerate the specimen.

- Conduct appropriate follow-up such as administering antibiotics or modifying wound treatment as ordered.

Diagnosing

The NANDA International nursing diagnoses (Herdman & Kamitsuru, 2014) that relate to clients who have skin wounds or who are at risk for skin breakdown are as follows:

- **Risk for Pressure Ulcer:** vulnerable to localized injury to the skin and/or underlying tissue usually over a bony prominence as a result of pressure, or pressure in combination with shear
- **Risk for Impaired Skin Integrity:** vulnerable to alteration in epidermis and/or dermis which may compromise health.
- **Impaired Skin Integrity:** altered epidermis and/or dermis
- **Impaired Tissue Integrity:** damage to mucous membrane, cornea, integumentary system, muscular fascia, muscle, tendon, bone, cartilage, joint capsule, and/or ligament.

Impaired Skin Integrity commonly applies to pressure ulcers and to wounds extending through the epidermis but not through the dermis. *Impaired Tissue Integrity* applies to pressure ulcers and to wounds extending into subcutaneous tissue, muscle, or bone. Additional nursing diagnoses may be appropriate for clients with existing impaired skin or tissue integrity. Examples of these diagnoses include:

- **Risk for Infection:** if the skin impairment is severe, the client is immunosuppressed, or the wound is caused by trauma
- **Acute Pain:** related to nerve involvement within the tissue impairment or as a consequence of procedures used to treat the wound.

Planning

The major goals for clients at *Risk for Impaired Skin Integrity* (pressure ulcer development) are to maintain skin integrity and to avoid potential associated risks. Clients with *Impaired Skin Integrity* need goals to demonstrate progressive wound healing and regain intact skin within a specified time frame.

Planning for Home Care

Increasingly, wound care is provided in the home rather than in health care facilities. The client and family assume much of the responsibility for assessing and treating existing wounds and for helping to prevent pressure ulcers. The accompanying Home Care Assessment feature outlines appropriate assessment for clients who have wounds or pressure ulcers or are at risk for developing pressure ulcers. In planning

for client discharge, nurses are accountable for teaching the client and family wound preventive and care measures. See Client Teaching for a model. A critical pathway can also be useful for planning client care at home (see the example).

Implementing

Nursing interventions for maintaining skin integrity and wound care involve supporting wound healing, preventing pressure ulcers, treating pressure ulcers, dressing and cleaning wounds, supporting and immobilizing wounds, and applying heat and cold.

Supporting Wound Healing

The four major areas in which nurses can help clients develop optimal conditions for wound healing are maintaining moist wound healing, providing sufficient nutrition and hydration, preventing wound infections, and proper positioning.

CLIENT TEACHING

Skin Integrity

MAINTAINING INTACT SKIN

- Discuss relationship between adequate nutrition (especially fluids, protein, vitamins B and C, iron, and calories) and healthy skin.
- Demonstrate appropriate positions for pressure relief.
- Establish a turning or repositioning schedule.
- Demonstrate application of appropriate skin protection agents and devices.
- Instruct to report persistent reddened areas.
- Identify potential sources of skin trauma and means of avoidance.

PROMOTING WOUND HEALING

- Discuss importance of adequate nutrition (especially fluids, protein, vitamins B and C, iron, and calories).
- Instruct in wound assessment and provide mechanism for documenting.
- Emphasize principles of asepsis, especially hand hygiene and proper methods of handling used dressings.
- Provide information about signs of wound infection and other complications to report.
- Reinforce appropriate aspects of pressure ulcer prevention.
- Demonstrate wound care techniques such as wound cleansing and dressing changing.
- Discuss pain control measures, if needed.

Home Care Assessment Wound Care and Prevention of Pressure Ulcers

PATIENT-CENTERED CARE

CLIENT AND ENVIRONMENT

- **Current level of knowledge:** understanding of the cause of the wound or risk for developing a pressure ulcer; prevention or treatment strategies
- **Self-care abilities for mobility:** physical ability to change position, ambulate, and transfer including the use of assistive devices
- **Self-care abilities for wound care:** manual dexterity and visual acuity necessary to perform skin assessments and wound treatments
- **Facilities:** presence of running water, garbage, bathroom needed to perform wound care and contain potentially infectious materials
- **Current level of nutrition:** eating habits and preferences, laboratory values indicating need for teaching or other intervention

FAMILY

- **Caregiver availability, skills, and responses:** understanding of the cause of the wound or risk for developing a pressure ulcer; prevention or treatment strategies; willingness to assist with wound care and actions to prevent pressure ulcers
- **Family role changes and coping:** effect on financial status, parenting and spousal roles, sexuality, social roles
- **Alternate potential primary or respite caregivers:** for example, other family members, volunteers, church members, paid caregivers or housekeeping services; available community respite care (adult day care, senior centers, etc.)

COMMUNITY

- **Resources:** availability and familiarity with possible sources of assistance such as equipment and supply companies, organizations that offer medical supplies or financial assistance, home health agencies

Critical Pathway
Wound Management
ASSESSMENT DATA Nursing Assessment for José Alonzo

José Alonzo is a 42-year-old construction worker who was injured at work when a wheelbarrow filled with cement rolled into him and pushed him off a 4-foot ledge. He suffered several bruises and one 9-cm (3.5-in.) laceration on the anterior aspect of the lower left leg. The laceration was covered with a sterile compression dressing at the scene by paramedics. Prior to irrigation and cleansing with normal saline, the wound contained particles of cement and dirt. Marcella James, a nurse practitioner, sutured the wound with silk suture and discharged Mr. Alonzo. Mr. Alonzo is to return to the outpatient clinic for suture removal in 10 days. He asks the nurse whether he can use

an aloe herbal ointment on the wound and drink a healing herbal tea that his wife makes.

Physical Examination

Height: 177.8 cm (5'10")
 Weight: 72.7 kg (160 lb)
 Temperature: 37°C (98.6°F)
 Pulse rate: 88 beats/min
 Respirations: 24/min
 Blood pressure: 136/90 mmHg
 Expected Length of Treatment: 7 to 10 days

Outcomes Client verbalizes understanding of teaching, including wound care, signs and symptoms to report, follow-up care.

Date _____

Outpatient setting

Deficient Knowledge Provide simple, brief instructions regarding injury and treatment.
 Encourage client to ask questions and seek assistance.
 Assess the client's knowledge about wound care.
 Review written instruction sheet for wound care with client and provide copy.

Wound Care Instruct client about foods high in protein and vitamin C and encourage adequate intake.
 Irrigate and clean the wound with normal saline.
 Surgical consultation for wound closure.
 Following wound closure, apply dry sterile dressing.

Medications Tetanus toxoid if indicated.

At time of suture removal:
 Client is afebrile.
 Client has a dry, clean wound with edges well approximated, healing by first intention.

Date _____

Daily for 10 days (Client activities)

Follow written discharge teaching regarding wound care and dressing change.
 Call primary care provider with questions or problems and return to office in 10 days for suture removal.

Diet high in protein and vitamin C.
 Cultural remedies that will not interfere with healing.
 Change dressing daily and prn to keep dressing dry and clean.
 Inspect wound daily and report any signs and symptoms of infection (redness, pain, warmth, drainage, swelling, or fever).
 Only if ordered.

Moist Wound Healing

The dressing and frequency of change should support moist wound bed conditions. Wound beds that are too dry or disturbed too often fail to heal (Sussman, 2012).

Nutrition and Fluids

Clients should be assisted to take in at least 2,500 mL of fluids a day unless conditions contraindicate this amount. Although there is no evidence that excessive doses of vitamins or minerals enhance wound healing, adequate amounts are extremely important. The nurse should ensure that clients receive sufficient protein, vitamins C, A, B₁, B₅, and zinc. Obtaining a registered dietitian consultation for wound healing nutrition is helpful for ensuring that correct supplementation needs are met.

Preventing Infection

There are two main aspects to controlling wound infection: preventing microorganisms from entering the wound, and preventing the transmission of bloodborne pathogens to or from the client to others. See Table 36–3, and see Chapter 31  for more information about infection prevention.

Positioning

To promote wound healing, clients must be positioned to keep pressure off the wound (sometimes referred to as *off-loading*). Changes of position and transfers can be accomplished without shear or friction damage. In addition to proper positioning, the client should be assisted to be as mobile as possible because activity enhances circulation. If the client cannot move independently, range-of-motion exercises and a turning schedule are implemented.

Preventing Pressure Ulcers

To reduce the likelihood of pressure ulcer development in all clients, the nurse employs a variety of preventive measures to maintain the skin integrity and instructs the client, support people, and caregivers in how to prevent pressure ulcers. The Institute for Healthcare Improvement (2011) delineates two major steps: identifying clients at risk, and reliably implementing prevention strategies for all clients who are identified as being at risk. Specifically, the nurse conducts a pressure ulcer admission assessment for all clients and reassesses risk for all hospitalized clients daily. For clients at risk, the nurse also optimizes nutrition and hydration, inspects skin daily, minimizes pressure, and manages moisture by keeping the client dry and moisturizing skin.

TABLE 36-3

Guidelines for Preventing Infection and the Transmission of Bloodborne Pathogens

Standard Precautions

- Wear gloves when touching blood and body fluids, mucous membranes, or nonintact skin of all clients, and when handling items or surfaces soiled with blood or body fluids.
- Cleanse hands thoroughly if contaminated with blood or body fluids and after removing gloves.

Wound Care

- Cleanse hands before and after caring for wounds.
- Wear gloves, masks, and protective eyewear as appropriate if procedures commonly cause droplets or splashing of blood or body fluids (e.g., wound irrigation).
- Touch an open or fresh surgical wound only when wearing sterile gloves or using a sterile instrument.
- Remove or change dressings over closed wounds when they become wet.

Providing Nutrition

Because an inadequate intake of calories, protein, vitamins, and iron is believed to be a risk factor for pressure ulcer development, nutritional supplements should be considered for nutritionally compromised clients. The diet should be similar to that which supports wound healing, as discussed earlier. Monitor weight regularly to help assess nutritional status. Pertinent lab work should also be monitored including lymphocyte count, protein (especially albumin), and hemoglobin.

Maintaining Skin Hygiene

Obtain baseline data using the established tool and then reassess the skin at least daily in the hospital and weekly at home. When bathing the client, the nurse should minimize the force and friction applied to the skin, using mild cleansing agents that minimize irritation and dryness and that do not disrupt the skin's "natural barriers." Also, avoid using hot water, which increases skin dryness and irritation. Nurses can minimize dryness by avoiding exposure to cold and low humidity. Dry skin is best treated with moisturizing lotions applied while the skin is moist after bathing. The client's skin should be kept clean and dry and free of irritation and maceration by urine, feces, sweat, or incomplete drying after a bath. Apply skin protection if indicated. Dimethicone-based creams or alcohol-free barrier films are available in liquid, spray, and moist wipe format and are very effective in preventing moisture or drainage from collecting on the skin. In most cases, the nurse can apply these without a primary care provider's order.

Avoiding Skin Trauma

Providing the client with a smooth, firm, and wrinkle-free foundation on which to sit or lie helps prevent skin trauma. To prevent injury due to friction and shearing forces, clients must be positioned, transferred, and turned correctly. For bedridden clients, shearing force can be reduced by elevating the head of the bed to no more than 30°, if this position is not contraindicated by the client's condition. (For example, clients with respiratory disorders may find it easier to breathe in Fowler's position.) When the head of the bed is raised, the skin and superficial fascia stick to the bed linen while the deep fascia

and skeleton slide down toward the bottom of the bed. As a result, blood vessels in the sacral area become twisted, and the tissues in the area can become ischemic and necrotic. Baby powder and cornstarch are never used as friction or moisture prevention. These powders create harmful abrasive grit that is damaging to tissues and they are considered a respiratory hazard when airborne. Instead, use moisturizing creams and protective films, such as transparent dressings and alcohol-free barrier films.

Frequent shifts in position, even if only slight, effectively change pressure points. The client should shift weight 10° to 15° every 15 to 30 minutes and, whenever possible, exercise or ambulate to stimulate blood circulation.

When lifting a client to change position, nurses should use a lifting device such as a trapeze rather than dragging the client across or up in bed. The friction that results from dragging the skin against a sheet can cause blisters and abrasions, which may contribute to more extensive tissue damage. Therefore, using devices or a lift team to lift the client's weight off the bed surface is the method of choice—and can help prevent back injuries to nurses.

Any at-risk client confined to bed—even when a special support mattress is used—should be repositioned at least every 2 hours, depending on the client's need, to allow another body surface to bear the weight. Six body positions can usually be used: prone, supine, right and left lateral (side-lying), and right and left Sims' positions. When a lateral position is used, the nurse should avoid positioning the client directly on the trochanter and instead position the client on a 30° angle. A written schedule should be established for turning and repositioning.

In addition, massage over bony prominences should be avoided. Traditionally, nurses have used massage to stimulate blood circulation, with the intention of preventing pressure ulcers. However, scientific evidence does not support this belief. In fact, vigorous massage may lead to deep tissue trauma (Bates-Jensen, 2012).

Providing Supportive Devices

In order for circulation to remain uncompromised, pressure on the bony prominences should remain below capillary pressure for as much time as possible through a combination of turning, positioning, and use of pressure-relieving surfaces. The nurse should review the manufacturer's product descriptions that report the amount of time that the pressure between the surface and the bony prominence is above or below specified levels and determine if this is adequate to protect a particular client.

For clients confined to bed, several types of support surfaces can be used to relieve pressure. The overlay mattress is applied on top of the standard bed mattress. A replacement mattress is used instead of the standard mattress; most are made of foam and gel combinations. Specialty beds replace hospital beds. They provide pressure relief, eliminate shearing and friction, and decrease moisture. Examples are high-air-loss beds, low-air-loss beds, and beds that provide kinetic therapy. Kinetic beds provide continuous passive motion or oscillation therapy, which is intended to counteract the effects of a client's immobility. Table 36-4 lists selected mechanical devices for reducing pressure on body parts.

When a client is confined to bed or to a chair, pressure-reducing devices, such as pillows made of foam, gel, air, or a combination of these, can be used. When the client is sitting, weight should be

TABLE 36-4 Mechanical Devices for Reducing Pressure on Body Parts

Device	Description/Comments
Gel flotation pads	Polyvinyl, silicone, or Silastic pads filled with a gelatinous substance similar to fat.
Pillows and wedges (foam, gel, air, fluid)	Supports positioning and offloads bone on bone contact.
Heel protectors (sheepskin boots, padded splints, off-loading inflatable boots, foam blocks)	Can raise or “float” a body part (e.g., heels) off the surface. Prevent shearing and limit pressure on heel area (Figure 36-7 ■).
Memory foam mattress/ chair pad	Polyurethane foam mattress distributes weight over bony areas evenly. Foam molds to the body.
Alternating pressure mattress	Composed of a number of cells in which the pressure alternately increases and decreases; uses a pump.
Water bed	Support surface filled with water. Water temperature can be controlled.
Static low-air-loss (LAL) bed	Consists of many air-filled cushions divided into four or five sections. Separate controls permit each section to be inflated to a different level of firmness; thus pressure can be reduced on bony prominences but increased under other body areas for support (Figure 36-8 ■).
Active or second-generation LAL bed	Like the static LAL, but in addition gently pulsates or rotates from side to side, thus stimulating capillary blood flow and facilitating movement of pulmonary secretions.
Air-fluidized (AF) bed (static high-air-loss bed)	<p>Forced temperature-controlled air is circulated around millions of tiny silicone-coated beads, producing a fluid-like movement. Provides uniform support to body contours. Decreases skin maceration by its drying effect. Moisture from the client penetrates the linens and soaks the beads. Airflow forces the beads away from the client and rapidly dries the sheet. A major disadvantage is that the head of the bed cannot be elevated.</p> <p>Some beds are a unique combination of air fluidized therapy and low-air-loss therapy on an articulating frame. These are used with clients who require head elevation.</p>

PRACTICE GUIDELINES

Treating Pressure Ulcers

- Minimize direct pressure on the ulcer. Reposition the client at least every 2 hours. Make a schedule, and record position changes on the client's chart. Provide devices to minimize or float pressure areas.
- Clean the pressure ulcer with every dressing change. The method of cleaning depends on the stage of the ulcer, products available, and agency protocol. Skill 36-2 details the steps involved in irrigating a wound.
- Clean and dress the ulcer using surgical asepsis. Never use alcohol or hydrogen peroxide because they are cytotoxic to tissue beds.
- If the pressure ulcer is infected, obtain a sample of the drainage for culture and sensitivity to antibiotic agents (see Skill 36-1).
- Teach the client to move frequently, even if only slightly, to relieve pressure.
- Provide range-of-motion (ROM) exercises and mobility as the client's condition permits (see Chapter 44 ∞).

distributed over the entire seating surface so that pressure does not center on just one area. To protect a client's heels in bed, supports such as wedges or pillows can be used to raise the heels completely off the bed. Doughnut-type devices should not be used since they limit blood flow and can cause tissue damage to the areas in direct contact with the device (Bates-Jensen, 2012).

Treating Pressure Ulcers

Pressure ulcers are a challenge for nurses because of the number of variables involved (e.g., risk factors, types of ulcers, and degrees of impairment) and the numerous treatment measures advocated. Infections are the most serious complications of pressure ulcers. In treating pressure ulcers, nurses should follow the agency protocols and the primary care provider's orders, if any. Prompt treatment can prevent further tissue damage and pain and facilitate wound healing. See the accompanying Practice Guidelines regarding treating pressure ulcers.

The RYB Color Code

To guide wound care, the nurse can use the RYB color code of wounds. This concept is based on the color of an open wound—red, yellow, or black (RYB)—rather than the depth or size of a wound. On this scheme, the goals of wound care are to protect (cover) red, cleanse yellow, and debride black.

Wounds that are red are usually in the late regeneration phase of tissue repair (i.e., developing granulation tissue). They need to be protected to avoid disturbance to regenerating tissue. The nurse protects red wounds by (a) gentle cleansing (i.e., use of a noncytotoxic wound cleanser applied without pressure); (b) protecting periwound skin with alcohol-free barrier film; (c) filling dead space with hydrogel or alginate; (d) covering with an appropriate dressing such as transparent film, hydrocolloid dressing, or a clear absorbent acrylic dressing; and (e) changing the dressing as infrequently as possible.

Yellow wounds are characterized primarily by liquid to semiliquid "slough" that is often accompanied by purulent drainage or previous infection. The nurse cleanses yellow wounds to remove nonviable tissue. Methods used may include applying damp-to-damp normal saline dressings, irrigating the wound, using absorbent dressing materials such as impregnated hydrogel or alginate dressings, and consulting with the primary care provider about the need for a topical antimicrobial to minimize bacterial growth.

Black wounds are covered with thick necrotic tissue, or eschar. Black wounds require **debridement** (removal of the necrotic material). Removal of nonviable tissue from a wound must occur before

the wound can be staged or heal. Debridement may be achieved in four different ways: sharp, mechanical, chemical, and autolytic. In *sharp debridement*, a scalpel or scissors is used to separate and remove dead tissue. In many settings, specially trained nurses (wound ostomy continence nurses [WOCNs]), physical therapists, and physician assistants are permitted to perform sharp debridement. *Mechanical debridement* is accomplished through scrubbing force or damp-to-damp dressings. *Chemical debridement* is more selective than sharp or mechanical techniques. Collagenase enzyme agents such as papain-urea are currently most recommended for this use. In *autolytic debridement*, dressings such as hydrocolloid and clear absorbent acrylic dressings trap the wound drainage against the eschar. The body's own enzymes in the drainage break down the necrotic tissue. Although this method takes longer than the other three, it is the most selective and therefore causes the least damage to healthy surrounding and healing tissues. The use of fly larvae (maggots, *Phaenicia sericata* and other species) can be extremely effective in cleansing chronic wounds because the maggots secrete enzymes that break down necrotic tissue (while leaving healthy tissue untouched), eat bacteria, and decrease bacterial growth through the rise in surface pH that results from their presence (Strohal, 2013).

When the eschar is removed, the wound is treated as yellow, then red. When more than one color is present, the nurse treats the most serious color first, that is, black, then yellow, then red.

Dressing Wounds

Dressings are applied for the following purposes:

- To protect the wound from mechanical injury
- To protect the wound from microbial contamination
- To provide or maintain moist wound healing
- To provide thermal insulation
- To absorb drainage or debride a wound or both
- To prevent hemorrhage (when applied as a pressure dressing or with elastic bandages)
- To splint or immobilize the wound site and thereby facilitate healing and prevent injury.

Types of Dressings

Various dressing materials are available to cover wounds. The type of dressing used depends on (a) the location, size, and type of the wound; (b) the amount of exudate; (c) whether the wound requires debridement or is infected; and (d) such considerations as frequency of dressing change, ease or difficulty of dressing application, and cost (Table 36-5).

TABLE 36–5 Selected Types of Wound Dressings

Dressing	Description	Purpose	Indications	Examples
Transparent film	Adhesive plastic, semipermeable, nonabsorbent dressings allow exchange of oxygen between the atmosphere and wound bed. They are impermeable to bacteria and water.	To provide protection against contamination and friction; to maintain a clean moist surface that facilitates cellular migration; to provide insulation by preventing fluid evaporation; and to facilitate wound assessment.	IV dressing Central line dressing Superficial wounds Pressure ulcers stage I	Bioclusive, Op-Site, Polyskin, Tegaderm
Impregnated nonadherent	Woven or nonwoven cotton or synthetic materials are impregnated with petrolatum, saline, zinc-saline, antimicrobials, or other agents. Require secondary dressings to secure them in place, retain moisture, and provide wound protection.	To cover, soothe, and protect partial- and full-thickness wounds without exudate.	Postoperative dressing over staple/sutures Superficial burns	Adaptic, Aquaphor gauze, Carrasyn, Xeroform dressings
Hydrocolloids	Waterproof adhesive wafers, pastes, or powders. Wafers, designed to be worn for up to 7 days, consist of two layers. The inner adhesive layer has particles that absorb exudates and form a hydrated gel over the wound; the outer film provides an occlusive seal.	To absorb exudate; to produce a moist environment that facilitates healing but does not cause maceration of surrounding skin; to protect the wound from bacterial contamination, foreign debris, and urine or feces; and to prevent shearing.	Pressure ulcers stage II–IV Autolytic debridement of eschar Partial-thickness wounds	Comfeel, DuoDERM, RepliCare, Restore, Tegaserb
Clear absorbent acrylic	Transparent absorbent wafer designed to be worn 5–7 days. The acrylic layer absorbs exudates and evaporates the excess off the transparent membrane.	Maintains a transparent membrane for easy wound bed assessment, provides bacterial and shearing protection. Maintains moist wound healing. Can be used with alginates to provide packing to deeper wound beds.	Pressure ulcers Skin tears Venous stasis ulcers Surgical wounds Wounds undergoing chemical debridement agents	Tegaderm absorbent
Hydrogels	Glycerin or water-based nonadhesive jelly-like sheets, granules, or gels are oxygen permeable, unless covered by a plastic film. Requires secondary occlusive dressing.	To liquefy necrotic tissue or slough, rehydrate the wound bed, and fill in dead space.	Pressure ulcers Skin tears Partial-thickness wounds	Carrasyn, Elasto-Gel, Nu-Gel, Purilon, Tegaderm, Vigilon
Polyurethane foams	Nonadherent hydrocolloid dressings; these need to have their edges taped down or sealed. Require secondary dressings to obtain an occlusive environment. Surrounding skin must be protected to prevent maceration. Easy to cut and fit to wound.	To absorb up to heavy amounts of exudate; to provide and maintain moist wound healing; to provide thermal insulation.	Light to highly exudating wounds Pressure ulcers Skin tears Venous stasis ulcers Surgical wounds Wounds undergoing chemical debridement agents	Allevyn, Curafoam, Flexzan, Lyofoam, VigiFOAM
Alginates (exudate absorbers)	Nonadherent dressings of powder, beads or granules, ropes, sheets, or paste conform to the wound surface and absorb up to 20 times their weight in exudate; require a secondary dressing.	To provide a moist wound surface by interacting with exudate to form a gelatinous mass; to absorb exudate; to eliminate dead space or pack wounds; and to support debridement.	Pressure ulcers Skin tears Venous stasis ulcers Surgical wounds Wounds undergoing chemical debridement agents	AlgiDerm, Curasorb, Debrisan, Kaltostat, Sorbsan
Collagen	Gels, pastes, powders, granules, sheets, sponges derived from animal sources, often cow or pig.	Assists with stopping bleeding, helps recruit cells into the wound and stimulates their proliferation to facilitate healing.	Clean, moist wounds	Biostep, Cellerate RX, NU-GEL, Promogran

Transparent Dressings Transparent dressings are often applied to wounds including ulcerated or burned skin areas. These dressings offer several advantages:

- They act as temporary skin.
- They are nonporous, nonabsorbent, self-adhesive dressings that do not require changing as other dressings do. They are often left in place until healing has occurred or as long as they remain intact.
- Because they are transparent, the wound can be assessed through them.
- Because they are semiocclusive, the wound remains moist and can retain a small amount of serous exudate, which promotes epithelial growth, hastens healing, and reduces the risk of infection.
- Because they are elastic, they can be placed over a joint without disrupting the client's mobility.
- They adhere only to the skin area around the wound and not to the wound itself because they keep the wound moist.
- They allow the client to shower or bathe without removing the dressing.

Hydrocolloid Dressings Hydrocolloid dressings (see Table 36–5) are frequently used over pressure ulcers. These dressings offer several advantages:

- They last 3 to 7 days.
- They do not need a “cover” dressing and are water resistant, so the client can shower or bathe.
- They can be molded to uneven body surfaces.
- They act as temporary skin and provide an effective bacterial barrier.
- They decrease pain and thus reduce the need for analgesics.
- They absorb moderate drainage and therefore can be used on slowly draining wounds.
- They contain wound odor.

These dressings have certain limitations, however:

- They are occlusive, are opaque, and obscure wound visibility.
- They have a limited absorption capacity.
- They can facilitate anaerobic bacterial growth.
- They can soften and wrinkle at the edges with wear and movement.
- They can be difficult to remove and may leave a residue on the skin.

Because of these limitations, hydrocolloid dressings should not be used for infected wounds or those with deep tracts or *fistulas* (abnormal passages that develop between a hollow organ and the skin or between two hollow organs).

Securing Dressings The nurse tapes the dressing over the wound, ensuring that the dressing covers the entire wound and does not become dislodged. The correct type of tape must be selected for the purpose. The nurse follows these steps:

1. Place the tape so that the dressing cannot be folded back to expose the wound. Place strips at the ends of the dressing, and space tapes evenly in the middle.
2. Ensure that the tape is long enough and wide enough to adhere to several inches of skin on each side of the dressing, but not so long or wide that the tape loosens with activity (Figure 36–9 ■).

Figure 36–9 ■ The strips of tape should be placed at the ends of the dressing and must be sufficiently long and wide to secure the dressing. The tape should adhere to intact skin.

Figure 36–10 ■ Dressings over moving parts must remain secure in spite of the client's movement. Place the tape over a joint at a right angle to the direction the joint moves.

3. Place the tape in the opposite direction from the body action, for example, across a body joint or crease, not lengthwise (Figure 36–10 ■).

Montgomery straps (tie tapes) are used for wounds requiring frequent dressing changes (Figure 36–11 ■). These straps prevent skin irritation and discomfort caused by removing the adhesive each time the dressing is changed.

Medical tapes can cause injuries if used incorrectly. Blisters will form if too much tension is applied while placing the tape, when edema has collected after the tape was placed, and when alcohol or benzoic-based prep solutions are used under the tape. Medical tape manufacturers issue safety guidelines for specific tape products. Before using medical tapes read the safety guidelines for indications of use and safe application and removal.

Figure 36–11 ■ Montgomery straps, or tie tapes, are used to secure large dressings that require frequent changing.

Cleaning Wounds

Wound cleaning involves the removal of debris, such as foreign materials, excess slough, necrotic tissue, bacteria, and other microorganisms. The choices of cleaning agent and method depend largely on agency protocol and the primary care provider's preference. Recommended guidelines for cleaning wounds are shown in the accompanying Practice Guidelines. Commonly used methods to clean a surgical wound and drain site are shown in Chapter 37 ∞.

Wound Irrigation and Packing

An irrigation (lavage) is the washing or flushing out of an area. Sterile technique is required for a wound irrigation because there is a break in the skin integrity.

Irrigation pressures should range from 4 to 15 pounds per square inch (psi). Below 4 psi, such as when using a bulb syringe, the irrigation may not be effective, and above 15 psi it may damage tissues. A 30- to 60-mL piston syringe with a 19-gauge needle or catheter provides approximately 8 psi. Using piston syringes instead of bulb syringes to irrigate a wound also reduces the risk of aspirating drainage. For deep wounds with small openings, a sterile straight catheter may also be necessary. Some providers advocate the use of a commercial oral water jet for wound cleansing. This can be effective if kept at the lowest setting since middle settings often exceed 40 psi and can drive microorganisms further into the wound

(Bates-Jensen, Schultz, & Ovington, 2012). Frequently used irrigation solutions are sterile normal saline, lactated Ringer's solution, and antibiotic solutions. Skill 36-2 details the steps involved in irrigating a wound.

PRACTICE GUIDELINES

Cleaning Wounds

- Follow standard precautions for personal protection. Wear gloves, gown, goggles, and mask as indicated.
- Use solutions such as isotonic saline or wound cleansers to clean or irrigate wounds. If antimicrobial solutions are used, make sure they are well diluted.
- Microwave heating of liquids to be used on the wound is not recommended. When possible, warm the solution to body temperature before use. **Rationale:** *This prevents lowering the wound temperature, which slows the healing process. Microwave heating could cause the solution to become too hot.*
- If a wound is grossly contaminated by foreign material, bacteria, slough, or necrotic tissue, clean the wound at every dressing change. **Rationale:** *Foreign bodies and devitalized tissue act as a focus for infection and can delay healing.*
- If a wound is clean, has little exudate, and reveals healthy granulation tissue, avoid repeated cleaning. **Rationale:** *Unnecessary cleaning can delay wound healing by traumatizing newly produced, delicate tissues, reducing the surface temperature of the wound, and removing exudate, which itself may have bactericidal properties.*
- Use gauze squares or nonwoven swabs that do not shed fibers. Avoid using cotton balls and other products that shed fibers onto the wound surface. **Rationale:** *The fibers become embedded in granulation tissue and can act as foci for infection. They may also stimulate "foreign body" reactions, prolonging the inflammatory phase of healing and delaying the healing process.*
- Clean superficial noninfected wounds by irrigating them with normal saline. **Rationale:** *The hydraulic pressure of an irrigating stream of fluid dislodges contaminating debris and reduces bacterial colonization.*
- Avoid drying a wound after cleaning it. **Rationale:** *This helps retain wound moisture.*
- Hold cleaning sponges with forceps or with a sterile gloved hand.
- Clean from the wound in an outward direction to avoid transferring organisms from the surrounding skin into the wound.
- Consider not cleaning the wound at all if it appears to be clean.

Irrigating a Wound

PURPOSES

- To clean the area
- To apply heat and hasten the healing process
- To apply an antimicrobial solution

ASSESSMENT

Assess the client's record to determine

- Previous appearance and size of the wound
- Character of the exudate

- Presence of pain and the time of the last pain medication
- Clinical signs of systemic infection
- Allergies to the wound irrigation agent or tape.

Continued on page 850

Irrigating a Wound—continued

PLANNING

- Before irrigating a wound, determine (a) the type of irrigating solution to be used, (b) the frequency of irrigations, and (c) the temperature of the solution.
- If possible, schedule the irrigation at a time convenient for the client. Some irrigations require only a few minutes and others can take much longer.
- Determine if the client requires premedication for pain or other pain management techniques prior to wound care (see Chapter 46 ∞).

DELEGATION

Due to the need for aseptic technique and assessment skills, wound irrigations are not delegated to UAP. However, UAP may observe the wound and dressing during usual care and must report abnormal findings to the nurse. Abnormal findings must be validated and interpreted by the nurse.

INTERPROFESSIONAL PRACTICE

Irrigating wounds may be within the scope of practice for other health care providers. For example, in addition to nurses, physical therapists may irrigate wounds before treatment. Although the therapist may verbally communicate their findings and plan to the health care team members, the nurse must also know where to locate their documentation in the client's medical record.

IMPLEMENTATION

Preparation

Check that the irrigating fluid is at the proper temperature.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss how the results will be used in planning further care or treatments.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Prepare the client.
 - Assist the client to a position in which the irrigating solution will flow by gravity from the upper end of the wound to the lower end and then into the basin.
 - Place the waterproof drape under the wound and over the bed. ①

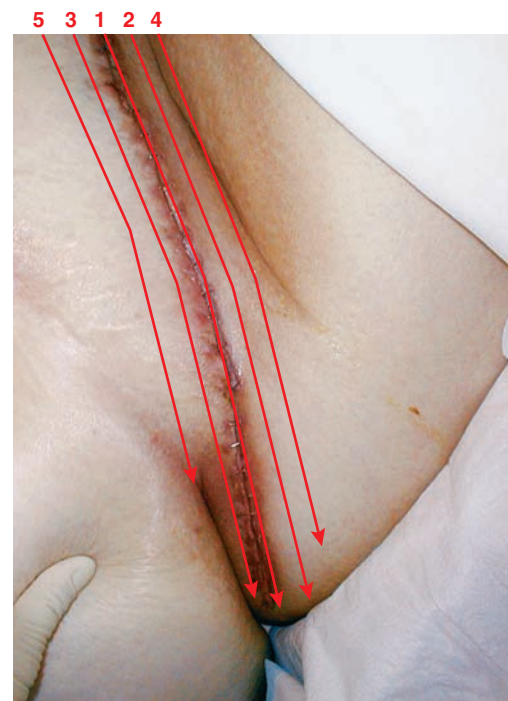

① Placing the waterproof pad under the wound.

Equipment

- Sterile dressing equipment and dressing materials
- Sterile irrigation set or individual supplies, including:
 - Sterile syringe (e.g., a 30- to 60-mL syringe) with a catheter of an appropriate size (e.g., #18 or #19) or an irrigating (catheter) tip syringe
 - Sterile graduated container for irrigating solution
 - Basin for collecting the used irrigating solution
 - Moisture-proof sterile drape
- Moisture-proof bag
- Irrigating solution, usually 200 mL (6.5 oz) of solution warmed to body temperature, according to the agency's or primary care provider's choice
- Goggles, gown, and mask
- Clean gloves
- Sterile gloves

Although a wound may already be contaminated, sterile equipment is usually used during irrigation to prevent the possibility of adding new nonresident microorganisms to the site. In settings outside of hospitals, some reusable supplies such as irrigating syringes or basins may be cleaned and used again for a specific wound.

- Apply clean gloves and remove and discard the old dressing.
- If indicated, clean the wound from the cleanest area toward the least clean. If the wound is circular, this would be from the center of the wound outward. For a linear wound, cleanse from top to bottom, beginning in the middle and moving progressively laterally. ②

② Cleaning a wound from the midpoint outward and from top to bottom.

Courtesy of Cory Patrick Hartley, RN.

Irrigating a Wound—continued

- Use a separate swab for each stroke, and discard each swab after use. **Rationale:** *This prevents the introduction of microorganisms to other wound areas.*
 - Assess the wound and drainage.
 - Remove and discard clean gloves.
 - Perform hand hygiene.
5. Prepare the equipment.
 - Open the sterile dressing set and supplies.
 - Pour the ordered solution into the solution container.
 - Position the basin below the wound to receive the irrigating fluid.
 6. Irrigate the wound.
 - Apply clean gloves.
 - Instill a steady stream of irrigating solution into the wound. Make sure all areas of the wound are irrigated.
 - Use either a syringe with a catheter attached or with an irrigating tip to flush the wound. ③
 - If you are using a catheter to reach tracks or crevices, insert the catheter into the wound until resistance is met. Do not force the catheter. **Rationale:** *Forcing the catheter can cause tissue damage.*
 - Continue irrigating until the solution becomes clear (no exudate is present).
 - Dry the area around the wound. **Rationale:** *Moisture left on the skin promotes the growth of microorganisms and can cause skin irritation and breakdown.*
 - Remove and discard clean gloves.
 - Perform hand hygiene.
 7. Assess and dress the wound.
 - Assess the appearance of the wound again, noting in particular the type and amount of exudate still present and the presence and extent of granulation tissue.
 - Using sterile technique, apply a dressing to the wound based on the amount of drainage expected (see Table 36–5).

③ Irrigating an open wound.

- Remove and discard gloves.
 - Perform hand hygiene.
8. Document the irrigation and the client's response in the client record using forms or checklists supplemented by narrative notes when appropriate. Electronic health records will use a designated wound/skin documentation sheet.

SAMPLE DOCUMENTATION

6/5/15 1530 Midline abdominal wound 7 cm with intact sutures except for center 3 cm. open area with moderate amt. thin serosang drainage. Irrigated with NS until clear. Redressed using sterile technique. _____ N. Jamaghani, RN

EVALUATION

- Perform follow-up based on findings that deviate from expected or normal for the client. Relate findings to previous assessment data if available.
- Report significant deviations from normal to the primary care provider.

Gauze **packing** using the damp-to-damp technique has been used to pack wounds that require debridement. In this technique, moist 4×4 non-cotton-filled gauzes are packed in the wound to absorb exudate but they are not allowed to dry before removal. However, newer advanced dressing materials have significant advantages over the use of gauze. See the accompanying Practice Guidelines for issues related to using damp-to-damp dressings.

Many of the techniques described here for dressing wounds may be combined depending on the specific type of wound. In addition, therapies are constantly being designed and evaluated. One example is negative pressure wound therapy, also termed vacuum-assisted closure (VAC), wound VAC, vacuum sealing, and topical negative pressure, which refers to the use of suction equipment to apply negative pressure to a variety of wound types. This therapy has been shown to speed tissue generation, reduce swelling around the wound, and enhance wound healing by providing a moist and protected environment (Gabriel & Gupta, 2012). Sterile foam sponges are placed into a clean wound and covered with a transparent adhesive drape, and

then a hole is cut in the drape to allow insertion of the vacuum tubing (Figure 36–12 ■). For maximum effectiveness the vacuum is applied for almost 24 hours each day and portable systems are available for ambulatory clients.

Supporting and Immobilizing Wounds

Bandages and binders serve various purposes:

- Supporting a wound (e.g., a fractured bone)
- Immobilizing a wound (e.g., a strained shoulder)
- Applying pressure (e.g., elastic bandages on the lower extremities to improve venous blood flow)
- Securing a dressing (e.g., for an extensive abdominal surgical wound)
- Retaining warmth (e.g., a flannel bandage on a rheumatoid joint).

There are several types of bandages and binders and several ways in which they are applied. When correctly applied, they promote healing, provide comfort, and can prevent injury (see the accompanying Practice Guidelines).

PRACTICE GUIDELINES

Issues Related to the Use of Damp Gauze Versus Advanced Dressings

- To keep the gauze damp, it must be changed or remoistened with saline frequently. **Rationale:** *If the gauze is allowed to dry out, removal results in pain and disruption of wound healing through drying of the surface and tissue adherence to the gauze.*
- A wound requires moisture and warmth for optimal healing. Evaporation of the saline causes wound cooling, vasoconstriction, and dehydration.
- Moistened gauze does not prevent introduction of bacteria into the wound.
- Gauze is easy to use and can be manipulated to fit almost any wound.
- The diversity of advanced dressings may be confusing for clients and health care providers.
- Although gauze is much less expensive than advanced dressings (e.g., polymers, alginates, collagens), the cost per week can be higher due to the number of dressing changes required (Wet-to-dry saline, 2011). Including the price of the dressing, gloves, saline, and tape, the materials cost for a gauze dressing change twice per day versus an advanced dressing three times per week is very similar. However, including the cost per nurse home visit, the gauze dressing is almost five times as expensive.
- Wounds have been shown to heal twice as quickly with advanced dressings compared to gauze.

Conclusions: Practitioners should become familiar with the range and uses of advanced dressing materials. The selection of dressing materials must consider time, material cost, client comfort, and speed of wound healing.

LIFESPAN CONSIDERATIONS Pressure Ulcer and Wound Care**INFANTS**

The skin of infants is more fragile than that of older children and adults, and more susceptible to infection, shearing from friction, and burns.

CHILDREN

- Staphylococcus and fungus are two major infectious agents affecting the skin of children. Abrasions or small lacerations, commonly experienced by children, provide an entry in the skin for these organisms. Minor wounds should be cleansed with warm, soapy water, and covered with a sterile bandage. Children should be instructed not to touch the wound.
- With more serious skin lesions, remind the child not to touch the wound, drains, or dressing. Cover with an appropriate bandage that will remain intact during the child's usual activities. Cover a transparent dressing with opaque material if viewing the site is distressing to the child. Restrain only when all alternatives have been tried and when absolutely necessary.

- For younger children, demonstrate wound care on a doll. Reassure that the wound will not be permanent and that nothing will fall out of the body.

OLDER ADULTS

- Hold wrinkled skin taut during application of a transparent dressing. Obtain assistance if needed.
- Skin is more fragile and can easily tear with removal of tape (especially adhesive tape). Use paper tape and tape remover as indicated, keeping tape use to the minimum required. Use extreme caution during tape removal.
- Older adults who are in long-term care facilities often have the following conditions: immobility, malnutrition, and incontinence—all of which increase the risk for development of skin breakdown.
- Skin breakdown can occur as quickly as within 2 hours, so assessments should be done with each repositioning of the client.
- A thorough assessment of a client's heels should be done every shift. The skin can break down quickly from friction of movement in bed.

Home Care Considerations Wound Care**PATIENT-CENTERED CARE**

- Perform appropriate client teaching for promoting wound healing and maintenance of healthy skin.
- Instruct family about hygiene and medical asepsis; hand cleansing before and after dressing changes; and using a clean area for storage of dressing supplies.
- Instruct the client and family on where to obtain needed supplies. Be sensitive to the cost of dressings (e.g., transparent barriers are costly) and suggest less expensive alternatives if necessary. Be creative in the use of household items for padding pressure areas.
- Instruct the client and family in proper disposal of contaminated dressings. All contaminated items should be double bagged in moisture-proof bags.
- Verify how the client may bathe with the wound (i.e., does the wound need to be covered with a waterproof barrier or should it be cleansed in the shower?).
- Tap water may be used to cleanse wounds instead of normal saline (Fernandez & Griffiths, 2012).

PRACTICE GUIDELINES**Bandaging**

- Whenever possible, bandage the part in its normal position, with the joint slightly flexed. **Rationale:** *This avoids putting strain on the ligaments and the muscles of the joint.*
- Pad between skin surfaces and over bony prominences. **Rationale:** *This prevents friction from the bandage and consequent abrasion of the skin.*
- Always bandage body parts by working from the distal to the proximal end. **Rationale:** *This aids the return flow of venous blood.*
- Bandage with even pressure. **Rationale:** *This prevents interference with blood circulation.*
- Whenever possible, leave the end of the body part (e.g., the toe) exposed. **Rationale:** *You will be able to assess the adequacy of the blood circulation to the extremity.*
- Cover dressings with bandages at least 5 cm (2 in.) beyond the edges of the dressing. **Rationale:** *This prevents the dressing and wound from becoming contaminated.*

Many types of materials are used for bandages. Gauze is one of the most commonly used, because it is light and porous and readily molds to the body. It is also relatively inexpensive, so it is generally discarded when soiled. Gauze is used to retain dressings on wounds and to bandage the fingers, hands, toes, and feet. It supports dressings and at the same time permits air to circulate; it can be impregnated with petroleum jelly or other medications for application to wounds.

Elasticized bandages are applied to provide pressure to an area. They are commonly used as tensor bandages or as partial stockings to provide support and improve the venous circulation in the legs.

The width of the bandage used depends on the size of the body part to be bandaged. For example, a 2.5-cm (1-in.) bandage is used for a finger, a 5-cm (2-in.) bandage for an arm, and a 7.5- or 10-cm (3- or 4-in.) bandage for a leg. Padding (e.g., abdominal pads and gauze squares) is frequently used to cover bony prominences (e.g., the elbow) or to separate skin surfaces (e.g., the fingers).

Before applying a bandage, the nurse needs to know its purpose and to assess the area requiring support (see accompanying Practice Guidelines). When bandages are used to secure dressings, the nurse wears gloves to prevent contact with body fluids.

Bandages

A **bandage** is a strip of cloth used to wrap some part of the body. Bandages are available in various widths, most commonly 1.5 to 7.5 cm (0.5 to 3 in.). They are usually supplied in rolls for easy application to a body part.

Basic Turns for Roller Bandages

Applying bandages to various parts of the body involves one or more of five basic bandaging turns: circular, spiral, spiral reverse, recurrent, and figure-eight. *Circular* turns are used to anchor bandages and to

PRACTICE GUIDELINES

Assessing Before Applying Bandages or Binders

- Inspect and palpate the area for swelling.
- Inspect for the presence of and status of wounds (open wounds will require a dressing before a bandage or binder is applied).
- Note the presence of drainage (amount, color, odor, viscosity).
- Inspect and palpate for adequacy of circulation (skin temperature, color, and sensation). **Rationale:** *Pale or cyanotic skin, cool temperature, tingling, and numbness can indicate impaired circulation.*
- Ask the client about any pain experienced (location, intensity, onset, quality).
- Assess the ability of the client to reapply the bandage or binder when needed.
- Assess the capabilities of the client regarding activities of daily living (e.g., to eat, dress, comb hair, bathe) and assess the assistance required during the convalescence period.

terminate them. Circular turns usually are not applied directly over a wound because of the discomfort the bandage would cause.

Spiral turns are used to bandage parts of the body that are fairly uniform in circumference, for example, the upper arm or upper leg. *Spiral reverse* turns are used to bandage cylindrical parts of the body that are not uniform in circumference, for example, the lower leg or forearm. *Recurrent* turns are used to cover distal parts of the body, for example, the end of a finger, the skull, or the stump of an amputation. *Figure-eight* turns are used to bandage an elbow, knee, or ankle, because they permit some movement after application.

Circular Turns

- Hold the bandage in your dominant hand, keeping the roll upmost, and unroll the bandage about 8 cm (3 in.). This length of unrolled bandage allows good control for placement and tension.
- Apply the end of the bandage to the part of the body to be bandaged. Hold the end down with the thumb of the other hand (Figure 36–13 ■).
- Encircle the body part a few times or as often as needed, making sure that each layer overlaps one half to two thirds of the previous layer. This provides even support to the area.
- The bandage should be firm, but not too tight. Ask the client if the bandage feels comfortable. A tight bandage can interfere with

Figure 36–13 ■ Starting a bandage with circular turns.

Figure 36–14 ■ Applying spiral turns.

blood circulation, whereas a loose bandage does not provide adequate protection.

- Secure the end of the bandage with tape or clips if there is no Velcro fastener.

Spiral Turns

- Make two circular turns. Two circular turns anchor the bandage.
- Continue spiral turns at about a 30° angle, each turn overlapping the preceding one by two thirds the width of the bandage (Figure 36–14 ■).
- Terminate the bandage with two circular turns, and secure the end as described for circular turns.

Spiral Reverse Turns

- Anchor the bandage with two circular turns, and bring the bandage upward at about a 30° angle.
- Place the thumb of your free hand on the upper edge of the bandage (Figure 36–15A ■). The thumb will hold the bandage while it is folded on itself.
- Unroll the bandage about 15 cm (6 in.), and then turn your hand so that the bandage falls over itself (Figure 36–15B).
- Continue wrapping the bandage around the limb, overlapping each previous turn by two thirds the width of the bandage. Make each bandage turn at the same position on the limb so that the turns of the bandage will be aligned (Figure 36–15C).
- Terminate the bandage with two circular turns, and secure the end as described for circular turns.

Recurrent Turns

- Anchor the bandage with two circular turns.
- Fold the bandage back on itself, and bring it centrally over the distal end to be bandaged (Figure 36–16 ■).
- Bring the bandage back over the end to the right of the center bandage but overlapping it by two thirds the width of the bandage.
- Bring the bandage back on the left side, also overlapping the first turn by two thirds the width of the bandage.
- Continue this pattern of alternating right and left until the area is covered. Overlap the preceding turn by two thirds the bandage width each time.
- Terminate the bandage with two circular turns (Figure 36–17 ■). Secure the end appropriately.

Figure 36-15 ■ Applying spiral reverse turns.

Figure 36-16 ■ Starting a recurrent bandage.

Figure 36-18 ■ Applying a figure-eight bandage.

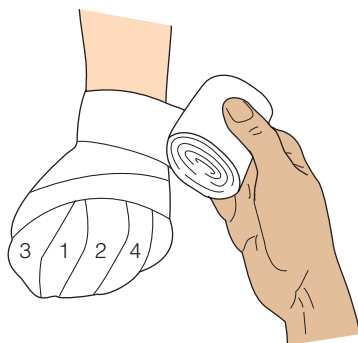

Figure 36-17 ■ Completing a recurrent bandage.

Figure-Eight Turns

- Anchor the bandage with two circular turns.
- Carry the bandage above the joint, around it, and then below it, making a figure-eight (Figure 36-18 ■).
- Continue above and below the joint, overlapping the previous turn by two thirds the width of the bandage.
- Terminate the bandage above the joint with two circular turns, and then secure the end appropriately.

Binders

A **binder** is a type of bandage designed for a specific body part; for example, the triangular binder (sling) fits the arm. Binders are used to

support large areas of the body, such as the abdomen or chest. Binders can be simple, inexpensive, and customizable by using plain material such as the triangular sling described below, or they can be of commercial design. Commercial binders, such as the hook-and-loop (Velcro) binder, are often easier to use, more expensive, and slightly less modifiable than customized binders.

Arm Sling

- Ask the client to flex the elbow to an 80° angle or less, depending on the purpose. The thumb should be facing upward or inward toward the body. **Rationale:** An 80° angle is sufficient to support the forearm, to prevent swelling of the hand, and to relieve pressure on the shoulder joint (e.g., to support the paralyzed arm of a stroke client whose shoulder might otherwise become dislocated). A more acute angle is preferred if there is swelling of the hand.
- If a triangle sling is used, place one end of the unfolded binder over the shoulder of the uninjured side so that the binder falls down the front of the chest of the client with the point of the triangle (apex) under the elbow of the injured side.
- Take the upper corner, and carry it around the neck until it hangs over the shoulder on the injured side.
- Bring the lower corner of the binder up over the arm to the shoulder of the injured side. Using a square knot, secure this corner to the upper corner at the side of the neck on the injured side (Figure 36-19 ■). **Rationale:** A square knot will not slip. Tying the knot at the side of the neck prevents pressure on the bony prominences of the vertebral column at the back of the neck.

Figure 36-19 ■ A triangle arm sling.

Figure 36-21 ■ A straight abdominal binder.

Figure 36-20 ■ A commercial arm sling.

- Fold the sling neatly at the elbow, and secure it with safety pins or tape. It may be folded and fastened at the front.
- If a commercial sling is used, it may also include a second strap that goes around the back of the client's chest from the finger end of the sling to the elbow (Figure 36-20 ■). **Rationale:** *This strap holds the arm close to the body at all times, providing shoulder immobilization such as is used following a shoulder dislocation or surgery.*
- Make sure the wrist is supported, to maintain alignment.
- Remove the sling periodically to inspect the skin for indications of irritation, especially around the site of the knot.

Straight Abdominal Binder

- Place the binder smoothly around the body, commonly with the upper border of the binder at the waist and the lower border at the level

- of the gluteal fold. A binder placed over the waist interferes with respiration; one placed too low interferes with elimination and walking.
- Apply padding over the iliac crests if the client is thin.
- Bring the ends around the client, overlap them, and secure them with pins, clips, or Velcro (Figure 36-21 ■). If used, orient the pins horizontally to allow for comfort when bending.

Heat and Cold Applications

Heat and cold are applied to the body for local and systemic effects. Table 36-6 lists the physiological effects of heat and cold.

Local Effects of Heat

Heat has been a long-standing remedy for aches and pains, and people often equate heat with comfort and relief. Heat causes vasodilation and increases blood flow to the affected area, bringing oxygen, nutrients, antibodies, and leukocytes.

Application of heat promotes soft tissue healing and increases suppuration. A possible disadvantage of heat is that it increases capillary permeability, which allows extracellular fluid and substances such as plasma proteins to pass through the capillary walls and may result in edema or an increase in preexisting edema. Heat is often used for clients with musculoskeletal problems such as joint stiffness from arthritis, contractures, and low back pain.

Local Effects of Cold

Generally, the physiological effects of cold are opposite to the effects of heat. Cold lowers the temperature of the skin and underlying tissues and causes **vasoconstriction**. Vasoconstriction reduces blood flow to the affected area and thus reduces the supply of oxygen and metabolites, decreases the removal of wastes, and produces skin pallor and coolness. Prolonged exposure to cold results in impaired

LIFESPAN CONSIDERATIONS Applying Bandages and Binders

CHILDREN

- Allow the child to help with the procedure by holding supplies, opening boxes, counting turns, and so on.
- If a young client is apprehensive, demonstrate the procedure on a doll or stuffed animal.
- Encourage the child to decorate the bandage.
- Teach the caregivers to apply bandages and binders safely.

OLDER ADULTS

- Older clients may need extra support during the procedure, especially if arthritis, contractures, or tremors are present.
- Avoid constricting the client's circulation with a tight bandage or binder. Observe skin and bony prominences frequently for signs of impaired circulation. The risk for skin breakdown increases with age.

Home Care Considerations Applying Bandages and Binders

PATIENT-CENTERED CARE

- Assess the client's or caregiver's ability and willingness to perform the bandaging procedure.
- Ensure that the client has the proper supplies and knows how to obtain replacement supplies.
- The client should have two sets of bandages or two binders so that there is one to wear while the other is being washed. Bandages and binders should be washed inside a mesh laundry bag to keep them from becoming twisted and to prevent Velcro or hooks from catching on other laundry.
- Instruct the client's caregiver on the importance of and how to:
 1. Cleanse hands thoroughly before handling dressing supplies and applying the bandage.
 2. Report skin breakdown, redness, pain, or pallor of the affected area.
 3. Check for adequate peripheral circulation after applying the bandage.

TABLE 36-6

Physiological Effects of Heat and Cold

Heat	Cold
Vasodilation	Vasoconstriction
Increases capillary permeability	Decreases capillary permeability
Increases cellular metabolism	Decreases cellular metabolism
Increases inflammation	Slows bacterial growth, decreases inflammation
Sedative effect	Local anesthetic effect

circulation, cell deprivation, and subsequent damage to the tissues from lack of oxygen and nourishment. The signs of tissue damage due to cold are a bluish purple, mottled appearance of the skin, numbness, and sometimes blisters and pain. Cold is most often used for sports injuries (e.g., sprains, strains, fractures) to limit postinjury swelling and bleeding.

Systemic Effects of Heat and Cold

Heat applied to a localized body area, particularly a large body area, may cause excessive peripheral vasodilation, which produces a drop in blood pressure. A significant drop in blood pressure can cause fainting. Clients who have heart or pulmonary disease and who have circulatory disturbances such as arteriosclerosis are more prone to this effect than healthy people are. With extensive cold applications and vasoconstriction, a client's blood pressure can increase because blood is shunted from the cutaneous circulation to the internal blood vessels. Shivering, a generalized effect of prolonged cold, is a normal response as the body attempts to warm itself.

Thermal Tolerance

Various parts of the body differ in tolerance to heat and cold. The physiological tolerance of individuals also varies (Box 36-3). Specific conditions necessitate precautions in the use of hot or cold applications:

- **Neurosensory impairment:** People with sensory impairments are unable to perceive that heat is damaging the tissues and are at risk for burns or are unable to perceive discomfort from cold and prevent tissue injury.
- **Impaired mental status:** People who are confused or have an altered level of consciousness need monitoring during applications to ensure safe therapy.
- **Impaired circulation:** People with peripheral vascular disease, diabetes, or congestive heart failure lack the normal ability to

BOX 36-3

Variables Affecting Physiological Tolerance to Heat and Cold

- **Body part.** The back of the hand and foot are not very temperature sensitive. In contrast, the inner aspect of the wrist and forearm, the neck, and the perineal area are temperature sensitive.
- **Size of the exposed body part.** The larger the area exposed to heat and cold, the lower the tolerance.
- **Individual tolerance.** The very young and the very old generally have the lowest tolerance. Individuals who have neurosensory impairments may have a high tolerance, but the risk of injury is greater.
- **Length of exposure.** People feel hot and cold applications most while the temperature is changing. After a period of time, tolerance increases.
- **Intactness of skin.** Injured skin areas are more sensitive to temperature variations.

dissipate heat via the blood circulation, which puts them at risk for tissue damage with heat and cold applications.

- **Immediately after injury or surgery:** Heat increases bleeding and swelling.
- **Open wounds:** Cold can decrease blood flow to the wound, thereby inhibiting healing.

Adaptation of Thermal Receptors

Temperature (thermal) receptors adapt to temperature changes. When they are subjected to an abrupt change in temperature, the receptors are strongly stimulated initially. This strong stimulation declines rapidly during the first few seconds and then more slowly during the next half hour or more as the receptors adapt to the new temperature.

Nurses and clients need to understand this adaptive response when applying heat and cold. Clients may be tempted to change the temperature of a thermal application because of the change in thermal sensation following adaptation. Increasing the temperature of a hot application after adaptation can result in serious burns. Decreasing the temperature of a cold application can result in pain and serious impairment of circulation to the body part. Table 36-7 lists temperatures of hot and cold applications.

Rebound Phenomenon

The rebound phenomenon occurs at the time the maximum therapeutic effect of the hot or cold application is achieved and the opposite effect begins. For example, heat produces maximum vasodilation in 20 to 30 minutes; continuation of the application beyond 30 minutes brings tissue congestion, and the blood vessels then constrict. If the heat application is continued, the client is at risk for burns because the

TABLE 36-7 Temperatures for Hot and Cold Applications

Description	Temperature	Application
Very cold	Below 15°C (59°F)	Ice bags
Cold	15°C–18°C (59°F–65°F)	Cold pack
Cool	18°C–27°C (65°F–80°F)	Cold compresses
Tepid	27°C–37°C (80°F–98°F)	Alcohol sponge bath
Warm	37°C–40°C (98°F–104°F)	Warm bath, aquathermia pads
Hot	40°C–46°C (104°–115°F)	Hot soak, irrigations, hot compresses*
Very hot	Above 46°C (Above 115°F)	Hot water bags for adults*

*Note: The temperature of the water used to create the hot soak or compress, or to fill a hot water bottle, exceeds the surface temperature of 43°C (110°F) which is safe to apply to skin.

constricted blood vessels are unable to dissipate the heat adequately via the blood circulation.

With cold applications, maximum vasoconstriction occurs when the involved skin reaches a temperature of 15°C (60°F). The ruddiness of the skin of a person who has been walking in cold weather is due to oxygenated red blood cells trapped in the skin when vasoconstriction occurs. Below 15°C, vasodilation begins. This mechanism is protective: It helps to prevent freezing of body tissues normally exposed to cold, such as the nose and ears. Continued cold causes alternating vasodilation and vasoconstriction (called the Lewis Hunting effect).

SAFETY ALERT!

SAFETY

An understanding of the rebound phenomenon is essential for the nurse and client. Thermal applications must be halted *before* the rebound phenomenon begins.

Applying Heat and Cold

Heat can be applied to the body in both dry and moist forms. Dry heat is applied locally by means of a hot water bottle, aquathermia pad, disposable heat pack, or electric pad. Moist heat can be provided

by compress, hot pack, soak, or sitz bath. Selected indications for the use of heat and cold are found in Table 36–8.

Dry cold is generally applied locally by means of a cold pack, ice bag, ice glove, or ice collar. In addition, continuous cold therapy (cryotherapy) following joint surgery or injury can be delivered by a cooling unit similar to the aquathermia pad (Su et al., 2012). Moist cold can be provided by compress or a cooling sponge bath.

For all local applications of heat or cold, the nurse needs to follow these guidelines:

- Determine the client's ability to tolerate the therapy.
- Identify conditions that might contraindicate treatment (e.g., bleeding, circulatory impairment).
- Explain the application to the client.
- Assess the skin area to which the heat or cold will be applied.
- Ask the client to report any discomfort.
- Return to the client 15 minutes after starting the heat or cold therapy, and observe the local skin area for any untoward signs (e.g., redness). Stop the application if any problems occur.
- Remove the equipment at the designated time, and dispose of it appropriately.
- Examine the area to which the heat or cold was applied, and record the client's response.

For contraindications to the use of heat or cold, see Box 36–4.

Hot Water Bag

A hot water bag or bottle has been a common source of dry heat used in the home. It is convenient and relatively inexpensive. However, because of the danger of burning from improper use, many agencies now use other devices.

The following temperatures of the water used to fill the bag are considered safe in most situations and provide the desired effect: normal adult and child over 2 years, 46°C to 52°C (115°F to 125°F); debilitated or unconscious adult, or child under 2 years, 40.5°C to 46°C (105°F to 115°F).

The nurse follows these steps to apply a hot water bag:

- Measure the temperature of the water using a bath thermometer.
- Fill the bag about two-thirds full.
- Expel the remaining air and secure the top. With the air removed, the bag can be molded to the body part.

TABLE 36-8 Selected Indications of Heat and Cold

Indication	Effect of Heat	Effect of Cold
Muscle spasm	Relaxes muscles and increases their contractility.	Relaxes muscles and decreases muscle contractility.
Inflammation	Increases blood flow, softens exudates.	Vasoconstriction decreases capillary permeability, decreases blood flow, slows cellular metabolism.
Pain	Relieves pain, possibly by promoting muscle relaxation, increasing circulation, and promoting psychological relaxation and a feeling of comfort; acts as a counterirritant.	Decreases pain by slowing nerve conduction rate and blocking nerve impulses; produces numbness, acts as a counterirritant, increases pain threshold.
Contracture	Reduces contracture and increases joint range of motion by allowing greater distention of muscles and connective tissue.	
Joint stiffness	Reduces joint stiffness by decreasing viscosity of synovial fluid and increasing tissue distensibility.	
Traumatic injury		Decreases bleeding by constricting blood vessels; decreases edema by reducing capillary permeability.

BOX 36-4 Contraindications to the Use of Heat and Cold

Determine the presence of any conditions indicating the need for special precautions during heat and cold therapy:

- *Neurosensory impairment.* Individuals with sensory impairments are unable to perceive that heat is damaging the tissues and are at risk for burns, or they are unable to perceive discomfort from cold and are unable to prevent tissue injury.
- *Impaired mental status.* Individuals who are confused or have an altered level of consciousness need monitoring and supervision during applications to ensure safe therapy.
- *Impaired circulation.* Individuals with peripheral vascular disease, diabetes, or congestive heart failure lack the normal ability to dissipate heat via the blood circulation, which puts them at risk for tissue damage with heat applications. Cold applications are contraindicated for these individuals.
- *Open wounds.* Tissues around an open wound are more sensitive to heat and cold.

Determine the presence of any conditions contraindicating the use of heat:

- *The first 24 hours after traumatic injury.* Heat increases bleeding and swelling.

- *Active hemorrhage.* Heat causes vasodilation and increases bleeding.
- *Noninflammatory edema.* Heat increases capillary permeability and edema.
- *Skin disorder that causes redness or blisters.* Heat can burn or cause further damage to the skin.

Determine the presence of any conditions contraindicating the use of cold:

- *Open wounds.* Cold can increase tissue damage by decreasing blood flow to an open wound.
- *Impaired circulation.* Cold can further impair nourishment of the tissues and cause tissue damage. In clients with Raynaud's disease, cold increases arterial spasm.
- *Allergy or hypersensitivity to cold.* Some clients have an allergy to cold that may be manifested by an inflammatory response, for example, erythema, hives, swelling, joint pain, and occasional muscle spasm. Some react with a sudden increase in blood pressure, which can be hazardous if the person is hypersensitive.

Figure 36-22 ■ Hot water bottles with cloth covers.

- Dry the bag and hold it upside down to test for leakage.
- Wrap the bag in a towel or cover and place it on the body site (Figure 36-22 ■).
- Remove after 30 minutes or in accordance with agency protocol.

Aquathermia Pad

The aquathermia pad (also referred to as a K-pad) is constructed with tubes containing water. The pad is attached by tubing to an electrically powered control unit that has an opening for water and a temperature gauge (Figure 36-23 ■). Some aquathermia pads have an absorbent surface through which moist heat can be applied. The other surface of the pad is waterproof. These pads are disposable.

Figure 36-23 ■ An aquathermia heating unit.
Courtesy Adroit Medical Systems, Inc.

To apply an aquathermia pad, the nurse carries out the following steps:

- Fill the reservoir of the unit two-thirds full of water as specified by the manufacturer.
- Set the desired temperature. Check the manufacturer's instructions. Most units are set at 40°C (104°F) for adults.
- Cover the pad and plug in the unit. Check for any leaks or malfunctions of the pad before use.
- Apply the pad to the body part. The treatment is usually continued for 30 minutes. Check orders and agency protocol.
- Use tape or gauze ties to hold the pad in place. Never use safety pins. They can cause leakage.
- If unusual redness or pain occurs, discontinue the treatment, and report the client's reaction.

Hot and Cold Packs

Commercially prepared hot and cold packs (Figure 36-24 ■) provide heat or cold for a designated time. Directions on the package tell how to initiate the heating or cooling process, for example, by striking, squeezing, or kneading the pack.

Figure 36–24 ■ Commercially prepared disposable hot and cold packs. Cold compress, Dynarex; Susanna Price © Dorling Kindersley.

Electric Heating Pads

Electric pads provide a constant, even heat, are lightweight, and can be molded to a body part. Electric pads, however, can burn if the setting is too high. Some models have waterproof covers for use when the pad is placed over a moist dressing.

In applying electric pads, the nurse follows these guidelines:

- Do not insert sharp objects (e.g., pins) into the pad. The pin could damage a wire and cause an electric shock.
- Ensure that the body area is dry unless there is a waterproof cover on the pad. Electricity in the presence of water can cause a shock.
- Use pads with a preset heating switch so a client cannot increase the heat.
- Do not place the pad under the client. Heat will not dissipate, and the client may be burned.

Ice Bags, Ice Gloves, and Ice Collars

Ice bags (Figure 36–25 ■), ice gloves, and ice collars are filled either with ice chips or with an alcohol-based solution. They are applied to the body to provide cold to a localized area (e.g., a collar is often applied to the throat following a tonsillectomy). Always wrap the container in a towel or cover.

Compresses

Compresses can be either warm or cold. A **compress** is a moist gauze dressing applied to a wound or injury. When hot compresses

Figure 36–25 ■ Disposable ice bag.

are ordered, the solution is heated to the temperature indicated by the order or according to agency protocol, for example, 40.5°C (105°F). When there is a break in the skin or when the body part (e.g., an eye) is vulnerable to microbial invasion, sterile technique is necessary; therefore, sterile gloves are needed to apply the compress and all materials must be sterile.

Soaks

A soak refers to immersing a body part (e.g., an arm) in a solution or to wrapping a part in gauze dressings and then saturating the dressing with a solution. Sterile technique is generally indicated for open wounds, such as a burn or an unhealed surgical incision. Determine agency protocol regarding the temperature of the solution. Hot soaks are frequently done to soften and remove encrusted secretions and dead tissue.

Sitz Baths

A **sitz bath**, or hip bath, is used to soak a client's perineal or rectal area. The client sits in a special tub or chair. Disposable sitz baths are also available for home or hospital use (Figure 36–26 ■).

The temperature of the water should be from 40°C to 43°C (104°F to 110°F), unless the client is unable to tolerate the heat. Determine agency protocol. Some sitz tubs have temperature indicators attached to the water taps. The duration of the bath is generally 20 minutes, depending on the client's health. Follow these steps to provide a sitz bath:

- Assist the client into the bath. Provide support for the client's feet; a footstool can prevent pressure on the backs of the thighs.
- Provide a bath blanket for the client's shoulders, and eliminate drafts to prevent chilling.
- Observe the client closely during the bath for signs of faintness, dizziness, weakness, accelerated pulse rate, and pallor.
- Maintain the water temperature.
- Following the sitz bath, assist the client out of the bath. Help the client to dry.

Figure 36–26 ■ A plastic single-client sitz bath.

Cooling Sponge Baths

The purpose of a cooling sponge bath is to reduce a client's fever by promoting heat loss through conduction and vaporization. Cool sponge baths are used with extreme caution, and only for clients with very high temperatures, such as over 40°C (104°F), because rapid skin temperature drop can cause chills that actually increase heat production. The bath is accompanied by antipyretic medication that acts to reset the hypothalamus set point. The temperatures for cooling sponge baths range from 27°C to 37°C (80°F to 98°F).

To provide a cooling sponge bath, the nurse should:

- Sponge the face, arms, legs, back, and buttocks. The chest and abdomen are not usually sponged. Each area is sponged slowly and gently. Rubbing may increase heat production.
- Leave each area wet and cover with a damp towel.
- Place ice bags and cold packs, if used, or a cool cloth on the forehead for comfort and in each axilla and at the groin. These areas contain large superficial blood vessels that help the transfer of heat.
- Sponge one body part and then another. The sponge bath should take about 30 minutes. A bath given more quickly tends to increase the body's heat production by causing shivering.

- Discontinue the bath if the client becomes pale or cyanotic or shivers, or if the pulse becomes rapid or irregular.
- Reassess the vital signs at 15 minutes and after completing the sponge bath.

Evaluating

The goals established during the planning phase are evaluated according to specific desired outcomes also established in that phase. To judge whether client outcomes have been achieved, the nurse uses data collected during care, such as skin status over bony prominences, nutritional and fluid intake, mental status, signs of healing if an ulcer is present, and so on. If outcomes are not achieved, the nurse should explore the reasons why:

- Has the client's physical condition changed?
- Were risk factors correctly identified?
- Were appropriate devices and techniques used?
- Was the client unable to comply with instructions about moving and turning? Why?
- Were appropriate pressure-relieving devices used, and were they applied correctly?
- Was the repositioning schedule adhered to?
- Are the client's nutritional and fluid intake adequate?
- Were appropriate measures used to control incontinence and protect the client's skin?
- Was the wound supported and immobilized effectively?
- Were stringent aseptic practices implemented when cleaning and changing dressings to prevent infection?
- Was the client receiving antineoplastic or anti-inflammatory medications that interfere with healing?
- Was nonviable tissue removed by autolytic, chemical, mechanical, or surgical debridement?
- Was the appropriate dressing applied to maintain moist wound healing?

Wound and skin care, like many other aspects of nursing, is a constantly evolving area of practice. Nurses should ensure that they are using the most current and evidence-based practices available. Excellent sources of this information are the professional organizations dedicated to skin and wound practices (Box 36–5).

BOX 36–5 Wound Care Organizations

American Professional Wound Care Association (APWCA)—www.apwca.org The APWCA is a membership organization incorporating the various medical specialties involved in treating complex wounds. The mission of APWCA is to help decrease the rate of complications from all wounds, including acute, chronic, postsurgical, postradiation, reconstructive, and other problematic wounds. The association's goal is to accelerate wound healing and preserve and/or enhance the quality of life for these clients.

Association for the Advancement of Wound Care (AAWC)—www.aawconline.org Headquartered in the United States, the AAWC is a nonprofit, international multidisciplinary organization for wound care. This organization is open to everyone involved in wound care, including clinicians, clients and their lay caregivers, facilities, industry, students, retirees, and others interested in the care of wounds. The AAWC was founded to spread wound awareness by promoting excellence in education, clinical practice, public policy, and research. *Ostomy Wound Management* and *WOUNDS* are the official journals of the AAWC.

Dermatology Nurses' Association (DNA)—www.dnanurse.org DNA is a professional nursing organization comprised of a diverse group of individuals committed to quality care through sharing knowledge and expertise. The core purpose of the DNA is to promote excellence in dermatologic care. The DNA official journal is *Dermatology Nursing*.

National Alliance of Wound Care (NAWC)—www.nawccb.org NAWC membership organization provides educational, research, and advocacy opportunities to members. The alliance is open to all wound care professionals and corporations doing business in the field of wound care.

Wound Ostomy Continence Nurses (WOCN)—www.wocn.org WOCN is an international society of more than 4,000 nurse professionals who are experts in the care of clients with wound, ostomy, and continence problems. Membership also is open to students, corporate colleagues, and all individuals who share the mission and goals of the society. The WOCN publishes the *Journal of Wound Ostomy Continence Nursing*.

Critical Thinking Checkpoint

You have been assigned to care for Mr. Johns, a 74-year-old client being treated for a urinary tract disorder. Mr. Johns suffered a cerebrovascular accident (stroke) 6 months ago and has had difficulty ambulating and attending to his own needs because of right-sided weakness. While assessing Mr. Johns you note that he is thin for his height, is incontinent of foul-smelling urine, and has deeply red-ened areas on his right hip, coccyx, and entire peritoneal area. Mr. Johns is alert and oriented to person, place, and time, but he has decreased sensation on his entire right side. He spends most of his time in bed or sitting at his bedside in a chair due to his difficulty with ambulation.

1. What data suggest that Mr. Johns is particularly vulnerable to pressure ulcer development?
2. What additional information do you need in order to use the Braden scale to determine Mr. Johns' potential for pressure ulcer development?
3. What independent measures can you take to protect Mr. Johns' skin from further breakdown?
4. Considering that Mr. Johns does not have any areas of skin breakdown, why is it important to institute treatment for pressure ulcers at this time?

See Critical Thinking Possibilities on student resource website.

Chapter 36 Review

CHAPTER HIGHLIGHTS

- Maintaining skin integrity is an important independent function of nursing.
- Wounds are described as intentional or unintentional, closed or open, and clean, clean contaminated, contaminated, or dirty (infected).
- A pressure ulcer is injury caused by force that results in damage to underlying tissues. Pressure ulcers usually occur over bony prominences.
- Two other factors that act in conjunction with pressure to produce a pressure ulcer are friction and shearing forces.
- Several factors increase the risk for the development of pressure ulcers: immobility and inactivity, inadequate nutrition, fecal and urinary incontinence, decreased mental status, diminished sensation, excessive body heat, advanced age, and certain chronic medical conditions.
- There are stages of pressure ulcers, which vary according to the degree of tissue damage.
- Several risk assessment tools are available to identify clients at risk for pressure ulcer development. They include scoring systems to evaluate a person's degree of risk.
- The types of wound healing are distinguished by the amount of tissue loss: primary intention healing and secondary intention healing.
- The wound-healing process has three phases: inflammatory, proliferative, and maturation.
- Major types of wound exudate are serous, purulent, and sanguineous. Exudate can be a combination of two or three of these types (e.g., serosanguineous). The process of pus formation is referred to as suppuration.
- The main complications of wound healing are hemorrhage, infection, dehiscence, and evisceration, each of which is identifiable by specific clinical signs and symptoms.
- Factors affecting wound healing include developmental stage, nutritional status, lifestyle, and medications.
- Meticulous skin assessment of common pressure ulcer sites by the nurse is an important ongoing assessment activity for clients at risk.
- Essential data for assessing wounds include wound appearance, size, drainage, swelling, pain, and the presence of tubes and drains.
- When a pressure ulcer is present, the nurse describes the ulcer in terms of location, size, depth, stage, color, condition of the wound bed and surrounding skin, and clinical signs of infection, if present.
- Laboratory data that may be used to assess the progress of wound healing include leukocyte count, hemoglobin, blood coagulation studies, serum protein analysis, and wound cultures. Nurses are usually responsible for obtaining specimens of wound drainage for culture.
- The NANDA International nursing diagnoses *Risk for Pressure Ulcer*, *Risk for Impaired Skin Integrity*, *Impaired Skin Integrity*, and *Impaired Tissue Integrity* apply to clients at risk for developing and to those with pressure ulcers.
- Nursing diagnoses related to clients with wounds may include *Risk for Infection and Pain*.
- Major goals for clients at risk for developing pressure ulcers are to maintain skin integrity and to avoid potential associated risks.
- Major nursing responsibilities related to wound care include assisting the client in maintaining moist wound healing, obtaining sufficient nutrition and fluids, preventing wound infections, and proper positioning.
- Nursing interventions to prevent the formation of pressure ulcers include conducting ongoing assessment of risk factors and skin status, providing skin care to maintain skin integrity, ensuring adequate nutrition and hydration, implementing measures to avoid skin trauma, providing supportive devices, and client teaching.
- Treatment for pressure ulcers varies according to the stage of the ulcer and agency protocol.
- The RYB color code of wounds can assist nurses to provide appropriate nursing interventions for wounds that heal by secondary intention. In this scheme, the nurse protects red, cleanses yellow, and debrides black wounds.
- Wound care may involve cleaning/irrigating, protecting, hydrating, and covering wounds; applying heat and cold; and applying bandages and binders.
- Various types of dressing materials are available to protect wounds, absorb exudate, and keep the wound bed moist, thus facilitating healing.

- The type of dressing used depends on (a) location, size, and type of the wound; (b) amount of exudate; (c) whether or not the wound requires debridement, is infected, or has sinus tracts; and (d) such considerations as frequency of dressing change, ease or difficulty of dressing applications, and cost.
- Synthetic dressings have been developed for use with specific types of wounds. These include transparent adhesive films, impregnated nonadherent dressings, hydrocolloids, hydrogels, polyurethane foams, clear acrylic dressings, and alginates. The nurse must be aware of the specific purposes of each and their indications for use.
- Bandages and binders are used to hold dressings in place, apply pressure to wounds, support circulation, and immobilize joints.
- Heat and cold produce specific local physiological and systemic responses that account for their therapeutic effects.
- Various parts of the body differ in tolerance to heat and cold. The physiological tolerance of individuals also varies. Specific conditions such as neurosensory and circulatory impairments necessitate precautions when applying heat or cold.
- When applying heat or cold, clients and nurses need to be aware of the effects of thermal receptor adaptation and the rebound phenomenon.

TEST YOUR KNOWLEDGE

- Your client has a Braden scale score of 17. Which is the appropriate nursing action?
 - Assess the client again in 24 hours; the score is within normal limits.
 - Implement a turning schedule; the client is at increased risk of skin breakdown.
 - Apply a transparent wound barrier to major pressure sites; the client is at moderate risk of skin breakdown.
 - Request an order for a special low-air-loss bed; the client is at very high risk of skin breakdown.
- Proper technique for performing a wound culture includes which of the following?
 - Cleansing the wound prior to obtaining the specimen
 - Swabbing for the specimen in the area with the largest collection of drainage
 - Removing crusts or scabs with sterile forceps and then culturing the site beneath
 - Waiting 8 hours following a dose of antibiotic to obtain the specimen
- A client has a pressure ulcer with a shallow, partial skin thickness, eroded area but no necrotic areas. The nurse would treat the area with which dressing?
 - Alginate
 - Dry gauze
 - Hydrocolloid
 - No dressing is indicated
- Thirty (30) minutes after application is initiated, the client requests that the nurse leave the heating pad in place. The nurse explains the following to the client:
 - Heat application for longer than 30 minutes can actually cause the opposite effect (constriction) of the desired one (dilation).
 - It will be acceptable to leave the pad in place if the temperature is reduced.
 - It will be acceptable to leave the pad in place for another 30 minutes if the site appears satisfactory when assessed.
 - It will be acceptable to leave the pad in place as long as it is moist heat.
- Which statement, if made by the client or family member, would indicate the need for further teaching?
 - "If a skin area gets red but then the red goes away after turning, I should report it to the nurse."
 - "Putting foam pads under my heels or other bony areas can help decrease pressure."
 - "If my father cannot turn himself in bed, I should help him change position every 4 hours."
 - "The skin should be washed with only warm water (not hot) and lotion put on while it is still a little wet."
- Your client is only comfortable lying on the right or left side (not on the back or stomach). List four potential sites of pressure ulcers you must assess.
 -
 -
 -
 -
- An appropriate nursing diagnosis for a client with large areas of skin excoriation resulting from scratching an allergic rash is
 - Risk for Impaired Skin Integrity.*
 - Impaired Skin Integrity.*
 - Impaired Tissue Integrity.*
 - Risk for Infection.*
- Which of the following are primary risk factors for pressure ulcers? Select all that apply.
 - Low-protein diet
 - Insomnia
 - Lengthy surgical procedures
 - Fever
 - Sleeping on a waterbed
- Which of the following items are used to perform wound irrigation? Select all that apply.
 - Clean gloves
 - Sterile gloves
 - Refrigerated irrigating solution
 - 60-mL syringe
 - Forceps
- Which of the following indicates proper use of a triangle arm sling?
 - The elbow is kept flexed at 90° or more.
 - The knot is placed on either side of the vertebrae of the neck.
 - The sling extends to just proximal of the hand.
 - The sling is removed every 2 hours to check for circulation and skin integrity.

Advances in wound dressing technology have resulted in numerous dressing choices. The establishment of a moist wound environment under modern wound dressings and creating the optimal healing response are the goals of these dressings. However, wound dressings, particularly traditional dressings such as gauze, frequently result in tissue damage that impairs the wound healing response. This review demonstrates the ways traditional, as well as modern, wound dressings may disturb wounds and suggests how best to address this aspect of the wound dressings to treat acute as well as chronic wounds.

37 Perioperative Nursing

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Discuss various types of surgery according to the purpose, degree of urgency, and degree of risk.
2. Describe the phases of the perioperative period.
3. Identify essential aspects of preoperative assessment.
4. Give examples of pertinent nursing diagnoses for surgical clients.
5. Identify nursing responsibilities in planning perioperative nursing care.
6. Describe essential preoperative teaching, including pain assessment and management, moving, leg exercises, and deep-breathing and coughing exercises.
7. Describe essential aspects of preparing a client for surgery.
8. Compare various types of anesthesia.
9. Identify essential nursing assessments and interventions during the immediate postanesthetic phase.
10. Demonstrate ongoing nursing assessments and interventions for the postoperative client.
11. Identify potential postoperative complications and describe nursing interventions to prevent them.
12. Verbalize the steps used in:
 - a. Teaching moving, leg exercises, deep breathing, and coughing.
 - b. Applying antiemboli stockings.
 - c. Managing gastrointestinal suction.
 - d. Cleaning a sutured wound and changing a dressing on a wound with a drain.
 - e. Removing sutures and staples.
13. Evaluate the effectiveness of perioperative nursing interventions.
14. Recognize when it is appropriate to delegate perioperative skills to unlicensed assistive personnel.
15. Demonstrate appropriate documentation and reporting of perioperative skills.

INTRODUCTION

Surgery is a unique experience of a planned physical alteration encompassing three phases: preoperative, intraoperative, and postoperative. These three phases are together referred to as the **perioperative period**. Perioperative nursing is the delivery of nursing care through the framework of the nursing process. It also includes collaborating with members of the health care team, making nursing referrals, and delegating and supervising nursing care.

The **preoperative phase** begins when the decision to have surgery is made; it ends when the client is transferred to the operating table. The nursing activities associated with this phase include assessing the client, identifying potential or actual health problems, planning specific care based on the individual's needs, and providing preoperative teaching for the client, the family, and significant others.

The **intraoperative phase** begins when the client is transferred to the operating table and ends when the client is admitted to the postanesthesia care unit (PACU), also called the postanesthetic room or recovery room (RR). The nursing activities related to this

phase include a variety of specialized procedures designed to create and maintain a safe therapeutic environment for the client and the health care personnel. These activities include interventions that provide for the client's safety, maintaining an aseptic environment, ensuring proper functioning of equipment, and providing the surgical team with the instruments and supplies needed during the procedure.

The **postoperative phase** begins with the admission of the client to the postanesthesia area and ends when healing is complete. During the postoperative phase, nursing activities include assessing the client's response (physiological and psychological) to surgery, performing interventions to facilitate healing and prevent complications, teaching and providing support to the client and support people, and planning for home care. The goal is to assist the client to achieve the most optimal health status possible.

Perioperative nursing is practiced in hospital-based inpatient and outpatient surgical/laser/endoscopy suites, physician office-based surgical suites (outpatient), and/or freestanding outpatient/ambulatory surgical centers. Outpatient procedures do not require

an overnight hospital stay. The client goes to the outpatient site the day of surgery, has the procedure, and leaves the same day.

The perioperative nurse's role is underscored by the nursing process and all the care activities inherent in that process regardless of the health care setting in which it is operationalized.

TYPES OF SURGERY

Surgical procedures are commonly grouped according to (a) purpose, (b) degree of urgency, and (c) degree of risk.

Purpose

Surgical procedures may be categorized according to their purpose (Box 37-1).

Degree of Urgency

Surgery is classified by its urgency and necessity to preserve the client's life, body part, or body function. **Emergency surgery** is performed immediately to preserve function or the life of the client. Surgeries to control internal hemorrhage or repair a fracture are examples of emergency surgeries. **Elective surgery** is performed when surgical intervention is the preferred treatment for a condition that is not imminently life threatening (but may ultimately threaten life or well-being), or to improve the client's life. Examples of elective surgeries include cholecystectomy for chronic gallbladder disease, hip replacement surgery, and plastic surgery procedures such as breast reduction.

Degree of Risk

Surgery is also classified as major or minor according to the degree of risk to the client. **Major surgery** involves a high degree of risk, for a variety of reasons: It may be complicated or prolonged, large losses of blood may occur, vital organs may be involved, or postoperative complications may be likely. Examples are organ transplant, open heart surgery, and removal of a kidney. In contrast, **minor surgery** normally involves little risk, produces few complications, and is often performed in an outpatient setting. Examples are breast biopsy, removal of tonsils, and cataract extraction.

The degree of risk involved in a surgical procedure is affected by the client's age, general health, nutritional status, presence of sleep apnea, use of medications, and mental status.

AGE

Neonates/infants and older clients are greater surgical risks than children and adults. Age and developmental status affect a child's ability

to cope with the physiological and psychological stresses of surgery. Neonates and infants have a higher metabolic rate and a different physiological makeup than adults. These differences cause a substantially different response to a surgical procedure. For example, the blood volume in an infant is small, and fluid reserves are limited. This increases the risk of volume depletion during surgery, resulting in inadequate oxygenation of body tissues. Because of the infant's relatively large body surface area and immature temperature regulatory mechanisms, the risk of hypothermia during surgery is significant. Other organ systems, such as the kidneys, liver, and immune system, also have not achieved maturity in infants, affecting their ability to metabolize and eliminate drugs and resist infection.

Toddlers and older children are better able to withstand surgery physiologically, but they often fear separation from their parents, strangers, bodily injury/mutilation, and death. The child's developmental level and age-appropriate communication are important in implementing the pediatric plan of care. The parent-child relationship, the parents' coping abilities, and the preoperative teaching and support will affect how well the child is able to deal with these surgical fears and the level of anxiety experienced.

The older adult (65 years and older) often has fewer physiological reserves to meet the extra demands caused by surgery. The physiological deficits of aging increase the surgical risk for the older adult. For example, because of a lower percentage of body water, decreased kidney function, and a decreased thirst response, older clients are at greater risk for fluid and electrolyte imbalances. Many older clients demonstrate changes in liver and kidney function, both of which can affect response to anesthesia and other medications that may be administered during the perioperative period. The older client may be poorly nourished, which can impair healing. Declines in sensory function (hearing in particular) or the presence of dementia make it more difficult to understand directions and teaching. In addition, the older client is more likely to have a chronic disease, such as cardiovascular disease, chronic lung disease, or diabetes, that affects healing and responses to medication and surgery.

GENERAL HEALTH

Surgery is least risky when the client's general health is good. Any infection or pathophysiology increases the risk. It is important for the nurse to assess the client for an upper respiratory tract infection, which together with a general anesthetic can adversely affect respiratory function. When a client is at high risk for infection, antibiotics may be administered parenterally within 1 hour of surgery and continued for 24 to 72 hours after surgery. This practice allows time for drugs to reach therapeutic levels in the tissues but does not permit bacterial resistance to develop. Common health problems that increase surgical risk and may lead to the decision to postpone or cancel surgery are listed in Box 37-2.

NUTRITIONAL STATUS

Adequate nutrition is required for normal tissue repair. Surgery increases the body's need for nutrients that help with the tissue healing and prevention of infection required during the postoperative period. Obesity and malnutrition increase surgical risk.

Obesity contributes to postoperative complications such as pneumonia, wound infections, and wound separation. Both clients with obesity and those who are underweight are vulnerable to pressure ulcer formation due to the positioning required for surgery.

BOX 37-1 Purposes of Surgical Procedures

Diagnostic	Confirms or establishes a diagnosis; for example, biopsy of a mass in a breast.
Palliative	Relieves or reduces pain or symptoms of a disease; it does not cure; for example, resection of nerve roots.
Ablative	Removes a diseased body part; for example, removal of a gallbladder (cholecystectomy).
Constructive	Restores function or appearance that has been lost or reduced; for example, cleft palate repair.
Transplant	Replaces malfunctioning structures; for example, kidney transplant.

BOX 37-2 Health Problems That Increase Surgical Risk

- Malnutrition can lead to delayed wound healing, infection, and reduced energy. Protein and vitamins are needed for wound healing; vitamin K is essential for blood clotting.
- Obesity leads to hypertension, impaired cardiac function, and impaired respiratory ventilation. Clients with obesity are also more likely to have delayed wound healing and wound infection because adipose tissue impedes blood circulation and its delivery of nutrients, antibodies, and enzymes required for wound healing.
- Cardiac conditions such as angina pectoris, recent myocardial infarction, hypertension, and heart failure weaken the heart. Well-controlled cardiac problems generally pose minimal operative risk.
- Blood coagulation disorders may lead to severe bleeding, hemorrhage, and subsequent shock.
- Upper respiratory tract infections or chronic obstructive pulmonary disease (COPD) adversely affect pulmonary function, especially when exacerbated by the effects of general anesthesia. They also predispose the client to postoperative lung infections.
- Renal disease impairs regulation of the body's fluids and electrolytes and excretion of drugs and other toxins.
- Diabetes mellitus predisposes the client to wound infection and delayed healing.
- Liver disease (e.g., cirrhosis) impairs the liver's abilities to detoxify medications used during surgery, produce the prothrombin necessary for blood clotting, and metabolize nutrients essential for healing.
- Uncontrolled neurologic disease such as epilepsy may result in seizures during surgery or recovery.

The perioperative nurse provides padding and other measures to protect the client's skin over pressure points during surgery.

Many vitamins and minerals are essential in wound healing (Table 37-1). A malnourished client is at risk for delayed wound healing, wound infection, and fluid and electrolyte alterations. If a client has serious malnutrition, the surgery may be postponed to improve the nutritional status. If the surgery cannot be delayed, parenteral or enteral nutrition may be initiated.

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) is a common condition caused by partial or complete obstruction of the upper airway during sleep. Breathing is briefly interrupted during sleep with periods of apnea lasting at least 10 seconds. Recent studies have shown that clients

with OSA who undergo surgery appear to be at increased risk for pulmonary complications (Memtsoudis, Besculides, & Mazumdar, 2013). Of concern is that 80% to 90% of U.S. adults who have OSA are unaware that they have it, which puts these clients at risk at the time of surgery and makes client safety a priority (Lakdawala, 2011; Memtsoudis et al., 2013). The Joint Commission recommends using a sleep apnea screening tool for the perioperative area (Lakdawala, 2011). A number of screening tools have been developed such as the STOP questionnaire, which asks four questions related to Snoring, Tiredness during the daytime, Observed apnea, and high blood Pressure (STOP). The use of a preoperative OSA screening tool increases the awareness of the health care team to closely monitor the previously undiagnosed surgical client who may be at high risk for OSA.

MEDICATIONS

The regular use of certain medications can increase surgical risk. Consider these examples:

- *Anticoagulants* increase blood coagulation time.
- *Tranquilizers* may interact with anesthetics, increasing the risk of respiratory depression.
- *Corticosteroids* may interfere with wound healing and increase the risk of infection.
- *Diuretics* may affect fluid and electrolyte balance.

Clients may be unaware of the potential adverse interactions of medications and may fail to report the use of medications for conditions unrelated to the indication for surgery. The astute nurse interviewer should question the client and family about the use of commonly prescribed medications, over-the-counter (OTC) preparations, and any herbal remedies for specific conditions mentioned during the nursing history.

MENTAL STATUS

Disorders that affect cognitive function, such as mental illness, mental retardation, or developmental delay, affect the client's ability to understand and cope with the stresses of surgery. These clients also may require medication such as anticonvulsants or antipsychotic drugs that can interact with anesthetic and analgesic medications used during and after surgery.

Clients with dementia may have difficulty understanding proposed surgical procedures and may respond unpredictably to anesthetics. Manifestations of dementia such as confusion, disorientation, and agitation also may be aggravated by the change of environment in the hospital, interfering with the client's ability to cooperate with pre- and postoperative care.

Extreme anxiety also increases surgical risk and interferes with the client's ability to process information and respond appropriately to instructions. In some instances, professional counseling is indicated prior to surgery. It is also important to determine whether clients have coping skills and support systems to help them.

PREOPERATIVE PHASE

Preoperative Consent

Prior to any surgical procedure, informed consent is required from the client or legal guardian. Informed consent implies that the client has been informed and involved in decisions affecting his or her health. The surgeon is responsible for obtaining the informed

TABLE 37-1 Vitamins and Minerals Essential to Wound Healing

Vitamin or Mineral	Function
Vitamin A	Promotes epithelialization and enhances collagen synthesis
Vitamin B complex	Cofactor of the enzyme system
Vitamin C (ascorbic acid)	Essential for collagen synthesis affecting wound tensile strength
Vitamin K	Essential in the synthesis of prothrombin and thus coagulation
Iron, zinc, and copper	Involved in collagen synthesis

consent by providing the following information to the client or legal guardian:

- The nature of and the reason for the surgery
- All available options and the risks associated with each option
- The risks of the surgical procedure and its potential outcomes
- Name and qualifications of the surgeon performing the procedure
- The right to refuse consent or later withdraw consent.

The surgeon documents the informed consent conversation with the client or legal guardian in the preoperative progress note.

The surgical consent form, provided by the health care facility where the surgery will be performed, protects the client from incorrect/unwanted procedures and the surgeon and facility from litigation related to unauthorized surgeries or uninformed clients. This consent form becomes part of the client's medical record and goes to the operating room with the client.

Although the surgeon maintains legal responsibility for ensuring that the client has given informed consent, the nurse may witness the client's signature on the consent form. In doing so, the nurse ensures that the consent form is signed and serves as a witness to the signature, not to the fact that the client is informed. If the nurse assesses that the client does not understand the procedure to be performed, the surgeon is contacted and requested to speak with the client before surgery can proceed.

Informed consent is only possible when the client understands the provided information, that is, speaks the language and is conscious, mentally competent, and not sedated. Informed consent may not be given by a minor. Specific guidelines regarding consent for minors vary among the states. Nurses must be aware of their responsibilities regarding consent and of the particular hospital's policies (see Chapter 4 ∞).

●○● NURSING MANAGEMENT

Assessing

Preoperative assessment includes collecting and reviewing physical, psychological, and social client data to determine the client's needs throughout the three perioperative phases. The client's mobility and ability to function should also be assessed in the preoperative phase. The perioperative nurse collects the data by interviewing the client in the presurgical care unit or by telephone prior to the day of surgery. When data cannot be collected directly, the perioperative nurse uses other data sources such as the nursing admission assessment. Although forms vary considerably among agencies, Box 37–3 summarizes essential preoperative information that should be included.

Physical Assessment

Preoperatively, the nurse performs a brief but complete physical assessment, paying particular attention to systems that could affect the client's response to anesthesia or surgery. A brief or "mini" mental status examination provides valuable baseline data for evaluating the client's mental status and alertness after surgery. It is also important to evaluate the client's ability to understand what is happening. For example, assessment of hearing and vision help guide perioperative teaching. Respiratory and cardiovascular assessments not only provide baseline data for evaluating the client's postoperative status but also may alert care providers to a problem (e.g., a respiratory infection or irregular pulse rate) that may affect the client's response to surgery and anesthesia. Other systems (gastrointestinal, genitourinary, and musculoskeletal) are examined to provide baseline data (see Chapter 30 ∞).

BOX 37–3 Preoperative Assessment Data

- **Current health status.** Essential information includes general health status and the presence of any chronic diseases, such as diabetes or asthma, that may affect the client's response to surgery or anesthesia. Note any physical limitations that may affect the client's mobility or ability to communicate after surgery, as well as any prostheses such as hearing aids or contact lenses.
- **Allergies.** Include allergies to prescription and nonprescription drugs, food allergies, and allergies to tape, latex, soaps, or antiseptic agents. Some food allergies may indicate a potential reaction to drugs or substances used during surgery or diagnostic procedures; for example, an allergy to seafood alerts the nurse to a potential allergy to iodine-based dyes or soaps commonly used in hospitals.
- **Medications.** List all current medications (prescribed and OTC). It may be vital to maintain a blood level of some medications (e.g., anticonvulsants) throughout the surgical experience; others, such as anticoagulants or aspirin, increase the risks of surgery and anesthesia and need to be discontinued several days prior to surgery. It is important to include in the list any OTC drugs and herbal remedies the client currently takes.
- **Previous surgeries.** Previous surgical experiences may influence the client's physical and psychological responses to surgery or may reveal unexpected responses to anesthesia.
- **Mental status.** The client's mental status and ability to understand and respond appropriately can affect the entire perioperative experience. Note any developmental disabilities, mental illness, history of dementia, or excessive anxiety related to the procedure.
- **Understanding of the surgical procedure and anesthesia.** The client should have a good understanding of the planned procedure and what to expect during and after surgery as well as the expected outcome of the procedure.
- **Smoking.** Smokers may have more difficulty clearing respiratory secretions after surgery, increasing the risk of postoperative complications such as pneumonia and atelectasis and delayed wound healing.
- **Obstructive sleep apnea (OSA).** The majority of adults do not know that they have OSA, which puts them at risk for postoperative pulmonary complications. Furthermore, when asked if they have sleep apnea, clients often state that they do not have a sleeping problem. Lakdawala (2011) points out that because many clients do not fully understand OSA, The Joint Commission recommends using a sleep apnea screening tool for the perioperative area (p. 16).
- **Alcohol and other mind-altering substances.** Use of substances that affect the central nervous system, liver, or other body systems can affect the client's response to anesthesia and surgery, and postoperative recovery.
- **Coping.** Clients with a healthy self-concept who have successfully employed appropriate coping mechanisms in the past are better able to deal with the stressors associated with surgery.
- **Social resources.** Determine the availability of family or other caregivers as well as the client's social support network. These resources are important to the client's recovery, particularly for the client undergoing same-day or short-stay surgery.
- **Cultural and spiritual considerations.** Culture and spirituality influence the client's response to surgery; respecting cultural and spiritual beliefs and practices can reduce preoperative anxiety and improve recovery.

TABLE 37-2 Routine Preoperative Screening Tests

Test	Rationale
Complete blood count (CBC)	RBCs, hemoglobin (Hgb), and hematocrit (Hct) are important to the oxygen-carrying capacity of the blood; WBCs are an indicator of immune function
Blood grouping and crossmatching	Determined in case blood transfusion is required during or after surgery
Serum electrolytes (Na ⁺ , K ⁺ , Ca ²⁺ , Mg ²⁺ , Cl ⁻ , HCO ₃ ⁻)	To evaluate fluid and electrolyte status
Fasting blood glucose	High levels may indicate undiagnosed diabetes mellitus
Blood urea nitrogen (BUN) and creatinine	To evaluate renal function
ALT, AST, LDH, and bilirubin	To evaluate liver function
Serum albumin and total protein	To evaluate nutritional status
Urinalysis	To determine urine composition and possible abnormal components (e.g., protein or glucose) or infection
Chest x-ray	To evaluate respiratory status and heart size
Electrocardiogram (ECG) (all clients over 40 years of age and/or clients with preexisting cardiac conditions)	To identify preexisting cardiac problems or disease
Pregnancy test (all female clients of childbearing age)	To identify if the client is pregnant

Screening Tests

The surgeon and/or anesthesiologist orders preoperative diagnostic tests. Abnormalities may warrant treatment prior to surgery. The nurse's responsibility is to check the orders carefully, to see that they are carried out, and to ensure that the results are obtained and in the client's record prior to surgery. Table 37-2 lists routine preoperative screening tests. In addition to these routine tests, diagnostic tests directly related to the client's disease are usually appropriate (e.g., gastroscopy to clarify the pathologic condition before gastric surgery).

Diagnosing

NANDA International (Herdman & Kamitsuru, 2014) nursing diagnoses that may be appropriate for the preoperative client include the following:

- *Deficient Knowledge* related to
 - A lack of education about the perioperative process
 - A lack of exposure to the specific perioperative experience.
- *Anxiety* related to
 - Effects of surgery on ability to function in usual roles
 - Outcome of exploratory surgery for malignancy
 - Risk of death
 - Loss of control during anesthesia or waking up during anesthesia
 - Perceived inadequate postoperative analgesia
 - Change in health status and/or body image.
- *Grieving* related to
 - Perceived loss of body part associated with planned surgery.
- *Ineffective Coping* related to
 - Lack of clear outcomes of surgery
 - Unresolved past negative experience with surgery.

Planning

The overall goal in the preoperative period is to ensure that the client is mentally and physically prepared for surgery. Examples of nursing activities to meet this goal are discussed in the *Implementing* section that follows.

Planning should involve the client, the family, and/or significant others. The perioperative nurse usually does preoperative care planning and teaching interventions on an outpatient basis either in person or via a telephone interview.

Planning for Home Care

For the perioperative client, discharge planning begins before admission for the planned procedure. Early planning to meet the discharge needs of the client is particularly important for outpatient procedures, because these clients are generally discharged within hours after the procedure is performed.

Discharge planning incorporates an assessment of the client's, family's, and significant others' abilities and resources for care, their financial resources, and the need for referrals and home health services. However, the extent of discharge planning and home care will vary significantly for clients having different types of surgery.

Implementing

The major nursing activity to ensure that the client is prepared for surgery is preoperative teaching.

Preoperative Teaching

Preoperative teaching is a vital part of nursing care. Studies have shown that preoperative teaching reduces clients' anxiety and postoperative complications and increases their satisfaction with the surgical experience. Effective preoperative teaching also facilitates the client's successful and early return to work and other activities of daily living (ADLs). Four dimensions of preoperative teaching have been identified as important to clients:

- **Information, including what will happen to the client, when, and what the client will experience, such as expected sensations and discomfort.** The nurse needs to listen carefully and attentively to the client to identify specific concerns and fears. Pain assessment and management are important to explain to the client because there will be discomfort after the procedure. Explain that the surgeon will order pain medication. Describe the 0-to-10 pain scale and how this is used to assess the client's level of pain. Stress the importance of working together to manage the pain because clients are able to move around easier and ambulate quicker when their pain is controlled. See Chapter 46 ∞ for more information about pain management.
- **Psychosocial support to reduce anxiety.** The nurse provides support by actively listening and providing accurate information. It is important to correct any misunderstandings the client may have.

- **The roles of the client and support people in preoperative preparation, the surgical procedure, and during the postoperative phase.** Understanding his or her role during the perioperative experience increases the client's sense of control and reduces anxiety. This includes what will be expected of the client, desired behaviors, self-care activities, and what the client can do to facilitate recovery.
- **Skills training.** This includes moving, deep breathing, coughing, splinting incisions with the hands or a pillow, and using an incentive spirometer.

If the client is scheduled for outpatient surgery, preoperative teaching is often provided before the day of surgery using some combination of videos and verbal and written instructions. The client may have an appointment with the outpatient perioperative nurse (usually scheduled to coincide with preoperative diagnostic testing) to discuss preoperative concerns and implement the teaching plan. Written instructions are always provided to reinforce verbal teaching. Teaching is further reinforced on admission the day of surgery and before discharge from the postanesthesia unit. Preoperative instructions are summarized in Box 37–4.

BOX 37–4 Preoperative Instructions

PREOPERATIVE REGIMEN

- Explain the need for preoperative tests (e.g., laboratory, x-ray, ECG).
- Discuss bowel preparation, if required.
- Discuss skin preparation, including operative area and preoperative bath or shower.
- Discuss preoperative medications, if ordered.
- Explain individual therapies ordered by the primary care provider, such as intravenous therapy, the insertion of a urinary catheter or nasogastric tube, use of a spirometer, or antiemboli stockings.
- Discuss the visit by the anesthetist.
- Explain the need to restrict food and oral fluids before surgery.
- Provide a general timetable for perioperative events, including the time of surgery.
- Discuss the need to remove jewelry, makeup, and all prostheses (e.g., eyeglasses, hearing aids, complete or partial dentures, wig) immediately before surgery.
- Inform client about the preoperative holding area, and give the location of the waiting room for support people.
- Teach ways to turn and move, leg exercises, deep-breathing and coughing exercises (see Skill 37-1), and splinting techniques.
- Complete the preoperative checklist.

POSTOPERATIVE REGIMEN

- Discuss the PACU's routines and emergency equipment.
- Review type and frequency of assessment activities.
- Discuss pain management.

- Explain usual activity restrictions and precautions related to getting up for the first time postoperatively.
- Describe usual dietary alterations.
- Discuss postoperative dressings and drains.
- Provide an explanation and tour of the intensive care unit if client is to be transferred there postoperatively.

OUTPATIENT SURGICAL CLIENTS

- Review all instructions in the preoperative and postoperative regimen.
 - Confirm place and time of surgery, including when to arrive (e.g., 1 to 1 1/2 hours before scheduled surgery) and where to register (e.g., reception desk).
- Discuss what to wear (e.g., clients having hand surgery should wear a garment with large sleeve openings to fit over a bulky dressing; all clients need to leave valuables at home).
- Explain the need for a responsible adult to drive or accompany the client home.
 - Discuss discharge criteria and how long the client should expect to stay postoperatively.
- Discuss medications, including specific preoperative medications and the client's current medication regimen.
- Communicate by telephone the evening before surgery to confirm time of surgery and arrival time.
- Communicate by telephone within 48 hours postoperatively to evaluate surgical outcomes and identify any problems or complications.

Evidence-Based Practice When Should Clients Receive Preoperative Education, How Should It Be Delivered, and What Content Should Be Included?

EVIDENCE-BASED PRACTICE

Hartley, Neubrandner, and Repede (2012) wanted answers to the question above specifically for postsurgical spinal surgery clients. They believe that there are key differences in the educational material that should be provided to clients requiring spinal surgery because of the clients' differing types of pain, unique characteristics that contribute to physical abilities, and restrictions postoperatively. They found that the literature shows that accurate preoperative information about postoperative expectations results in increased postoperative satisfaction. They used Barrett's Power as Knowing Participation in Change Theory as the theoretical framework for why preoperative education is important. "Involvement, freedom, awareness, and choices are all a part of the preoperative teaching process" (p. 67). The authors performed a literature review of several databases. They found limited research on postoperative education in spine-specific surgery. Thus, they focused on education and pain management in elective surgeries, mainly focusing on orthopedic surgeries. This resulted in the selection of 37 articles. The results revealed the following: mixed results in whether timing of education should be 1 to 2 weeks prior to surgery compared to the day before surgery; mixed

results between some clients preferring the education performed in a group setting with friends and family versus a one-on-one session; the importance of assessing clients' coping styles and amount of information that clients desire before teaching; that verbal information should be reinforced with written or other forms of media; and that the client should have the opportunity to ask questions. The literature found that important teaching content included pain management, complications, and bowel care.

IMPLICATIONS

Because of the limited number of studies, the authors concluded that there needs to be more specific research on the learning needs of the spinal surgery client. Whereas there are many similarities in the needs of different orthopedic clients, there are also specific differences such as amount and type of pain, use of an external brace, risk of postoperative ileus, limitations after surgery, and possible surgery complications. One of their points, however, relates to all surgical clients: All education should be structured to include essential content specific to the needs of the client.

When the client is a child, addressing the fears and anxieties of both the child and the family is vital. Parents need to know what to expect and to be able to express their concerns. Parents should be considered members of the perioperative

team and allowed to participate in providing as much care as possible.

Skill 37-1 provides guidelines for teaching clients about moving, leg exercises, deep breathing, and coughing.

Teaching Moving, Leg Exercises, Deep Breathing, and Coughing

PURPOSES

Moving

- To promote venous return
- To enhance lung expansion and mobilize secretions
- To stimulate gastrointestinal motility
- To facilitate early ambulation

Leg Exercises

- To promote venous return, thereby preventing thrombophlebitis and thrombus formation

ASSESSMENT

Assess

- Vital signs
- Discomfort
- Temperature and color of feet and legs
- Breath sounds
- Presence of dyspnea or cough

Deep Breathing and Coughing

- To enhance lung expansion and mobilize secretions, thereby preventing **atelectasis** (collapse of the alveoli) and pneumonia

- Learning needs of the client
- Anxiety level of the client
- Client experience with previous surgeries and anesthesia
- Incidence of postoperative nausea, vomiting, or other reaction to previous anesthesia

PLANNING

Before beginning to teach moving, leg exercises, deep-breathing exercises, and coughing, determine (a) the type of surgery, (b) the time of the surgery, (c) the name of the surgeon, (d) the preoperative orders, and (e) the agency's practices for preoperative care. Also, verify that the primary care provider has completed the medical history and physical examination and that the client or the family has signed the consent form.

DELEGATION

Assessment of the learning needs of the client and his or her support people and determining the teaching content and appropriate strategies for teaching requires application of professional knowledge and critical thinking. Preoperative teaching is conducted by the nurse and is not delegated to unlicensed assistive personnel (UAP). The UAP, however, can reinforce teaching, assist the client with the exercises, and report to the nurse if the client is unable to perform the exercises.

INTERPROFESSIONAL PRACTICE

Teaching moving, leg exercises, deep breathing, and coughing may be within the scope of practice for other health care providers. For example, in addition to nurses, both respiratory therapists and physical therapists may teach this information to the client. Although the therapists may verbally communicate their findings and plan to the health care team members, the nurse must also know where to locate their documentation in the client's medical record.

Equipment

- Pillow
- Teaching materials (e.g., audiovisual, written materials) if available at the agency

IMPLEMENTATION

Preparation

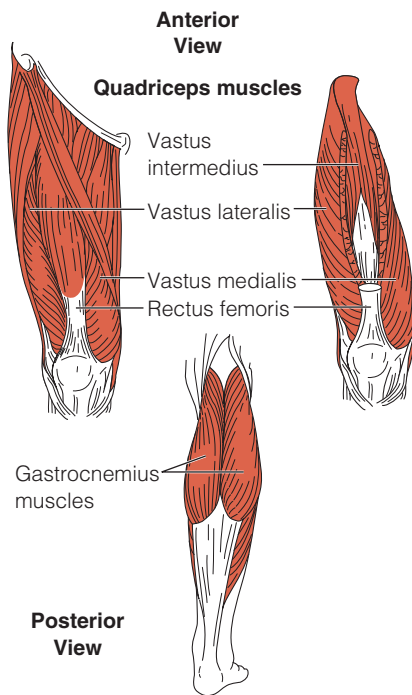

Ensure that potential distracters (e.g., pain, TV, visitors) to teaching are not present. Family and/or significant others should be included in the teaching plan, if appropriate.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to teach and the importance of the client's participation in the exercises he or she is going to be taught.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Show the client ways to turn in bed and to get out of bed.
 - Instruct a client who will have a right abdominal incision or a right-sided chest incision to turn to the left side of the bed and sit up as follows:
 - a. Flex the knees.
 - b. Splint the wound by holding the left arm and hand or a small pillow against the incision.
 - c. Turn to the left while pushing with the right foot and grasping a partial side rail on the left side of the bed with the right hand.
 - d. Come to a sitting position on the side of the bed by using the right arm and hand to push down against the mattress and swinging the feet over the edge of the bed.
 - e. Teach a client with a left abdominal or left-sided chest incision to perform the same procedure but splint with the right arm and turn to the right.
 - For clients with orthopedic surgery (e.g., hip surgery), use special aids, such as a trapeze, to assist with movement.
5. Teach the client the following three leg exercises:
 - Alternate dorsiflexion and plantar flexion of the feet.

Rationale: *This exercise is sometimes referred to as calf pumping, because it alternately contracts and relaxes the calf muscles, including the gastrocnemius muscles.* 1

Teaching Moving, Leg Exercises, Deep Breathing, and Coughing—continued

1 Leg muscles: anterior and posterior views.

- Flex and extend the knees, and press the backs of the knees into the bed while dorsiflexing the feet. 2 Instruct clients who cannot raise their legs to do isometric exercises that contract and relax the muscles.
 - Raise and lower the legs alternately from the surface of the bed. Flex the knee of the stable leg and extend the knee of the moving leg. 3 **Rationale:** *This exercise contracts and relaxes the quadriceps muscles.*
6. Demonstrate deep-breathing (diaphragmatic) exercises as follows:
 - Place your hands palms down on the border of your rib cage, and inhale slowly and evenly through the nose until the greatest chest expansion is achieved. 4
 - Hold your breath for 2 to 3 seconds.
 - Then exhale slowly through the mouth.
 - Continue exhalation until maximum chest contraction has been achieved.
 7. Help the client perform deep-breathing exercises.
 - Ask the client to assume a sitting position.
 - Place the palms of your hands on the border of the client's rib cage to assess respiratory depth.
 - Ask the client to perform deep breathing, as described in step 6.
 8. Instruct the client to cough voluntarily after five deep inhalations.
 - Ask the client to inhale deeply, hold the breath for a few seconds, and then cough once or twice.
 - Ensure that the client coughs deeply and does not just clear the throat.
 9. If the incision will be painful when the client coughs, demonstrate techniques to splint the abdomen.
 - Show the client how to support the incision by placing the palms of the hands on either side of the incision site or directly over the incision site, holding the palm of one hand over the other. **Rationale:** *Coughing uses the abdominal*

2 Flexing and extending the knees.

3 Raising and lowering the legs.

4 Demonstrating deep breathing.

and other accessory respiratory muscles. Splinting the incision may reduce pain while coughing if the incision is near any of these muscles.

- Show the client how to splint the abdomen with clasped hands and a pillow firmly held against the client's abdomen. 5

Teaching Moving, Leg Exercises, Deep Breathing, and Coughing—continued

10. Inform the client about the expected frequency of these exercises.
 - Instruct the client to start the exercises as soon after surgery as possible.
 - Encourage clients to carry out deep breathing and coughing at least every 2 hours, taking a minimum of five breaths at each session. Note, however, that the number of breaths and frequency of deep breathing vary with the client's condition. People who are susceptible to pulmonary problems may need deep-breathing exercises every hour. People with chronic respiratory disease may need special breathing exercises (e.g., pursed-lip breathing, abdominal breathing, exercises using various kinds of incentive spirometers). See Chapter 50 ∞.
11. Document the teaching and all assessments. Some agencies may have a preoperative teaching flow sheet. Check agency policy.

SAMPLE DOCUMENTATION

3/19/2015 0900 Instructed how to splint abdomen while deep breathing and coughing. Able to perform correctly. Stated that he will use this technique after surgery. _____ A. Moore, RN

EVALUATION

Document the outcome of the teaching plan such as:

- Client's demonstrated ability to perform moving, leg exercises, and deep-breathing and coughing exercises
- Client's verbalization of key information presented.

5 Splinting an incision with a pillow while coughing.

LIFESPAN CONSIDERATIONS Preoperative Teaching

Children

- Parents need to know what to expect and be able to express their concerns.
- Separation from parents often is the child's greatest fear; the time of separation should be minimized and parents allowed to interact with the child both immediately preceding and following the surgery.
- Teaching/communicating with children (both timing and content) should be geared to the child's developmental level and cognitive abilities (e.g., "You will have a sore tummy").
- Play is an effective teaching tool with children (e.g., the child can put a bandage on an incision on a doll).

Older Adults

- Assess hearing ability to ensure the older client hears the necessary information.
- Assess short-term memory. Presenting one focused idea at a time and repeating or reinforcing information may be necessary.

- Older adults are at greater risk for postoperative complications, such as pneumonia. Reinforce moving and deep-breathing and coughing exercises.
- Assess potential postoperative needs at this time. Arrangements can be made preoperatively to obtain necessary items. Examples are medical equipment, such as walkers, raised toilet seats, and bed trapezes; Meals-on-Wheels; and help with transportation.
- If the older client will need to be in extended care for a period of time after surgery, this is the time to initiate these plans.
- Assess the client for risk of pressure ulcer development postoperatively and be extra attentive to use of proper paddings and support devices to prevent injury during positioning and transfers in the operating room. Risks include:
 - Older age
 - Poor nutritional status
 - History of diabetes or cardiovascular problems
 - History of taking steroids, which cause increased bruising and skin breakdown.

Physical Preparation

Preoperative preparation includes the following areas: nutrition and fluids, elimination, hygiene, medications, sleep, care of valuables and prostheses, special orders, surgical skin preparation, temperature, safety protocols, vital signs, antiemboli stockings, and sequential compression devices. In many agencies a preoperative checklist is used on the day of surgery (Figure 37-1 ■). The nurse completes the agency's preoperative checklist following appropriate documenting procedures. It is essential that all pertinent records (laboratory records, x-ray films,

consents) be available for perioperative personnel to refer to them and that all physical preparation is completed to ensure client safety.

Nutrition and Fluids

Adequate hydration and nutrition promote healing. Nurses need to identify and record any signs of malnutrition or fluid imbalance. If the client is on intravenous (IV) fluids or on measured fluid intake, nurses must ensure that the fluid intake and output are accurately measured and recorded.

INITIALS	SIGNATURE AND TITLE	

Figure 37-1 ■ Sample preoperative checklist.

The order “NPO after midnight” has been a long-standing tradition because it was believed that anesthetics depress gastrointestinal functioning and there was a danger the client would vomit and aspirate during the administration of a general anesthetic. Reevaluation and research, however, do not support this tradition. As a result, the American Society of Anesthesiologists (ASA) revised its practice guidelines for preoperative fasting in healthy clients undergoing elective procedures. According to the ASA (2011), the current guidelines allow for:

- The consumption of clear liquids up to 2 hours before elective surgery requiring general anesthesia, regional anesthesia, or sedation analgesia
- The consumption of breast milk 4 hours before surgery
- A light breakfast (e.g., formula, milk, light meal such as tea and toast) 6 hours before the procedure
- A heavier meal (fried or fatty foods) 8 hours before surgery.

Elimination

Enemas before surgery are no longer routine, but cleansing enemas may be ordered if bowel surgery is planned. The enemas help prevent postoperative constipation and contamination of the surgical area

(during surgery) by feces. After surgery involving the intestines, peristalsis often does not return for 24 to 48 hours.

Prior to surgery an in-and-out/straight catheterization or an indwelling Foley catheter may be ordered to ensure that the bladder remains empty. This helps prevent inadvertent injury to the bladder, particularly during pelvic surgery. If the client does not have a catheter, it is important to empty the bladder prior to receiving preoperative medications.

Hygiene

In some settings, clients are asked to bathe or shower the evening or morning of surgery (or both). The purpose of hygienic measures is to reduce the risk of wound infection by reducing the amount of bacteria on the client’s skin. The bath includes a shampoo whenever possible.

The client’s nails should be trimmed and free of polish, and all cosmetics should be removed so that the nail beds, skin, and lips are visible when circulation is assessed during the perioperative phases.

Intraoperatively the client will be required to wear a surgical cap. The surgical cap contains the client’s hair and any microorganisms on the hair and scalp.

Before going into the operating room the client should remove all hair pins and clips because they may cause pressure or accidental damage to the scalp when the client is unconscious. The client also removes personal clothing and puts on an operating room gown.

Medications

The anesthetist or anesthesiologist may order routinely taken medications to be held the day of surgery. However, recent studies recommend continuing beta-blocker therapy for all clients taking a beta-blocker before admission for surgery (Elliott, 2013).

In some settings preoperative medications are given to the client prior to going to the operating room. Commonly used preoperative medications include the following:

- *Sedatives and tranquilizers* such as lorazepam (Ativan) are administered IV 15 to 20 minutes prior to surgery or by IM route 2 hours prior to procedure (Adams & Urban, 2013) to reduce anxiety and ease anesthetic induction.
- *Narcotic analgesics* such as morphine provide client sedation and reduce the required amount of anesthetic.
- *Anticholinergics* such as atropine, scopolamine, and glycopyrrolate (Robinul) reduce oral and pulmonary secretions and prevent laryngospasm.
- *Antiemetic agents* such as ondansetron (Zofran) are administered parenterally 30 minutes before the end of surgery to prevent nausea and vomiting (Adams & Urban, 2013).
- *Histamine-receptor antihistamines* such as cimetidine (Tagamet) and ranitidine (Zantac) reduce gastric fluid volume and gastric acidity.
- *Neurolept analgesic agents* such as Innovar induce general calmness and sleepiness.

Preoperative medications must be given at a scheduled time or “on call,” that is, when the operating room notifies the nurse to give the medication.

Sleep

Nurses should do everything to help the client sleep the night before surgery. Often a sedative is ordered. Adequate sleep helps the client manage the stress of surgery and helps healing. Oral benzodiazepines may be given several days prior to surgery to relieve anxiety and enhance rest (Adams & Urban, 2013).

Valuables

Valuables such as jewelry and money should be sent home with the client’s family or significant other. If valuables/money cannot be sent home, they need to be labeled and placed in a locked storage area per the agency’s policy. Removing jewelry also means removing body-piercing jewelry because there is a risk of injury from burns if an electrosurgical unit is used. If a client wishes not to remove a wedding band, the nurse can tape it in place. Wedding bands must be removed, however, if there is danger of the fingers swelling after surgery. Situations warranting removal include surgery on or cast application to an arm, or a mastectomy that involves removal of the lymph nodes. (Mastectomies may cause edema of the arm and hand.)

Prostheses

All prostheses (artificial body parts, such as partial or complete dentures, contact lenses, artificial eyes, and artificial limbs) and eyeglasses,

Culturally Responsive Care

PATIENT-CENTERED CARE

Body Piercing and Dermal Implants

Diccini, Malheiro Da Costa Nogueira, and Sousa (2009) write that body piercing is an ancient practice documented throughout the ages. For example, the Mayan civilization in 700 A.D. used body piercing commonly in the practice of their religion. Egyptian royalty and Roman soldiers pierced the nipples and genitalia (p. 161). And, in recent years the practice of body piercing has increased worldwide.

The most common sites for piercing are the earlobes, ear cartilage, tragus, nasal septum, eyebrow, tongue, lips, navel, breast nipples, and genitalia. Nurses need to assess the client for piercing, because piercings can produce medical complications such as bleeding, skin tears, or infections. Body piercing can affect client safety in the preoperative, intraoperative, and postoperative phases.

Moving the client from the bed to the stretcher and operating room table may place the client at risk for skin tears when the piercings are left in place. Clapham and Crooke (2011) report of anesthetic complications with tongue piercings relating to airway management and endotracheal intubation. Body piercing can also place the client and operating room staff at risk for electrical burns if the piercings are not removed. Thus, the client or nurse must remove the piercings prior to transport to surgery.

New forms of body decoration have recently emerged in the form of subdermal, transdermal, and microdermal implants, which cannot be removed. Wanzer and Hicks (2012) describe the implants. For the subdermal implants a pocket is created under the skin and a decorative shape made of silicone, Teflon, or metal is embedded to create a silhouette of the molded shape on the surface of the skin. Transdermal and microdermal implants have a footplate (or anchor) inserted into the epidermis with a thin piece of metal protruding from the skin. A piece of jewelry is then attached to this metal (p. C5).

The safety concern for the perioperative client with a subdermal implant is maintaining skin integrity because skin completely covers the implant. The transdermal and microdermal implants, however, create more safety concerns because of the protruding metal post. The safety risks relate to skin integrity as the client is transferred and positioned, and potential burn risks if electrocautery is used during the surgery.

wigs, and false eyelashes must be removed before surgery. Hearing aids are often left in place and the operating room personnel notified.

In some hospitals, dentures are placed in a locked storage area; in others they are placed in labeled containers and kept at the client’s bedside. Partial dentures can become dislodged and obstruct an unconscious client’s breathing. The nurse also checks for the presence of chewing gum or loose teeth. Loose teeth are a common problem with 5- or 6-year-olds undergoing tonsillectomy because they can become dislodged and/or aspirated during anesthesia.

Special Orders

The nurse checks the surgeon’s orders for special requirements (e.g., the insertion of a nasogastric tube prior to surgery, the administration of medications, such as insulin, or the application of anti-emboli stockings). For the technique of inserting a nasogastric tube, see Skill 47-1 in Chapter 47 ∞.

Skin Preparation

In most agencies, skin preparation is carried out during the intraoperative phase. The surgical site is cleansed with an antimicrobial to remove soil and reduce the resident microbial count to subpathogenic levels.

Temperature

Surgical clients are at risk of losing body heat; therefore, temperature management is an important aspect of perioperative client safety and comfort. Approximately 70% of surgical clients develop inadvertent or unplanned hypothermia during the perioperative period (Wu, 2013, p. 302). There are many possible causes for hypothermia including minimal clothing (i.e., only a hospital gown), inactivity while in the holding area, skin exposure during insertion of IV and during surgery, and intentionally low temperatures in the OR; in addition, the administration of anesthesia impairs both thermoregulation and the ability of the body to generate and retain heat (Bernard, 2013; Wu, 2013). Clients with extremes in body weight or condition are at risk for hypothermia because of body surface area-to-weight ratios (Lynch, Dixon, Leary, & Holm, 2010, p. 557). Complications associated with perioperative hypothermia include increased blood loss, delayed wound healing, increased risk of surgical site infection, and increased length of stay in the hospital. It is important for the client's temperature to be assessed during the entire perioperative experience to prevent unintended hypothermia. Researchers recommend prewarming or warming to reduce the complications of hypothermia. One method is to use a forced-air warming system, which consists of a power unit that generates warmed air and a fan that blows the warmed air through a hose into a disposable blanket that has direct contact with the client (Wu, 2013, p. 303). This method of warming can be started in the presurgical area and used throughout surgery and on into the PACU (Bernard, 2013). Studies have shown that warming improves postoperative recovery; however, it has not yet become a routine part of preoperative preparation (Wu, 2013).

Safety Protocols

The Joint Commission established the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery in 2004. This protocol involves three steps. The first step requires preoperative verification. The frequency and scope of the verification process depends on the type and complexity of the procedure. Possibilities include when the procedure is scheduled, at the time of preadmission testing and assessment, at the time of admission for the procedure, and before the client leaves the preprocedure area or enters the procedure room (Joint Commission, 2013, p. 13).

The second step involves marking of the operative site. The protocol does not specify the type of mark; however, The Joint Commission does require that the surgical site marking method be consistent throughout the facility and encourages client involvement. The facility chooses its own surgical site method (e.g., the client's initials, surgeon's initials, the word "YES"). The essential focus is that the mark must be

SAFETY ALERT!

SAFETY

2014 The Joint Commission National Patient Safety Goals (2013)

Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery

- Conduct a preprocedure verification process.
Rationale: *Hospitals should always make sure that any procedure is what the patient needs and is performed on the right person.*
- Mark the procedure site.
Rationale: *The purpose of the time-out is to conduct a final assessment that the correct patient, site, and procedure have been identified.*

unambiguous and a clear communication to all involved. The mark must be permanent and visible after the client has been prepped and draped for surgery. There is no clear consensus on who should mark the site. Because the mark is a communication tool about the client for members of the team, The Joint Commission (2013) suggests that the individual who knows the most about the client should mark the site. In most cases, that will be the person performing the procedure (p. 15).

The third step is called "time-out." Before surgery begins the surgical team takes a time-out to conduct a final verification of the correct client, procedure, and site. Any questions or concerns must be resolved before the procedure can begin.

Vital Signs

In the preoperative phase the nurse assesses and documents vital signs for baseline data. The nurse reports any abnormal findings, such as elevated blood pressure or elevated temperature.

Antiemboli Stockings

Antiemboli (elastic) stockings are firm elastic hose that compress the veins of the legs and thereby facilitate the return of venous blood to the heart. They also improve arterial circulation to the feet and prevent edema of the legs and feet. These stockings are frequently applied to surgical clients to prevent the potential postoperative problem of deep venous thrombosis (DVT).

There are several types of stockings. One type extends from the foot to the knee and another from the foot to midhigh. These stockings usually have a partial foot that exposes the heel or toes so that extremity circulation can be assessed. Elastic stockings usually come in small, medium, and large sizes. Skill 37-2 details the steps required to apply antiemboli stockings.

Applying Antiemboli Stockings

PURPOSES

- To facilitate venous return from the lower extremities
- To prevent venous stasis and DVT
- To reduce peripheral edema

ASSESSMENT

Assess and compare both lower extremities for

- Presence and volume (e.g., strong, faint, easily obliterated) of posterior tibial and dorsalis pedis pulses
- Skin color (note pallor, cyanosis, or other pigmentation)
- Skin temperature (e.g., warm, cool)
- Presence of edema
- Skin condition (e.g., thickened, shiny, taut)
- Homans' sign (pain in calf with passive dorsiflexion of the foot).

Applying Antiemboli Stockings—continued

PLANNING

Before applying antiemboli stockings, determine any potential or present circulatory problems and the surgeon's orders involving the lower extremities.

DELEGATION

UAP frequently remove and apply antiemboli stockings as part of hygiene care. The nurse should stress the importance of removing and reapplying the stockings and reporting any changes in the client's skin to the nurse. The nurse is responsible for assessment of the skin.

IMPLEMENTATION

Preparation

Take measurements as needed to obtain the appropriate size stockings.

- Measure the length of both legs from the heel to the gluteal fold (for thigh-length stockings) or from the heel to the popliteal space (for knee-length stockings).
- Measure the circumference of each calf and each thigh at the widest point.
- Compare the measurements to the size chart to obtain stockings of correct size. Obtain two sizes if there is a significant difference. **Rationale:** *Stockings that are too large for the client do not place adequate pressure on the legs to facilitate venous return, and may bunch, increasing the risk of pressure and skin irritation. Stockings that are too small may impede blood flow to the feet and cause skin breakdown.*

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Select an appropriate time to apply the stockings.
 - Apply stockings in the morning, if possible, before the client gets out of bed. **Rationale:** *In sitting and standing positions, the veins can become distended so that edema occurs; the stockings should be applied before this occurs.*
 - Assist the client who has been ambulating to lie down and elevate the legs for 15 to 30 minutes before applying the stockings. **Rationale:** *This facilitates venous return and reduces swelling.*
5. Prepare the client.
 - Assist the client to a lying position in bed.
 - Wash and dry the legs as needed.
6. Apply the stockings.
 - Reach inside the stocking from the top, and grasping the heel, turn the upper portion of the stocking inside out so the foot portion is inside the stocking leg. **Rationale:** *Firm elastic stockings are easier to fit over the foot and calf when inverted in this manner rather than bunching up the stocking.*
 - Ask the client to point the toes, then position the stocking on the client's foot. With the heel of the stocking down and stretching each side of the stocking, ease the stocking over the toes taking care to place the toe and heel portions of the stocking appropriately. **1** **Rationale:** *Pointing the toes makes application easier.*
 - Grasp the loose portion of the stocking at the ankle and gently pull the stocking over the leg, turning it right side out in the process. **2** and **3** If applying thigh-length stockings, stretch them over the knee until the top is below the gluteal fold.

Equipment

- Single-use tape measure (to prevent cross-infection)
- Clean knee or thigh antiemboli stockings of appropriate size.

1 Applying the stocking over the toes.

2 Pulling the stocking snugly over the leg.

3

Applying Antiemboli Stockings—continued

- Inspect the client's leg and stocking, smoothing any folds or creases. Ensure that the stocking is not rolled down or bunched at the top or ankle. Ensure that the stocking is distributed evenly and that the heel is properly centered in the heel pockets. **Rationale:** *Folds and creases can cause skin irritation under the stocking; bunching of the stocking can further impair venous return.*
 - Remove the stockings per agency policy, inspecting the legs and skin while the stockings are off.
 - Soiled stockings may be laundered by hand with warm water and mild soap. Hang to dry.
7. Document the procedure. Record the procedure, your assessment data, and when the stockings are removed and reapplied.

EVALUATION

- Remove antiembolism stockings per agency policy for skin care and inspection.
- Note the appearance of the legs and skin integrity, presence of edema, peripheral pulses, and skin color and temperature. Compare to previous assessment data.
- If complications occur, remove the stockings and report findings to the primary care provider.

LIFESPAN CONSIDERATIONS Antiemboli Stockings

CHILDREN

Antiemboli stockings are infrequently used on children.

OLDER ADULTS

- Because the elastic is quite strong in antiemboli stockings, the older adult may need assistance with putting on the stockings. Clients with arthritis may need to have another person put the stockings on for them.
- Many older adults have circulation problems and wear antiemboli stockings. It is important to check for wrinkles in

the stockings and to see if the stocking has rolled down or twisted. If so, correct immediately because the stockings must be evenly distributed over the limb to promote rather than hinder circulation.

- Stockings should be removed once each shift so that a thorough assessment can be made of the legs and feet. Redness and skin breakdown on the heels can occur quickly and go undetected if not thoroughly assessed on a regular basis.

Home Care Considerations Antiemboli Stockings

PATIENT-CENTERED CARE

- Teach the client or caregiver how to apply the antiemboli stockings.
- Stress the importance of no wrinkles or rolling down of the stockings and the rationale.
- Instruct the client or caregiver to remove the stockings daily and inspect the skin on the legs.
- Provide instructions about:
 - Laundering the stockings
 - The need for two pairs of stockings to allow for one pair to be worn while the other is being laundered
 - Replacing the stockings when they lose their elasticity.

Sequential Compression Devices

Clients who are undergoing surgery may benefit from a sequential compression device (SCD) to promote venous return from the legs. SCDs inflate and deflate plastic sleeves wrapped around the legs to promote venous flow. SCDs are discussed in Chapter 51 ∞ (see Skill 51-1).

Evaluating

The goals established during the planning phase are evaluated according to specific desired outcomes, also established in that phase.

INTRAOPERATIVE PHASE

The intraoperative nurse uses the nursing process to design, coordinate, and deliver care to meet the identified needs of clients whose protective reflexes or self-care abilities are potentially compromised because they are having operative or other invasive procedures.

Types of Anesthesia

Anesthesia is classified as *general* or *regional*. Anesthetic agents usually are administered by an anesthesiologist or a certified registered

nurse anesthetist (CRNA). **General anesthesia** is the loss of all sensation and consciousness. Under general anesthesia, protective reflexes such as cough and gag reflexes are lost. A general anesthetic acts by blocking awareness centers in the brain so that amnesia (loss of memory), analgesia (insensibility to pain), hypnosis (artificial sleep), and relaxation (rendering a part of the body less tense) occur. General anesthetics are usually administered by IV infusion or by inhalation of gases through a mask or through an endotracheal tube inserted into the trachea.

General anesthesia has certain advantages. Because the client is unconscious rather than awake and anxious, respiration and cardiac function are readily regulated. Also, the anesthesia can be adjusted to the length of the operation and the client's age and physical status. Its chief disadvantage is that it depresses the respiratory and circulatory systems. Some clients become more anxious about a general anesthetic than about the surgery itself. Often this is because they fear losing the capacity to control their own bodies.

Regional anesthesia is the temporary interruption of the transmission of nerve impulses to and from a specific area or region

DRUG CAPSULE

Benzodiazepine midazolam hydrochloride (Versed)**THE CLIENT UNDERGOING ANESTHESIA**

IV anesthetic agent used to induce general anesthesia.

Commonly used prior to conscious sedation to produce anxiolytic, hypnotic, anticonvulsant, muscle relaxant, and amnesic effects.

NURSING RESPONSIBILITIES

- Obtain baseline vital signs and level of consciousness before administration.
- Monitor vital signs, level of consciousness, and oxygen saturation q3–5min intraoperatively and postoperatively. Notify primary care provider or CRNA if there are any changes.

- Have resuscitative equipment readily available.
- A too rapid IV administration or excessive dose increases the risk of respiratory depression/arrest.
- Dosage must be individualized based on age, underlying disease, and desired effect. Too much or too little a dosage or improper administration may result in cerebral hypoxia, agitation, involuntary movement, hyperactivity, and/or combativeness.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

of the body. The client loses sensation in an area of the body but remains conscious. Several techniques are used:

- **Topical (surface) anesthesia** is applied directly to the skin and mucous membranes, open skin surfaces, wounds, and burns. The most commonly used topical agents are lidocaine (Xylocaine) and benzocaine. Topical anesthetics are readily absorbed and act rapidly.
- **Local anesthesia** (infiltration) is injected into a specific area and is used for minor surgical procedures such as suturing a small wound or performing a biopsy. Lidocaine or tetracaine 0.1% may be used.
- A **nerve block** is a technique in which the anesthetic agent is injected into and around a nerve or small nerve group that supplies sensation to a small area of the body. Major blocks involve multiple nerves or a plexus (e.g., the brachial plexus anesthetizes the arm); minor blocks involve a single nerve (e.g., a facial nerve).
- **Spinal anesthesia** is also referred to as a **subarachnoid block (SAB)**. It requires a lumbar puncture through one of the interspaces between lumbar disk 2 (L_2) and the sacrum (S_1). An anesthetic agent is injected into the subarachnoid space surrounding the spinal cord. Spinal anesthesia is often categorized as a low, mid, or high spinal. Low spinals (saddle or caudal blocks) are primarily used for surgeries involving the perineal or rectal areas. Mid-spinals (below the level of the umbilicus— T_{10}) can be used for hernia repairs or appendectomies, and high spinals (reaching the nipple line— T_4) can be used for surgeries such as cesarean sections.
- **Epidural (peridural) anesthesia** is an injection of an anesthetic agent into the epidural space, the area inside the spinal column but outside the dura mater.

Conscious sedation may be used alone or in conjunction with regional anesthesia for some diagnostic tests and surgical procedures.

Conscious sedation refers to minimal depression of the level of consciousness such that the client retains the ability to maintain a patent airway and respond appropriately to commands. IV narcotics such as morphine or fentanyl (Sublimaze) and anti-anxiety agents such as diazepam (Valium) or midazolam (Versed) are commonly used to induce and maintain conscious sedation. Conscious sedation increases the client's pain threshold and induces a degree of amnesia but allows for prompt reversal of its effects and a rapid return to normal ADLs. Procedures such as endoscopies, incision and drainage of abscesses, and even balloon angioplasty may be performed under conscious sedation.

●○● NURSING MANAGEMENT**Assessing**

On the day of surgery, after the client has been admitted to the hospital, the client's family members or significant others are escorted to a surgical holding area located outside of the operating room. This area is also known as a presurgical care unit (PSCU). The perioperative nurse confirms the client's identity and assesses the client's physical and emotional status. The nurse verifies the information on the preoperative checklist and evaluates the client's knowledge about the surgery and events to follow. The client's response to preoperative medications is assessed, as well as the placement and patency of tubes such as IV lines, nasogastric tubes, and urinary catheters.

Assessment continues throughout surgery, as the anesthesiologist or the CRNA continuously monitors the client's vital signs (including blood pressure, heart rate, respiratory rate, and temperature), ECG, and oxygen saturation. Fluid intake and urinary output are monitored throughout surgery, and blood loss is estimated. In addition, arterial and venous pressures, pulmonary artery pressures, and laboratory values such as blood glucose, hemoglobin, hematocrit, serum electrolytes, and arterial blood gases may be evaluated during surgery. Continual assessment is necessary to rapidly identify adverse responses to surgery or anesthesia and intervene promptly to prevent complications.

Diagnosing

NANDA nursing diagnoses that may be appropriate for the intraoperative client include the following:

- *Risk for Aspiration*
- *Ineffective Protection*
- *Impaired Skin Integrity*
- *Risk for Perioperative Positioning Injury*
- *Risk for Imbalanced Body Temperature*
- *Ineffective Peripheral Tissue Perfusion*
- *Risk for Deficient Fluid Volume.*

Planning

The overall goals of care in the intraoperative period are to maintain the client's safety and to maintain homeostasis. Examples of nursing activities to achieve these goals include the following:

- Position the client appropriately for surgery.
- Perform preoperative skin preparation.

- Assist in preparing and maintaining the sterile field.
- Open and dispense sterile supplies during surgery.
- Provide medications and solutions for the sterile field.
- Monitor and maintain a safe, aseptic environment.
- Manage catheters, tubes, drains, and specimens.
- Perform sponge, sharp, and instrument counts.
- Document nursing care provided and the client's response to interventions.

Implementing

Intraoperative interventions are carried out by the circulating nurse, the scrub person, and the registered nurse first assistant. The **circulating nurse** coordinates activities and manages client care by continually assessing client safety (e.g., client positioning) and by monitoring aseptic practice and the environment (e.g., temperature, humidity, and lighting). The Association of Operating Room Nurses (AORN) recommends that the circulating nurse must always be a perioperative RN and that a minimum of one perioperative RN circulator should be dedicated to each client undergoing a surgical procedure (AORN, 2011, 2012a). The **scrub person** is usually an RN, LPN, or certified surgical technologist (CST). They wear sterile gowns, gloves, caps, and eye protection. Their role is to assist the surgeons. The registered nurse first assistant (RNFA) has additional education and training and functions in an expanded perioperative nursing role. The RNFA assists the surgeon by controlling bleeding, using instruments, handling and cutting tissues, and suturing during the procedure (AORN, 2012b). The circulating nurse and the scrub person are responsible for accounting for all sponges, needles, and instruments at the close of surgery. This precaution prevents foreign bodies from being left inside the client.

Surgical Skin Preparation

Surgical skin preparation involves cleaning the surgical site, removing hair only if necessary, and applying an antimicrobial agent. In most surgery centers, skin preparation is done by surgery personnel near the time of surgery. The purpose of a surgical skin preparation is to reduce the risk of surgical site infections (SSIs), the most common type of health care–associated infection in the surgical population (Zinn et al., 2013, p. 552). This is done by:

- Removing transient microbes from the skin
- Reducing the resident microbial count to subpathogenic amounts in a short time and with the least amount of tissue irritation
- Inhibiting rapid rebound growth of microbes.

Skin preparation practices to reduce the risk of SSIs include the following:

- Clean the surgical site and surrounding areas. This can be accomplished before the surgical prep by having the client shower and shampoo or wash the surgical site before arriving in the surgical setting, or by washing the surgical site in the surgical setting immediately before applying an antimicrobial agent. Graling and Vasaly (2013) found that the use of a 2% chlorhexidine gluconate cloth bath preoperatively significantly reduced the incidence of SSIs.
- Remove hair from the surgical site only when necessary, for example, if it interferes with the surgical procedure. Personnel skilled in hair removal should use techniques that preserve skin integrity such as electric clippers to reduce the risk of traumatizing

the skin during hair removal. Razors can disrupt skin integrity so hair removal with a razor is not recommended. Skin trauma and abrasions increase the risk of microorganisms colonizing the surgical site. If hair is to be removed, it is done as close to the time of surgery as possible and not in the vicinity of the sterile field to avoid spreading of loose hair and potential contamination of the sterile field.

- Prepare the surgical site and surrounding area with an antimicrobial agent when indicated. A nontoxic antimicrobial agent with a broad range of germicidal action is used to inhibit the growth of microorganisms during and following the surgical procedure. Chlorhexidine gluconate and povidone-iodine are frequently used solutions. Alcohol is effective; however, its use is often restricted because of flammability.

Positioning

The position of the client during a surgical procedure is essential to the maintenance of client safety. Beckett (2010) states that inadequate padding and incorrect positioning can cause serious injury and long-term disability. The entire operating room team is responsible for minimizing the client's risk of perioperative complications related to positioning. The client's position can affect ventilation and circulation and impair peripheral nerve function. The anesthesiologist or nurse anesthetist is responsible in directing staff to protect the client from injury.

The client's position should provide:

- Optimal visualization of and access to the surgical site
- Optimal access to IV lines and monitoring devices
- Protection of the client from harm (anatomic and physiological considerations).

Positioning is performed after anesthesia is induced and before surgical draping of the client. The client is lifted into position to prevent shearing forces on the skin from sliding or rolling. The exact position for the client depends on the operation, that is, the surgical approach. For example, a lithotomy position is usually used for vaginal surgery.

Straps maintain positions on the operating table, and body prominences are frequently padded. The position should consider normal joint range of motion and good body alignment, thereby avoiding strain or injury to muscles, bones, and ligaments.

CLINICAL ALERT!

Be especially aware of the intraoperative position required for older adults. Because older adults are vulnerable to pressure ulcer formation, check the appropriate pressure points of that surgical position on the client.

Evaluating

The intraoperative nurse uses the goals developed during the planning stage (e.g., maintain client safety) and collects data to evaluate whether the desired outcomes have been achieved.

Documentation

The intraoperative nurse documents the perioperative plan of care including assessment, diagnosis, outcome identification, planning, implementation, and evaluation.

ANATOMY & PHYSIOLOGY REVIEW

Client Positioning

The most common position for a client during a surgical procedure is the supine position. This position provides approaches to the cranial, thoracic, and peritoneal body cavities as well as to all four extremities and the perineum. Proper body alignment and padding of potential pressure areas are essential to preventing client risk for injury during surgery.

The potential pressure areas are the occiput, scapulae, olecranon, thoracic vertebrae, sacrum, coccyx, and calcaneus. The nursing intervention is to pad and protect bony prominences, pressure sites, and vulnerable nerves with pressure-reducing devices made of foam or gel. Proper positioning must provide optimal exposure to the surgical site as well as provide for client comfort and safety.

A

B

A, Supine position during a surgical procedure; B, potential pressure points noted.

QUESTIONS

A 78-year-old male client scheduled for a colon resection is brought to the operating room. He weighs 180 pounds and has type 2 diabetes and a history of arthritis in his hips and shoulders.

1. What baseline assessments would you gather before taking this client to the operating room?

2. What areas on this client are most likely to be injured as a result of poor positioning or inadequate padding?
3. What is the priority nursing diagnosis and outcome for this client?

See student resource website for answers.

POSTOPERATIVE PHASE

Nursing during the postoperative phase is especially important for the client's recovery because anesthesia impairs the ability of clients to respond to environmental stimuli and to help themselves, although the degree of consciousness of clients will vary. Moreover, surgery itself traumatizes the body by disrupting protective mechanisms and homeostasis.

Immediate Postanesthetic Phase

Recovery of surgical clients who required anesthesia is performed in the PACU or RR. PACU nurses, often certified by the

American Society of PeriAnesthesia Nurses (ASPA), have specialized skills to care for clients recovering from anesthesia and surgery (Figure 37–2 ■).

During the immediate postanesthetic stage, an unconscious client is positioned on the side, with the face slightly down. A pillow is not placed under the head. In this position, gravity keeps the tongue forward, preventing occlusion of the pharynx and allowing drainage of mucus or vomitus out of the mouth rather than down the respiratory tree.

The nurse ensures maximum chest expansion by elevating the client's upper arm on a pillow. The upper arm is supported because the pressure of an arm against the chest reduces chest expansion potential. An artificial airway is maintained in place, and

Figure 37–2 ■ PACU nurse provides constant assessment and care for clients recovering from anesthesia and surgery.

the client is suctioned as needed until cough and swallowing reflexes return. Generally the client spits out an oropharyngeal airway when coughing returns. Endotracheal tubes are not removed until clients are awake and able to maintain their own airway. The client is then helped to turn, cough, and take deep breaths, provided that vital signs are stable. When spinal anesthesia is used, the client may be required to remain flat for a specified period. See Chapter 50 ∞ for information about artificial airways. Assessment of the client in the immediate postanesthetic period is summarized in Box 37–5.

The return of the client’s reflexes, such as swallowing and gagging, indicates that anesthesia is ending. Time of recovery from anesthesia varies with the kind of anesthetic agent used, its dosage, and the individual’s response to it. Nurses should arouse clients by calling them by name, and in a normal tone of voice repeatedly telling them that the surgery is over and that they are in the PACU.

The PACU nurse uses criteria developed by the anesthesia department to evaluate client readiness for discharge from the PACU. Aldrete and Kroulik (1970) were the first to introduce the Post-Anesthetic Recovery Score (PARS), also called the Aldrete Score, to provide an objective scoring system to help in the discharge decision-making process. The original Aldrete scoring system included assessment of muscle activity, respiration, circulation,

BOX 37–5 Clinical Assessment: Immediate Postanesthetic Phase

- Adequacy of airway
- Oxygen saturation
- Adequacy of ventilation:
 - Respiratory rate, rhythm, and depth
 - Use of accessory muscles
 - Breath sounds
- Cardiovascular status:
 - Heart rate and rhythm
 - Peripheral pulse amplitude and equality
 - Blood pressure
 - Capillary filling
- Level of consciousness:
 - Not responding
 - Arousable with verbal stimuli
 - Fully awake
 - Oriented to time, person, and place
- Presence of protective reflexes (e.g., gag, cough)
- Activity, ability to move extremities
- Skin color (pink, pale, dusky, blotchy, cyanotic, jaundiced)
- Fluid status:
 - Intake and output
 - Status of IV infusions (type of fluid, rate, amount in container, patency of tubing)
 - Signs of dehydration or fluid overload (see Chapter 52 ∞)
- Condition of operative site:
 - Status of dressing
 - Drainage (amount, type, and color)
- Patency of and character and amount of drainage from catheters, tubes, and drains
- Discomfort (i.e., pain) (type, location, and severity), nausea, vomiting
- Safety (i.e., necessity for side rails, call bell within reach)

consciousness, and color. In 1995, this scoring system was revised to replace the assessment of color with oxygen saturation and is called the Modified Aldrete. A rating of 0 to 2 is given to each assessment, depending on its absence or presence. The numbers given to each assessment are added up with a score of 10 indicating that the client is in the best possible condition. Many PACUs require a score of 9 for discharge. Table 37–3 is one example of an Aldrete PARS.

A number of scoring systems have been developed and there is no consensus regarding which specific assessments should be used to determine readiness for discharge (Phillips, Haesler, Street, & Kent, 2011). The ASPAN standards do not require use

TABLE 37–3 Aldrete Post-Anesthetic Recovery Score

Activity	Respiration	Circulation	Consciousness	Oxygen Saturation
2: Moves all extremities voluntarily/on command	2: Breathes deeply and coughs freely	2: BP ± 20 mmHg of preanesthetic level	2: Fully awake	2: Maintains value > 90% on room air
1: Some weakness in movement of extremities	1: Dyspneic, shallow or limited breathing (splinting)	1: BP ± 20–50 mmHg of preanesthetic level	1: Arousable on calling	1: Requires oxygen to maintain value > 90%
0: Unable to move extremities	0: Apneic	0: BP ± 50 mmHg of preanesthetic level	0: Not responding	0: Value > 90% with supplemental oxygen

From "A Postanesthetic Recovery Score," by J. A. Aldrete, and D. Kroulik, 1970, *Anesthesia and Analgesia*, 49, pp. 924–934; *Anesthesiology* (2nd ed.), by D. Longnecker, D. L. Brown, M. F. Newman, and W. Zapol, 2012, New York, NY: McGraw-Hill; and "New Criteria for Fast-Tracking After Outpatient Anesthesia: A Comparison with the Modified Aldrete's Scoring System," by P. F. White and D. Song, 1999, *Anesthesia and Analgesia*, 88, pp. 1069–1072.

of a scoring system. However, each facility should develop assessment and discharge criteria and may include a postanesthesia scoring system as a component of the discharge criteria (ASPAN, 2012). It is important for the nurse to use critical thinking and nursing judgment along with the discharge criteria.

Clients are usually discharged from the PACU when:

- They are conscious and oriented.
- They are able to maintain a clear airway and deep breathe and cough freely.
- Vital signs have been stable or consistent with preoperative vital signs for at least 30 minutes.
- Protective reflexes (e.g., gag, swallowing) are active.
- They are able to move all extremities.
- Intake and urinary output is adequate.
- They are afebrile or a febrile condition has been attended to.
- Dressings are dry and intact; there is no overt drainage.

Once the health status has stabilized, the client is returned to the nursing unit or the outpatient surgery discharge area.

Preparing for Ongoing Care of the Postoperative Client

While the client is in the operating room, the client's bed and room are prepared for the postoperative phase. In some agencies, the client is brought back to the unit on a stretcher and transferred to the bed in the room. In other agencies, the client's bed is brought to the surgery suite, and the client is transferred there. In the latter situation, the bed needs to be made with clean linens as soon as the client goes to surgery so that it can be taken to the operating room when needed. In addition, the nurse must obtain and set up any special equipment, such as an IV pole, suction, oxygen equipment, and orthopedic appliances (e.g., traction). If these are not requested on the client's record, the nurse should consult with the perioperative nurse or surgeon.

●○○ NURSING MANAGEMENT

Assessing

As soon as the client returns to the nursing unit, the nurse conducts an initial assessment. The sequence of these activities varies with the situation. For example, the nurse may need to check the primary care provider's stat orders before conducting the initial assessment; in such a case, nursing interventions to implement the orders can be carried out at the same time as assessment.

The nurse consults the surgeon's postoperative orders to learn the following:

- Food and fluids permitted by mouth
- IV solutions and IV medications
- Position in bed
- Medications ordered (e.g., analgesics, antibiotics)
- Laboratory tests
- Intake and output, which in some agencies are monitored for all postoperative clients
- Activity permitted, including ambulation.

The nurse also checks the PACU record for the following data:

- Operation performed
- Presence and location of any drains

- Anesthetic used
- Postoperative diagnosis
- Estimated blood loss
- Medications administered in the PACU.

Many hospitals have postoperative protocols for regular assessment of clients. In some agencies, assessments are made every 15 minutes until vital signs stabilize, every hour for the next 4 hours, then every 4 hours for the next 2 days. It is important that the assessments be made as often as the client's condition requires. The nurse assesses the following:

- **Level of consciousness.** Assess orientation to time, place, and person. Most clients are fully conscious but drowsy when returned to their unit. Assess reaction to verbal stimuli and ability to move extremities.
- **Vital signs.** Take the client's vital signs (pulse, respiration, blood pressure, and oxygen saturation level) every 15 minutes until stable or in accordance with agency protocol. Compare initial findings with PACU data. In addition, assess the client's lung sounds and assess for signs of common circulatory problems such as postoperative hypotension, hemorrhage, or shock. Hypovolemia due to fluid losses during surgery is a common cause of postoperative hypotension. Hemorrhage can result from insecure ligation of blood vessels or disruption of sutures. Massive hemorrhage or cardiac insufficiency can lead to shock postoperatively. Common postoperative complications with their manifestations and preventive measures are listed in Table 37–4.
- **Skin color and temperature,** particularly that of the lips and nail beds. The color of the lips and nail beds is an indicator of **tissue perfusion** (passage of blood through the vessels). Pale, cyanotic, cool, and moist skin may be a sign of circulatory problems.

CLINICAL ALERT!

Older adults may not show the classic signs of infection (e.g., fever, tachycardia, increased WBC count); instead there may be an abrupt change in their mental status.

- **Comfort.** Assess pain with the client's vital signs and as needed between vital sign measurements. Assess the location and intensity of the pain. Do not assume that reported pain is incisional; other causes may include muscle strains, flatus, and angina. Ask the client to rate pain on a scale of 0 to 10, with 0 being no pain and 10 the worst pain imaginable. Evaluate the client for objective indicators of pain: pallor, perspiration, muscle tension, and reluctance to cough, move, or ambulate. Determine when and what analgesics were last administered, and assess the client for any side effects of medication such as nausea and vomiting.
- **Fluid balance.** Assess the type and amount of IV fluids, flow rate, and infusion site. Monitor the client's fluid intake and output. In addition to watching for shock, assess the client for signs of circulatory overload, and monitor serum electrolytes. Anesthetics and surgery affect the hormones regulating fluid and electrolyte balance (aldosterone and antidiuretic hormone in particular), placing the client at risk for decreased urine output and fluid and electrolyte imbalances.
- **Dressing and bedclothes.** Inspect the client's dressings and bedclothes underneath the client. Excessive bloody drainage on

TABLE 37-4 Potential Postoperative Problems

Problem	Description	Cause	Clinical Signs	Preventive Interventions
RESPIRATORY				
Pneumonia	Inflammation of the alveoli	Infection, toxins, or irritants causing inflammatory process Immobility and impaired ventilation result in atelectasis and promote growth of pathogens	Elevated temperature, cough, expectoration of blood-tinged or purulent sputum, dyspnea, chest pain	Deep-breathing exercises and coughing, moving in bed, early ambulation
Atelectasis	A condition in which alveoli collapse and are not ventilated	Mucous plugs blocking bronchial passageways, inadequate lung expansion, analgesics, immobility	Dyspnea, tachypnea, tachycardia; diaphoresis, anxiety; pleural pain, decreased chest wall movement; dull or absent breath sounds; decreased oxygen saturation	Deep-breathing exercises and coughing, moving in bed, early ambulation
Pulmonary embolism	Blood clot that has moved to the lungs and blocks a pulmonary artery, thus obstructing blood flow to a portion of the lung	Stasis of venous blood from immobility, venous injury from fractures or during surgery, use of oral contraceptives high in estrogen, preexisting coagulation or circulatory disorder	Sudden chest pain, shortness of breath, cyanosis, shock (tachycardia, low blood pressure)	Turning, ambulation, antiemboli stockings, sequential compression devices (SCDs)
CIRCULATORY				
Hypovolemia	Inadequate circulating blood volume	Fluid deficit, hemorrhage	Tachycardia, decreased urine output, decreased blood pressure	Early detection of signs; fluid and/or blood replacement
Hemorrhage	Internal or external bleeding	Disruption of sutures, insecure ligation of blood vessels	Overt bleeding (dressings saturated with bright blood; bright, free-flowing blood in drains or chest tubes), increased pain, increasing abdominal girth, swelling or bruising around incision	Early detection of signs
Hypovolemic shock	Inadequate tissue perfusion resulting from markedly reduced circulating blood volume	Severe hypovolemia from fluid deficit or hemorrhage	Rapid weak pulse, dyspnea, tachypnea; restlessness and anxiety; urine output less than 30 mL/h; decreased blood pressure; cool, clammy skin, thirst, pallor	Maintain blood volume through adequate fluid replacement, prevent hemorrhage; early detection of signs
Thrombophlebitis	Inflammation of the veins, usually of the legs and associated with a blood clot	Slowed venous blood flow due to immobility or prolonged sitting; trauma to vein, resulting in inflammation and increased blood coagulability	Aching, cramping pain; affected area is swollen, red, and hot to touch; vein feels hard; discomfort in calf when foot is dorsiflexed (Homans' sign) or when client walks	Early ambulation, leg exercises, antiemboli stockings, SCDs, adequate fluid intake
Thrombus	Blood clot attached to wall of vein or artery (most commonly the leg veins)	Thrombophlebitis for venous thrombi; disruption or inflammation of arterial wall for arterial thrombi	<i>Venous:</i> same as thrombophlebitis <i>Arterial:</i> pain and pallor of affected extremity; decreased or absent peripheral pulses	<i>Venous:</i> same as thrombophlebitis <i>Arterial:</i> maintain prescribed position; early detection of signs
Embolus	Foreign body or clot that has moved from its site of formation to another area of the body (e.g., the lungs, heart, or brain)	Venous or arterial thrombus; broken intravenous catheter, fat, or amniotic fluid	In venous system, usually becomes a pulmonary embolus (see pulmonary embolism); signs of arterial emboli may depend on the location	Turning, ambulation, leg exercises, SCDs; careful maintenance of IV catheters

TABLE 37-4 Potential Postoperative Problems—*continued*

Problem	Description	Cause	Clinical Signs	Preventive Interventions
URINARY				
Urinary retention	Inability to empty the bladder, with excessive accumulation of urine in the bladder	Depressed bladder muscle tone from narcotics and anesthetics; handling of tissues during surgery on adjacent organs (rectum, vagina)	Fluid intake larger than output; inability to void or frequent voiding of small amounts, bladder distention, suprapubic discomfort, restlessness	Monitoring of fluid intake and output, interventions to facilitate voiding, urinary catheterization as needed
Urinary tract infection	Inflammation of the bladder, ureters, or urethra	Immobilization and limited fluid intake, instrumentation of the urinary tract	Burning sensation when voiding, urgency, cloudy urine, lower abdominal pain	Adequate fluid intake, early ambulation, aseptic straight catheterization only as necessary, good perineal hygiene
GASTROINTESTINAL				
Nausea and vomiting		Pain, abdominal distention, ingesting food or fluids before return of peristalsis, certain medications, anxiety	Complaints of feeling sick to the stomach, retching or gagging	IV fluids until peristalsis returns; then clear fluids, full fluids, and regular diet; antiemetic drugs if ordered; analgesics for pain
Constipation	Infrequent or no stool passage for abnormal length of time (e.g., within 48 h after solid diet started)	Lack of dietary roughage, analgesics (decreased intestinal motility), immobility	Absence of stool elimination, abdominal distention, and discomfort	Adequate fluid intake, high-fiber diet, early ambulation
Tympanites	Retention of gases within the intestines	Slowed motility of the intestines due to handling of the bowel during surgery and the effects of anesthesia	Obvious abdominal distention, abdominal discomfort (gas pains), absence of bowel sounds	Early ambulation; avoid using a straw, provide ice chips or water at room temperature
Postoperative ileus	Intestinal obstruction characterized by lack of peristaltic activity	Handling the bowel during surgery, anesthesia, electrolyte imbalance, wound infection	Abdominal pain and distention; constipation; absent bowel sounds; vomiting	Early ambulation; chewing gum; early oral intake and feeding
WOUND				
Wound infection	Inflammation and infection of incision or drain site	Poor aseptic technique; laboratory analysis of wound swab identifies causative microorganism	Purulent exudate, redness, tenderness, elevated body temperature, wound odor	Keep wound clean and dry, use surgical aseptic technique when changing dressings
Wound dehiscence	Separation of a suture line before the incision heals	Malnutrition (emaciation, obesity), poor circulation, excessive strain on suture line	Increased incision drainage, tissues underlying skin become visible along parts of the incision	Adequate nutrition, appropriate incisional support and avoidance of strain
Wound evisceration	Extrusion of internal organs and tissues through the incision	Same as for wound dehiscence	Opening of incision and visible protrusion of organs	Same as for wound dehiscence
PSYCHOLOGICAL				
Postoperative depression	Mental disorder characterized by altered mood	Weakness, surprise nature of emergency surgery, news of malignancy, severely altered body image, other personal matter; may be a physiological response to some surgeries	Anorexia, tearfulness, loss of ambition, withdrawal, rejection of others, feelings of dejection, sleep disturbances (insomnia or excessive sleeping)	Adequate rest, physical activity, opportunity to express anger and other negative feelings

dressings or on bedclothes, often appearing underneath the client, can indicate hemorrhage. The amount of drainage on dressings is recorded by describing the diameter of the stains or by denoting the number and type of dressings saturated with drainage.

- **Drains and tubes.** Determine color, consistency, and amount of drainage from all tubes and drains. All tubes should be patent, and tubes and suction equipment should be functioning. Drainage bags must be hanging properly.

Document the client's time of arrival and all assessments. Many agencies have progress flow records for this purpose. Alter the frequency, parameters, and priorities to meet the individual needs of the client.

Diagnosing

Because surgery can involve many body systems both directly and indirectly and is a complex experience for the client, the nursing diagnoses focus on a wide variety of actual, potential, and collaborative problems.

Actual and potential NANDA diagnoses (Herdman & Kamitsuru, 2014) for the postoperative client include the following:

- *Acute Pain*
- *Risk for Infection*
- *Risk for Injury*
- *Risk for Deficient Fluid Volume*
- *Ineffective Airway Clearance*
- *Ineffective Breathing Pattern*
- *Delayed Surgical Recovery*
- *Disturbed Body Image*.

Collaborative problems that may be experienced by the postoperative client are summarized in Table 37–4.

Planning

Postoperative care planning and discharge planning begin in the preoperative phase when preoperative teaching is implemented.

Planning for Home Care

To provide for continuity of care for the surgical client after discharge, the nurse needs to consider the client's needs for assistance with care

in the home setting. Discharge planning for both the day-surgery client and the client who has been hospitalized for several days following surgery incorporates an assessment of the client's and family's abilities for self-care, financial resources, and the need for referrals and home health services. The accompanying Home Care Assessment outlines a home care assessment for a surgical client; however, it is important to remember that surgical clients have diverse needs, and additional assessment data may be required. An individualized approach to surgical discharge planning must take into account the client's age, gender, surgical procedure, and family and community support for immediate and long-term nursing care in the home.

Implementing

Nursing interventions designed to promote client recovery and prevent complications include (a) pain management, (b) appropriate positioning, (c) incentive spirometry and deep-breathing and coughing exercises, (d) leg exercises, (e) early ambulation, (f) adequate hydration, (g) promoting urinary and gastrointestinal function, (h) diet, (i) suction maintenance, and (j) wound care.

Pain Management

Although pain is a sensory and emotional experience that serves to alert us to harm and initiate responses to avoid or minimize harm, pain in the surgical client has little protective value. It can, in fact, have detrimental effects, leading to stimulation of the sympathetic nervous system, tachycardia, shallow breathing, atelectasis, altered gas exchange, immobility, and immunosuppression. Chapter 46  provides a more in-depth discussion of pain and pain management.

Pain is usually greatest 12 to 36 hours after surgery, decreasing after the second or third postoperative day. During the initial postoperative period, patient-controlled analgesia (PCA) or continuous analgesic administration through an IV or epidural catheter is often prescribed. The nurse monitors the infusion or amount of analgesic administered by PCA, assesses the client's pain relief, and notifies the primary care provider if the client is experiencing unacceptable side effects or inadequate pain relief. As-needed (prn) parenteral or oral analgesics should be administered on a routine basis (every 2 to 6 hours, depending on the drug, route, and dose) for the first 24 to 36 hours. When routine analgesic administration is no longer

LIFESPAN CONSIDERATIONS Postoperative Care

CHILDREN

- Infants and young children may not be able to state their level of pain postoperatively, may be physically active, and may appear not to have much pain. Use nonverbal signs such as crying, fussiness, refusal to eat, disturbed sleep, increased heart rate, increased blood pressure, and agitation to assess pain.
- Children are often undermedicated for pain postoperatively. Nurses should be alert to subtle signs of pain and provide medication in a timely manner. Well-controlled pain levels facilitate the healing process in children.
 - Utilize a pediatric pain scale to assess pain.
- Some RR/PACUs allow parents to be present when their child wakes from surgery. Having the parent at the bedside has been shown to calm the child and reduce parental anxiety.

OLDER ADULTS

- Older adults have less efficient reserves and may take longer to recover postoperatively. Be attentive to vital signs,

intake and output, and mental status and note significant changes.

- Clients with dementia often experience an increase in confusion and agitation from the medications and anesthesia used during surgery. This poses a safety risk during the postoperative period and requires nursing staff to monitor these clients more frequently. It is important to maintain a calm, reassuring attitude. These changes are often long lasting, taking days or weeks to return to the preoperative level of cognition.
- Older adults may experience more fatigue and weakness after surgery. Encouraging activity is crucial, but it needs to be paced to prevent exhaustion.
- When surgery is done on an outpatient basis, nurses should follow up with phone calls that evening and the next day to check on the client's condition and make sure that postoperative instructions were understood.

Home Care Considerations Postoperative Instructions

PATIENT-CENTERED CARE

Adults want information about how their surgery and recovery period may affect activities they normally perform while recovering at home. This is important information for all surgical clients and particularly clients having outpatient surgery. Discuss the following areas:

- **Food.** Eat small portions at first because anesthesia and pain medications slow gastric emptying.
- **Bowel movements.** Constipation occurs frequently as a result of decreased gastrointestinal mobility due to many causes (e.g., anesthesia, decreased activity, pain medications). Discuss strategies to prevent constipation.
- **Sexual activity.** Intimacy such as gentle hugging and kissing is allowed for clients when they feel like it. Full sexual intercourse cannot be resumed until wound soreness and tenderness are resolved, approximately 2 to 4 weeks. Check with the surgeon for gynecologic procedures.
- **Wound care.** Discuss wound care, including the signs and symptoms of infection and when to notify the surgeon.
- **Lifting.** Be specific about weight limits, if appropriate. Relate the weight limit to everyday items (e.g., a gallon of milk weighs approximately 8 pounds).
- **Pain.** Provide information about the client's pain medications. Ask the client to describe his or her daily activities, and discuss ways to avoid or reduce painful activities.
- **Bathing.** Check with the surgeon because some prefer the wound to be kept dry. There is no evidence that water on a closed wound is harmful or interferes with wound healing. If allowed, inform the client to shower, letting the warm water wash over the incision and gently pat the incision dry.
- **Activities.** Advise the client that he or she will tire easily and to plan short activities with frequent rest breaks.

Home Care Assessment Surgical Clients

PATIENT-CENTERED CARE

CLIENT

- **Self-care abilities:** ability to manage hygiene and other self-care, to perform wound care as needed, to manage tubes and stomas, and to manage prescribed medications
- **Supplies required:** wound care supplies such as dressings, hypoallergenic tape, cleansing solutions, binders or slings, elastic wraps, irrigating syringe and solution
- **Assistive devices required:** walker, cane, raised toilet seat, commode, overhead trapeze, grab bars
- **Current level of knowledge:** postoperative pain management, wound care, dressing changes, urinary catheters or other drains, activity restrictions, dietary prescriptions, prescribed exercises (e.g., range of motion, postmastectomy exercises), infection control measures such as hand washing

FAMILY

- **Caregiver availability, skills, and responses:** willingness and ability to assume responsibility for care as needed (e.g., wound care, catheter and tube management, meal preparation, assistance with ADLs, shopping, transportation to and from appointments), other available caregivers

- **Family role changes and coping:** effect on parenting and spousal roles, sexuality, social roles, financial status
- **Financial resources:** ability to purchase necessary supplies and equipment; other sources of funding or financial assistance (e.g., Medicare, Medicaid)—see Chapter 6 ∞

HOME

- Elicit information from the client, the family, or significant other regarding the physical environment of the home and potential issues postoperatively. This may include presence of stairs, access to the home, and accessibility of the kitchen, bathroom, and bedroom.

COMMUNITY

- Available community resources such as equipment and supply companies, support and educational organizations and groups (e.g., ostomy clubs and Reach for Recovery), home health agencies or providers, access to pharmacy services, transportation services for medical care, Meals-on-Wheels, and other charitable support organizations

necessary, the prescribed analgesic is generally given before scheduled activities and rest periods.

An anti-inflammatory agent such as ibuprofen or ketorolac (Toradol) is often administered in conjunction with a narcotic analgesic to enhance pain relief. Clients need to be reminded that analgesics are most effective when taken on a regular basis or before pain becomes severe. Because muscle tension increases pain perception and responses, nurses need to use nonpharmacologic measures in addition to prescribed analgesia. These include ensuring that the client is warm and providing back rubs, position changes, diversional activities, and adjunctive measures such as imagery.

Positioning

Position the client as ordered. Clients who have had spinal anesthetics usually lie flat for 8 to 12 hours. An unconscious or semiconscious client is placed on one side with the head slightly elevated, if possible, or in a position that allows fluids to drain from the mouth. Unless contraindicated, elevation of affected extremities (e.g., following foot surgery) with the distal extremity higher than the heart promotes venous drainage and reduces swelling.

Deep-Breathing and Coughing Exercises

Deep-breathing exercises help remove mucus, which can form and remain in the lungs due to the effects of general anesthetic and analgesics. These drugs depress the action of both the cilia of the mucous membranes lining the respiratory tract and the respiratory center in the brain. By increasing lung expansion and preventing the accumulation of secretions, deep breathing helps prevent pneumonia and atelectasis, which may result from stagnation of fluid in the lungs.

An incentive spirometer is often ordered for the postoperative client to encourage deep breathing. This device measures the flow of air inhaled through a mouthpiece (see Chapter 50 ∞). The client is instructed to breathe in through the mouthpiece until a certain level is achieved (usually measured by a ball within an enclosed chamber). Inhalation and ventilation are enhanced using the incentive spirometer.

Deep breathing frequently initiates the coughing reflex. Voluntary coughing in conjunction with deep breathing facilitates the movement and expectoration of respiratory tract secretions.

Encourage the client to do deep-breathing and coughing exercises hourly, or at least every 2 hours, during waking hours for the

first few days. Assist the client to a sitting position in bed or on the side of the bed. The client can splint the incision with a pillow when coughing, or the nurse can splint the incision for the client to reduce discomfort.

Leg Exercises

Encourage the client to do leg exercises taught in the preoperative period every 1 to 2 hours during waking hours. Muscle contractions compress the veins, preventing the stasis of blood in the veins, a cause of **thrombus** (stationary clot adhered to the wall of a vessel) formation and subsequent **thrombophlebitis** (inflammation of a vein followed by formation of a blood clot) and **emboli** (a blood clot that has moved). Contractions also promote arterial blood flow.

Moving and Ambulation

Encourage the client to turn from side to side at least every 2 hours. Alternate turning allows for each lung to be in the uppermost position, allowing for maximum lung expansion. Avoid placing pillows or rolls under the client's knees because pressure on the popliteal blood vessels can interfere with blood circulation to and from the lower extremities. Clients who practice turning before surgery usually find it easier to do after surgery.

The client should ambulate as soon as possible after surgery in accordance with the surgeon's orders. Generally clients begin ambulation the evening of the day of surgery or the first day after surgery, unless contraindicated. Early ambulation prevents respiratory, circulatory, urinary, and gastrointestinal complications. It also prevents general muscle weakness. Schedule ambulation for periods after the client has taken an analgesic or when the client is comfortable. Ambulation should be gradual, starting with the client sitting on the bed and dangling the feet over the side. A client who cannot ambulate is periodically assisted to a sitting position in bed, if allowed, and turned frequently. The sitting position permits the greatest lung expansion.

Hydration

Maintain IV infusions as ordered to replace body fluids lost either before or during surgery. When oral intake is permitted, initially offer only small sips of water. Large amounts of water can induce vomiting because anesthetics and narcotic analgesics temporarily inhibit the motility of the stomach. The client who cannot take fluids by mouth may be allowed by the surgeon's orders to suck ice chips. Provide mouth care and place a mouthwash at the client's bedside. Postoperative clients often complain of thirst and a dry, sticky mouth. These discomforts are a result of the preoperative fasting period, preoperative medications (such as atropine), and loss of body fluid.

Measure the client's fluid intake and output for at least 2 days or until fluid balance is stable without an IV infusion. Ensuring adequate fluid balance is important. Sufficient fluids keep the respiratory mucous membranes and secretions moist, thus facilitating the expectoration of mucus during coughing. Also, an adequate fluid balance is important to maintain renal and cardiovascular function.

Urinary and Gastrointestinal Function

Anesthetic agents temporarily depress urinary bladder tone, which usually returns within 6 to 8 hours after surgery. Surgery in the pubic area, vagina, or rectum, during which the surgeon may manipulate the bladder, often causes urinary retention. Provide measures that promote urinary elimination. For example, help male clients stand at

the bedside, or female clients to a bedside commode if allowed, and ensure that fluid intake is adequate. Determine whether the client has any difficulties voiding and assess the client for bladder distention. Report to the surgeon if a client does not void within 8 hours following surgery, unless another time frame is specified.

If all measures to promote voiding fail, a urinary catheterization is often ordered (see Chapter 48 ∞). Measure the fluid intake and output (I&O) of all new postoperative clients. Generally I&O records are kept for at least 2 days or until the client reestablishes fluid balance without an IV or catheter in place.

Anesthetic agents, handling of the intestines during abdominal surgery, fasting, opioids for pain management, and inactivity all inhibit bowel peristalsis. Most clients regain bowel function several hours after surgery except in pelvic or abdominal surgery where the return is delayed for 24 to 48 hours or longer (Osborn, Wraa, Watson, & Holleran, 2010, p. 465). Assess the return of peristalsis by auscultating the abdomen. Gurgling and rumbling sounds indicate peristalsis. Bowel sounds should be carefully assessed every 4 to 6 hours. Oral fluids and food are usually started after the return of peristalsis.

Diet

The surgeon orders the client's postoperative diet. Depending on the extent of surgery and the organs involved, the client may be allowed nothing by mouth for several days or may be able to resume oral intake when nausea is no longer present. When "diet as tolerated" is ordered, offer clear liquids initially. If the client tolerates these with no nausea, the diet can often progress to full liquids and then to a regular diet, provided that gastrointestinal functioning is normal. Assist very weak clients to eat. Observe the client's tolerance of the food and fluids ingested and note and report the passage of flatus or abdominal distention.

Suction

Some clients return from surgery with a gastric or intestinal tube in place and orders to connect the tube to suction. For more information about gastrointestinal tubes, see Chapter 47 ∞. The suction ordered can be continuous or intermittent. Intermittent suction is applied when a single-lumen gastric tube is used to reduce the risk of damaging the mucous membrane near the distal port of the tube. Continuous suction may be applied if a double-lumen tube is in place (Figure 37-3 ■). Fluids and electrolytes must be replaced intravenously when gastric suction

Figure 37-3 ■ Nasogastric tubes used for gastric decompression. *Left:* Levin (single-lumen) tube; *right:* Salem sump (double-lumen) tube with antireflux valve.

or continuous drainage is ordered. Nasogastric tubes may be irrigated if the lumen becomes clogged. They are generally irrigated before and after tube feedings or the instillation of medications. Nasogastric

irrigation may require a primary care provider's order, particularly following gastrointestinal surgery. Skill 37-3 describes the management of gastrointestinal suction.

Managing Gastrointestinal Suction

PURPOSES

- To relieve abdominal distention
- To maintain gastric decompression after surgery
- To remove blood and secretions from the gastrointestinal tract
- To relieve discomfort (e.g., when a client has a bowel obstruction)
- To maintain the patency of the nasogastric tube

ASSESSMENT

Assess

- Presence of abdominal distention on palpation
- Bowel sounds
- Abdominal discomfort
- Vital signs for baseline data
- Amount and characteristics of drainage

PLANNING

Before initiating gastric suction, determine (a) whether the suction is continuous or intermittent, (b) the ordered suction pressure (a low suction pressure is between 80 and 100 mmHg, and a high pressure is between 100 and 120 mmHg), and (c) whether there is an order to irrigate the gastrointestinal tube and, if so, the type of solution to use.

DELEGATION

Managing gastrointestinal suction requires application of knowledge and problem solving and is not delegated to UAP. The UAP, however, can assist with emptying the drainage receptacle and reporting changes in amount and/or color of the drainage to the nurse.

Equipment

Initiating Suction

- Gastrointestinal tube in place in the client
- Basin

IMPLEMENTATION

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss the purpose(s) of the gastrointestinal suction.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.

Initiating Suction

4. Position the client appropriately.
 - Assist the client to a semi-Fowler's position if it is not contraindicated. **Rationale:** *In the semi-Fowler's position, the tube is not as likely to lie against the wall of the stomach and will therefore suction most efficiently. The semi-Fowler's position also prevents reflux of gastric contents, which could lead to aspiration.*
5. Confirm that the tube is in the stomach.
 - Apply clean gloves.
 - Check agency protocol for preferred methods to verify placement because clinical practice varies across health regions:
 - a. The method of inserting air into the tube with the syringe and listening with a stethoscope over the stomach (just below the xiphoid process) for a swish of air is often used at the bedside; however, a similar gurgling sound can be

- 50-mL syringe with an adapter
- Stethoscope
- Suction device for either continuous or intermittent suction
- Connector and connecting tubing
- Clean gloves

Maintaining Suction

- Graduated container as required to measure gastric drainage
- Basin of water
- Cotton-tipped applicators
- Ointment or lubricant
- Clean gloves

Irrigation

- Clean gloves
- Stethoscope
- Disposable irrigating set containing a sterile 50-mL syringe, moisture-resistant pad, basin, and graduated container
- Sterile normal saline (500 mL) or the ordered solution

heard when the tube is incorrectly placed in the lungs or esophagus (Lemyze, 2010) and recent evidence does not support this practice. For example, Tho, Mordiffi, Ang, and Chen (2011) found that there is "no evidence that supports the method of auscultation to confirm correct NG tube placement in the absence of aspirate" (p. 51). Furthermore, Boeykens, Steeman, and Duysburgh (2014) evaluated the auscultatory method and the pH measurement method and concluded that the auscultatory method was unreliable.

- b. Aspirate to obtain stomach contents. Secretions from the stomach are usually greenish but can be colorless with shreds of mucus. Distinguishing between respiratory and gastric secretions is subjective.
 - Check the acidity of gastric aspirate using a pH test strip. Gastric secretions often have a pH of 5 or less. The pH of the aspirate will increase if the client is on acid-inhibiting medication.
- c. X-ray examination is considered the gold standard for determining placement, especially for high-risk clients (e.g., critically ill, dysphagic, or unconscious).
- d. Use other methods in accordance with agency protocol. See Chapter 47 , Skill 47-1.
 - Remove and discard gloves.
 - Perform hand hygiene.

Managing Gastrointestinal Suction—continued

6. Set and check the suction.
 - Connect the appropriate suction regulator to the wall suction outlet and the collection device to the regulator. Intermittent suction regulators generally are used with single-lumen tubes and apply suction for a set interval (15 to 60 seconds), followed by an interval of no suction. Intermittent suction is set at 80 to 100 mmHg or as ordered by the primary care provider. Check the suction level by occluding the drainage tube and observing the regulator dial during a suction cycle. Continuous suction regulators are used with double-lumen (e.g., Salem sump) nasogastric tubes. Set continuous suction as ordered by the primary care provider, or at 60 to 120 mmHg.
 - If using a portable suction machine, turn on the machine and regulate the suction as above. The Gomco pump has two settings: low intermittent for single-lumen tubes, and high for double-lumen tubes.
 - Test for proper suctioning by holding the open end of the suction tube to the ear and listening for a sucking noise or by occluding the end of the tube with a thumb.
7. Establish gastric suction.
 - Connect the gastrointestinal tube to the tubing from the suction by using the connector.
 - If a Salem sump tube is in place, connect the larger lumen to the suction equipment. This double-lumen tube has a smaller tube running inside the primary suction tube. **Rationale:** *The smaller tube provides a continuous flow of atmospheric air through the drainage tube at its distal end and prevents excessive suction force on the gastric mucosa at the drainage outlets. Damage to the gastric mucosa is thus avoided.*
 - Always keep the air vent tube of a Salem sump tube open and above the level of the stomach when suction is applied. **Rationale:** *Closing the vent would stop the sump action and cause mucosal damage. Keeping the end of the air vent tube higher than the stomach prevents reflux of gastric contents into the air lumen of the tube.*
 - After suction is applied, watch the tubing for a few minutes until the gastric contents appear to be running through the tubing into the receptacle. A Salem sump tube makes a soft, hissing sound when it is functioning correctly.
 - If the suction is not working properly, check that all connections are tight and that the tubing is not kinked.
 - Coil and pin the tubing to the client's gown so that it does not loop below the suction bottle. **Rationale:** *If the tubing falls below the suction bottle, the suction may be obstructed because of the pressure required to push the fluid against gravity.*
8. Assess the drainage.
 - Observe the amount, color, odor, and consistency of the drainage. Normal gastric drainage has a mucoid (resembling mucus) consistency and is either colorless or yellow-green because of the presence of bile. A coffee-ground color and consistency may indicate bleeding.
 - Test the gastric drainage for pH and blood when indicated. A person who has had gastrointestinal surgery can be expected to have some blood in the drainage.

Maintaining Suction

9. Assess the client and the suction system regularly.
 - Assess the client every 30 minutes until the system is running effectively and then every 2 hours, or as the client's health indicates, to ensure that the suction is functioning properly. If the client complains of fullness, nausea, or epigastric pain or if the flow of gastric secretions is absent in the tubing or in the collection bottle, ineffective suctioning or blockage of the nasogastric tube is likely.
 - Inspect the suction system for patency of the system (e.g., kinks or blockages in the tubing) and tightness of the

connections. **Rationale:** *Loose connections can permit air to enter and thus decrease the effectiveness of the suction by decreasing the negative pressure.*

10. Relieve blockages if present.
 - Perform hand hygiene.
 - Apply clean gloves.
 - Check the suction equipment. To do this, disconnect the nasogastric tube from the suction over a collecting basin (to collect gastric drainage), and then, with the suction on, place the end of the suction tubing in a basin of water. If water is drawn into the drainage bottle, the suction equipment is functioning properly, but the nasogastric tube is either blocked or positioned incorrectly.
 - Reposition the client (e.g., to the other side) if permitted. **Rationale:** *This may facilitate drainage.*
 - Rotate the nasogastric tube and reposition it. This step is contraindicated for clients with gastric surgery. **Rationale:** *Moving the tube may interfere with gastric sutures.*
 - Irrigate the nasogastric tube as agency protocol states or on the order of the primary care provider (see steps 14 to 16).
 - Remove and discard gloves.
 - Perform hand hygiene.
11. Prevent reflux into the vent lumen of a Salem sump tube.

Rationale: *Reflux of gastric contents into the vent lumen may occur when stomach pressure exceeds atmospheric pressure. In this situation, gastric contents follow the path of least resistance and flow out the vent lumen rather than the drainage lumen.*

To prevent reflux:

 - Place the vent tubing higher than the client's stomach to prevent gastric fluid backup into the blue lumen air vent.
 - Keep the drainage lumen free of particulate matter that may obstruct the lumen (see steps 14 to 16 for irrigating a nasogastric tube).
12. Ensure client comfort.
 - Clean the client's nostrils as needed, using the cotton-tipped applicators and water. Apply a water-soluble lubricant or ointment.
 - Provide mouth care every 2 to 4 hours and as needed. Some postoperative clients are permitted to suck ice chips or a moist cloth to maintain the moisture of the oral mucous membranes.
13. Change the drainage receptacle according to agency policy.
 - Clamp the nasogastric tube and turn off the suction.
 - Apply clean gloves.
 - If the receptacle is graduated, determine the amount of drainage.
 - Disconnect the receptacle.
 - Inspect the drainage carefully for color, consistency, and presence of substances (e.g., blood clots).
 - Replace a full receptacle and attach it to the suction. Check agency policy.
 - Turn on the suction and unclamp the nasogastric tube.
 - Observe the system for several minutes to make sure function is reestablished.
 - Remove and discard gloves.
 - Perform hand hygiene.
 - Go to step 17.

Irrigating a Gastrointestinal Tube

14. Prepare the client and the equipment.
 - Place the moisture-resistant pad under the end of the gastrointestinal tube.
 - Turn off the suction.
 - Apply clean gloves.
 - Disconnect the gastrointestinal tube from the connector.
 - Determine that the tube is in the stomach. See step 5. **Rationale:** *This ensures that the irrigating solution enters the client's stomach.*

Managing Gastrointestinal Suction—continued

15. Irrigate the tube.

- Draw up the ordered volume of irrigating solution in the syringe; 30 mL of solution per instillation is usual, but up to 60 mL may be given per instillation if ordered.
- Attach the syringe to the nasogastric tube and slowly inject the solution.
- Gently aspirate the solution. **Rationale:** *Forceful withdrawal could damage the gastric mucosa.*
- If you encounter difficulty in withdrawing the solution, inject 20 mL of air and aspirate again, and/or reposition the client or the nasogastric tube. **Rationale:** *Air and repositioning may move the end of the tube away from the stomach wall.* If aspirating difficulty continues, reattach the tube and set to intermittent low suction, and notify the nurse in charge.
- Repeat the preceding steps until the ordered amount of solution is used.
- **Note:** A Salem sump tube can also be irrigated through the vent lumen without interrupting suction. However, only small quantities of irrigant can be injected via this lumen compared to the drainage lumen.
- After irrigating a Salem sump tube, inject 10 to 20 mL of air into the vent lumen while applying suction to the drainage lumen. **Rationale:** *This tests the patency of the vent and ensures sump functioning.*

16. Reestablish suction.

- Reconnect the nasogastric tube to suction.

- If a Salem sump tube is used, inject the air vent lumen with 10 mL of air after reconnecting the tube to suction.
- Observe the system for several minutes to make sure it is functioning.
- Remove and discard gloves.
- Perform hand hygiene.

17. Document all relevant information.

- Record the time suction was started. Also record the pressure established, the color and consistency of the drainage, and nursing assessments.
- During maintenance, record assessments, supportive nursing measures, and data about the suction system.
- When irrigating the tube, record verification of tube placement; the time of the irrigation; the amount and type of irrigating solution used; the amount, color, and consistency of the returns; the patency of the system following the irrigation; and nursing assessments.

SAMPLE DOCUMENTATION

3/20/2015 1300 Returned from PACU. Salem sump tube in place and connected to low continuous suction. Checked for correct placement. Draining small to moderate amount of tannish fluid.
 _____ R. Martinez, RN

EVALUATION

- Conduct appropriate follow-up such as relief of abdominal distention or discomfort, bowel sounds, character and amount of gastric drainage, integrity of nares, hydration of oral mucous membranes, patency of tube, and system functioning.
- Compare to previous findings if available.
- Report significant deviations from normal to the primary care provider.

Home Care Considerations GI Suction

PATIENT-CENTERED CARE

Instruct the caregiver to:

- Maintain suction as ordered; do *not* increase or decrease the suction without instructions from the nurse or primary care provider.
- Offer mouth care every 2 hours.

- Avoid tension and pulling on the tube by securing it to the gown.
- Check the patency of the tube if nausea or vomiting occurs.
- Report an increasing amount of bloody drainage.

Suction may also be applied to other drainage tubes such as chest tubes or a wound drain. The type and amount of suction is ordered by the primary care provider. Most agencies have wall suction units available (Figure 37-4 ■). A suction regulator with a drainage receptacle connects to a wall outlet that provides negative pressure. Check the receptacle frequently to prevent excess drainage from interfering with the suction apparatus; empty or change the receptacle according to agency policy. Portable electric suction units or pumps (e.g., the Gomco pump) may be used in the home or when wall suction is not available.

Wound Care

Most clients return from surgery with a sutured wound covered by a dressing, although in some cases the wound may be left unsutured. Dressings are inspected regularly to ensure that they are clean, dry,

and intact. Excessive drainage may indicate hemorrhage, infection, or an open wound.

When dressings are changed, the nurse assesses the wound for appearance, size, drainage, swelling, pain, and the status of a drain or tubes. Details about these assessments are outlined in the accompanying Practice Guidelines.

Because surgical incisions heal by primary intention, the nurse can expect the following sequential signs of healing:

1. **Absence of bleeding and the appearance of a clot binding the wound edges.** The wound edges are well approximated and bound by fibrin in the clot within the first few hours after surgical closure.
2. **Inflammation (redness and swelling) at the wound edges for 1 to 3 days.**

Figure 37-4 ■ Wall suction unit for generating negative pressure for nasogastric suction.

3. **Reduction in inflammation when the clot diminishes**, as granulation tissue starts to bridge the area. The wound is bridged and closed within 7 to 10 days. Increased inflammation associated with fever and drainage is indicative of wound infection; the wound edges then appear brightly inflamed and swollen.

PRACTICE GUIDELINES

Assessing Surgical Wounds

APPEARANCE

- Inspect color of wound and surrounding area and approximation of wound edges.

SIZE

- Note size and location of dehiscence, if present.

DRAINAGE

- Observe location, color, consistency, odor, and degree of saturation of dressings. Note number of gauzes saturated or diameter of drainage on gauze.

SWELLING

- Observe the amount of swelling; minimal to moderate swelling is normal in early stages of wound healing.

PAIN

- Expect severe to moderate postoperative pain for 3 to 5 days; persistent severe pain or sudden onset of severe pain may indicate internal hemorrhaging or infection.

DRAINS OR TUBES

- Inspect drain security and placement, amount and character of drainage, and functioning of collecting apparatus, if present.

4. **Scar formation.** Collagen synthesis starts 4 days after injury and continues for 6 months or longer.
5. **Diminished scar size over a period of months or years.** An increase in scar size indicates keloid formation.

See Chapter 36 ∞ for information about wound drainage, cleaning wounds, wound irrigation, hot and cold applications, and supporting and immobilizing wounds.

CLINICAL ALERT!

Assess the client immediately if he or she reports a “giving” or “popping” sensation in the incisional area. The client may be experiencing dehiscence or evisceration of the wound.

Surgical Dressings

Not all surgical dressings require changing. Sometimes surgeons in the operating room apply a dressing that remains in place until the sutures are removed, and no further dressings are required. In many situations, however, surgical dressings are changed regularly to prevent the growth of microorganisms.

In some instances a client may have a Penrose drain inserted (see the next section). In this situation the main surgical incision is considered cleaner than the surgical stab wound made for the drain insertion, because there is usually considerable drainage. The main incision is therefore cleaned first, and under no circumstances are materials that were used to clean the stab wound used subsequently to clean the main incision. In this way, the main incision is kept free of the microorganisms around the stab wound. Cleaning a wound and applying a sterile dressing are detailed in Skill 37-4.

Cleaning a Sutured Wound and Changing a Dressing on a Wound with a Drain

PURPOSES

- To promote wound healing by primary intention
- To prevent infection
- To assess the healing process
- To protect the wound from mechanical trauma

ASSESSMENT

Assess

- Client allergies to wound cleaning agents
- The appearance and size of the wound
- The amount and character of exudates
- Client complaints of discomfort
- The time of the last pain medication
- Signs of systemic infection (e.g., elevated body temperature, diaphoresis, malaise, leukocytosis)

Cleaning a Sutured Wound and Changing a Dressing on a Wound with a Drain—continued

PLANNING

Before changing a dressing, determine any specific orders about the wound or dressing.

DELEGATION

Cleaning a newly sutured wound, especially one with a drain, requires application of knowledge, problem solving, and aseptic technique. As a result, this procedure is not delegated to UAP. The nurse can ask the UAP to report soiled dressings that need to be changed or if a dressing has become loose and needs to be reinforced. The nurse is responsible for the assessment and evaluation of the wound.

Equipment

- Bath blanket (if necessary)
- Moisture-proof bag

IMPLEMENTATION

Preparation

Prepare the client and assemble the equipment.

- Obtain assistance for changing a dressing on a restless or confused adult. **Rationale:** *The person might move and contaminate the sterile field or the wound.*
- Assist the client to a comfortable position in which the wound can be readily exposed. Expose only the wound area, using a bath blanket to cover the client, if necessary. **Rationale:** *Undue exposure is physically and psychologically distressing to most people.*
- Make a cuff on the moisture-proof bag for disposal of the soiled dressings, and place the bag within reach. **Rationale:** *Making a cuff helps keep the outside of the bag free from contamination by the soiled dressings and prevents subsequent contamination of the nurse's hands or of sterile instrument tips when discarding dressing or sponges. Placement of the bag within reach prevents the nurse from reaching across the sterile field and the wound and potentially contaminating these areas.*
- Apply a face mask, if required. **Rationale:** *Some agencies require that a mask be worn for surgical dressing changes to prevent contamination of the wound by droplet spray from the nurse's respiratory tract.*

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss how the results will be used in planning further care or treatments.
2. Perform hand hygiene and observe other appropriate prevention control procedures.
3. Provide for client privacy.
4. Remove binders (see Chapter 36 ) and tape.
 - Remove binders, if used, and place them aside. Untie tie tapes, if used. Montgomery straps (tie tapes) are commonly used for wounds requiring frequent dressing changes. ① **Rationale:** *These straps prevent skin irritation and discomfort caused by removing the adhesive each time the dressing is changed.*
 - If adhesive tape was used, remove it by holding down the skin and pulling the tape gently but firmly toward the wound. **Rationale:** *Pressing down on the skin provides countertraction against the pulling motion. Tape is pulled toward the incision to prevent strain on the sutures or wound.*
5. Remove and dispose of soiled dressings appropriately.
 - Apply clean gloves and remove the outer abdominal dressing or surgipad.

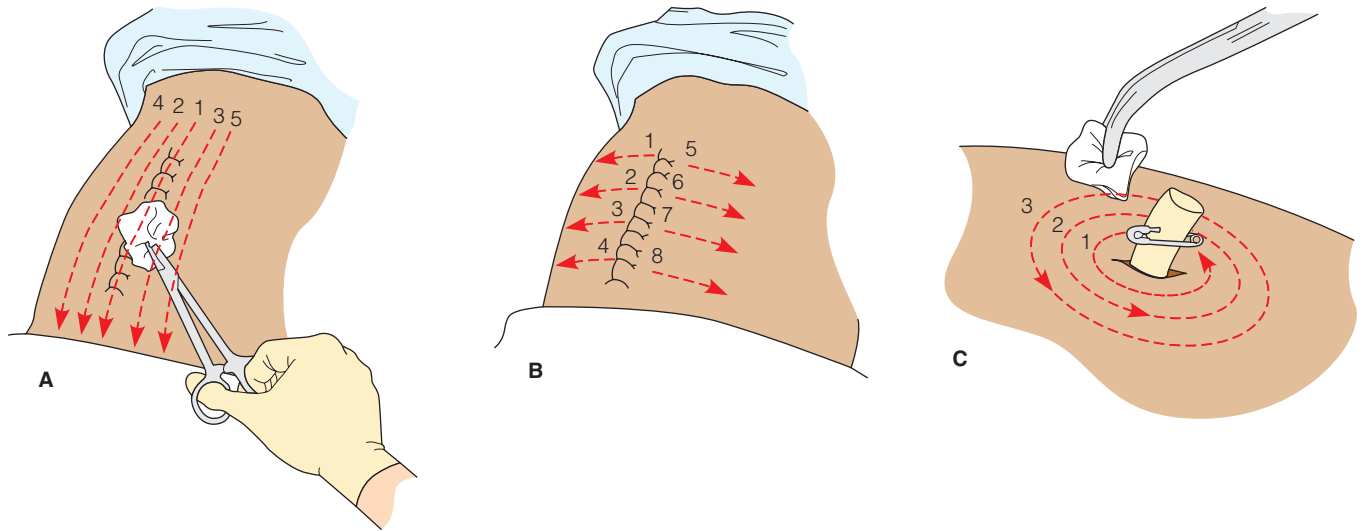

- Mask (optional)
- Acetone or another solution (if necessary to loosen adhesive)
- Clean gloves
- Sterile gloves
- Sterile dressing set; if none is available, gather the following sterile items:
 - Drape or towel
 - Gauze squares
 - Container for cleaning solution
 - Cleaning solution (e.g., normal saline)
 - Two pairs of forceps
 - Gauze dressings and surgipads
 - Applicators or tongue blades to apply ointments
- Additional supplies required for the particular dressing (e.g., extra gauze dressings and ointment, if ordered)
- Tape, tie tapes, or binder

① Montgomery straps holding dressing.

- Lift the outer dressing so that the underside is away from the client's face. **Rationale:** *The appearance and odor of the drainage may be upsetting to the client.*
- Place the soiled dressing in the moisture-proof bag without touching the outside of the bag. **Rationale:** *Contamination of the outside of the bag is avoided to prevent the spread of microorganisms to the nurse and subsequently to others.*
- Remove the underdressings, taking care not to dislodge any drains. If the gauze sticks to the drain, support the drain with one hand and remove the gauze with the other.
- Assess the location, type (color, consistency), and odor of wound drainage, and the number of gauzes saturated or the diameter of drainage collected on the dressings.
- Discard the soiled dressings in the bag as before.
- Remove and discard gloves in the moisture-proof bag.
- Perform hand hygiene.
- 6. Set up the sterile supplies.
 - Open the sterile dressing set, using surgical aseptic technique.
 - Place the sterile drape beside the wound.
 - Open the sterile cleaning solution and pour it over the gauze sponges in the plastic container.
 - Apply sterile gloves.
- 7. Clean the wound, if indicated.
 - Clean the wound, using your gloved hands or forceps and gauze swabs moistened with cleaning solution.

Cleaning a Sutured Wound and Changing a Dressing on a Wound with a Drain—continued

2 Methods of cleaning surgical wounds: A, cleaning the wound from top to bottom, starting at the center; B, cleaning a wound outward from the incision; C, cleaning around a Penrose drain site. For all methods, a clean sterile swab is used for each stroke.

- If using forceps, keep the forceps tips lower than the handles at all times. **Rationale:** This prevents their contamination by fluid traveling up to the handle and nurse’s wrist and back to the tips.
 - Use the cleaning methods illustrated and described in 2 or one recommended by agency protocol.
 - Use a separate swab for each stroke and discard each swab after use. **Rationale:** This prevents the introduction of microorganisms to other wound areas.
 - If a drain is present, clean it next, taking care to avoid reaching across the cleaned incision. Clean the skin around the drain site by swabbing in half or full circles from around the drain site outward, using separate swabs for each wipe 2 C.
 - Support and hold the drain erect while cleaning around it. Clean as many times as necessary to remove the drainage.
 - Dry the surrounding skin with dry gauze swabs as required. Do not dry the incision or wound itself. **Rationale:** Moisture facilitates wound healing.
8. Apply dressings to the drain site and the incision.
- Place a precut 4×4 gauze snugly around the drain 3, or open a 4×4 gauze to 4×8 in., fold it lengthwise to 2×8 in., and place it around the drain so that the ends overlap. **Rationale:** This dressing absorbs the drainage and helps prevent it from excoriating the skin. Using precut gauze or folding it as described, instead of cutting the gauze, prevents any threads from coming loose and getting into the wound, where they could cause inflammation and provide a site for infection.
 - Apply the sterile dressings one at a time over the drain and the incision. Place the bulk of the dressings over the drain

3 Precut gauze in place around a Penrose drain.

area and below the drain, depending on the client’s usual position. **Rationale:** Layers of dressings are placed for best absorption of drainage, which flows by gravity.

- Apply the final surgipad. Remove and discard gloves. Secure the dressing with tape or ties.
- Perform hand hygiene.

9. Document the procedure and all nursing assessments.

SAMPLE DOCUMENTATION

3/21/2015 1100 Abdominal dressing changed. Small amount of serosanguineous drainage—size of a half dollar—in middle of dressing. Incision approximated with slight redness at edges. Sutures intact _____ S. Jones, RN

EVALUATION

- Conduct appropriate follow-up, such as amount of granulation tissue or degree of healing; amount of drainage and its color, consistency, and odor; presence of inflammation; and degree of discomfort associated with the incision or drain site.
- Compare to previous findings, if available.
- Report significant deviations from normal to the primary care provider.

Home Care Considerations Cleaning a Sutured Wound

PATIENT-CENTERED CARE

Instruct caregivers to:

- Provide pain medication approximately 30 minutes before the procedure if the wound care causes pain or discomfort.
- Wash hands thoroughly and dry prior to handling wound care supplies and providing wound care.
- Clean and wipe dry a flat surface for the sterile field.
- Keep pets out of the area when setting up for and performing sterile procedures.
- Acquire all needed supplies before starting a sterile procedure.
- Maintain sterile or clean technique as instructed.
- Handle all sterile supplies from the outside of the wrapper or the edges.
- Do not touch the parts of supplies or equipment that will touch the client.
- Avoid skin injury by using paper tape or Montgomery straps instead of adhesive tape.
- Report any increasing wound drainage, pain, or redness, increasing swelling, or opening or gaping of wound edges.
- Place any soiled dressing materials in a waterproof bag and dispose of it according to public health recommendations.

Wound Drains and Suction

Surgical drains are inserted to permit the drainage of excessive sero-sanguineous fluid and purulent material and to promote healing of underlying tissues. These drains may be inserted and sutured through the incision line, but they are most commonly inserted through stab wounds a few centimeters away from the incision line so that the incision itself may be kept dry. Without a drain, some wounds would heal on the surface and trap the discharge inside, and an abscess might form. These drains (e.g., the **Penrose drain**) have an open end that drains onto a dressing.

A **closed-wound drainage system** consists of a drain connected to either an electric suction or a portable drainage suction, such as a Hemovac (Figure 37-5 ■) or Jackson-Pratt (Figure 37-6 ■). The closed system reduces the potential entry of microorganisms into the wound through the drain. The drainage tubes are sutured in place and connected to a reservoir. For example, the Jackson-Pratt drainage tube is connected to a reservoir that maintains constant low suction. These portable wound suctions also provide for accurate measurement of the drainage.

The surgeon inserts the wound drainage tube during surgery. Generally the suction is discontinued from 3 to 5 days postoperatively or when the drainage is minimal. Nurses are responsible for maintaining the wound suction, which hastens the healing process by draining excess exudate that might otherwise interfere with the formation of granulation tissue.

Closed-wound drainage systems have directions for use printed on the drainage container. When emptying the container,

the nurse should wear gloves and avoid touching the drainage port (Figure 37-7 ■). To reestablish suction, the nurse places the container on a solid, flat surface with the port open. The palm of one hand presses the top and bottom together while the other hand cleanses the opening and plug with an alcohol swab (Figure 37-8 ■). Replace the drainage plug before releasing hand pressure to reestablish the vacuum necessary for the closed drainage system to work.

Figure 37-6 ■ Two Jackson-Pratt devices compressed to facilitate collection of exudates.

Figure 37-5 ■ Hemovac closed-wound drainage system.

Figure 37-7 ■ Emptying drainage from Hemovac drainage system.

Home Care Considerations Closed-Wound Drainage System

PATIENT-CENTERED CARE

- Schedule regular nursing visits to teach wound care and to observe the drainage site.
- Teach the client or caregiver to empty, measure, and record the drainage at least once daily.
- Instruct the caregiver to observe the wound daily for signs of infection, such as redness, edema, tenderness, or purulent drainage. The client's temperature should be measured twice daily. **Rationale:** *Elevated temperature can indicate infection.*
- Ensure that the client has the proper supplies and knows how to obtain new items as needed.
- Notify the primary care provider of excess drainage, signs of infection, or occlusion of the tube.
- Determine when the primary care provider plans to remove the drain, and help the client keep the appointment.

Figure 37-8 ■ With one hand, press the top and bottom together. With the other hand, clean the opening and plug with an alcohol swab. Replace the plug before releasing hand.

Figure 37-9 ■ A surgical incision with retention sutures.
B. Slaven/Custom Medical Stock Photo.

Sutures

A **suture** is a thread used to sew body tissues together. Sutures used to attach tissues beneath the skin are often made of an absorbable material that disappears in several days. Skin sutures, by contrast, are made of a variety of nonabsorbable materials, such as silk, cotton, linen, wire, nylon, and Dacron (polyester fiber). Silver wire clips or staples are also available. Usually skin sutures are removed 7 to 10 days after surgery.

Various suturing methods are used. Skin sutures can be broadly categorized as either interrupted (each stitch is tied and knotted separately) or continuous (one thread runs in a series of stitches and is tied only at the beginning and at the end of the run).

Retention sutures are very large sutures used in addition to skin sutures for some incisions (Figure 37-9 ■). They attach underlying tissues of fat and muscle as well as skin and are used to support incisions in individuals who are obese or when healing may be prolonged. They are frequently left in place longer than skin sutures (14 to 21 days) but in some instances are removed at the same time as the skin sutures. To prevent these large sutures from irritating the incision, the surgeon may place rubber tubing over them or a roll of gauze under them extending down the incision line.

The primary care provider orders the removal of sutures. In some agencies, only primary care providers remove sutures; in others, registered nurses and nursing students with appropriate supervision may do so. Agency policies about removal of retention sutures vary. The nurse should verify whether they are to be removed and who may remove them.

Figure 37-10 ■ Contents of a suture removal tray.

Sterile technique and special suture scissors are used in suture removal. The scissors have a short, curved cutting tip that readily slides under the suture (Figure 37-10 ■). Wire clips or staples are removed with a special instrument that squeezes the center of the clip to remove it from the skin (Figure 37-11 ■). Guidelines for removing sutures and staples follow:

- Before removing skin sutures, verify (a) the orders for suture removal (in many instances, only *alternate* sutures are removed one day, and the remaining sutures are removed a day or two later) and (b) whether a dressing is to be applied following the suture

Figure 37-11 ■ Staple remover.

removal. Some primary care providers prefer no dressing; others prefer a small, light gauze dressing to prevent friction from clothing.

- Inform the client that suture removal may produce slight discomfort, such as a pulling or stinging sensation, but should not be painful.
- Remove dressings and clean the incision in accordance with agency protocol. Cleaning the suture line with an antimicrobial solution before and after suture removal may help prevent infection.
- Apply sterile gloves.
- Remove sutures as follows:
 - a. Grasp the suture at the knot with a pair of forceps.
 - b. Place the curved tip of the suture scissors under the suture as close to the skin as possible, either on the side opposite the knot (Figure 37-12 ■) or directly under the knot. Cut the suture. Sutures are cut as close to the skin as possible on one side of the visible part because the suture material that is visible to the eye is in contact with resident bacteria of the skin and must not be pulled beneath the skin during removal. Suture material that is beneath the skin is considered free from bacteria.

Figure 37-12 ■ Removing a skin suture.
Bojan Fatur/Getty Images.

- c. With the forceps or hemostat, pull the suture out in one piece. Inspect the suture carefully to make sure that all suture material is removed. Suture material left beneath the skin acts as a foreign body and causes inflammation.
- Discard the suture onto a piece of sterile gauze or into the moisture-proof bag, being careful not to contaminate the forceps tips.
 - Continue to remove alternate sutures, that is, the third, fifth, seventh, and so forth. Alternate sutures are removed first so that remaining sutures keep the skin edges in close approximation and prevent any dehiscence from becoming large.
 - If no dehiscence occurs, remove the remaining sutures. If dehiscence does occur, do not remove the remaining sutures, and report the dehiscence to the nurse in charge.
 - If Steri-Strips are ordered by the primary care provider, apply them to the wound after removing the sutures or clips. Some primary care providers order Steri-Strip application to provide additional support to the healing wound.
 - Reapply a dressing, if indicated.
 - Document the suture removal; number of sutures removed; appearance of the incision; application of a dressing, Steri-Strips, or butterfly tapes (if appropriate); client teaching; and client tolerance of the procedure.
 - Remove staples as follows:
 - a. Remove dressings and clean the incision in accordance with agency protocol.
 - b. Place the lower tips of a sterile staple remover under the staple.
 - c. Squeeze the handles together until they are completely closed (Figure 37-13 ■). Pressing the handles together causes the staple to bend in the middle and pulls the edges of the staple out of the skin. Do not lift the staple remover when squeezing the handles.
 - d. When both ends of the staple are visible, gently move the staple away from the incision site.
 - e. Hold the staple remover over a disposable container and release the staple remover handles, which releases the staple.

Home Care Teaching

To ensure continuity of care and restoration of the client's health, nurses must meet the learning needs of clients and their support

Figure 37-13 ■ Removing surgical clips or staples.

Home Care Considerations Removing Sutures or Staples**PATIENT-CENTERED CARE**

- | | |
|---|---|
| <ul style="list-style-type: none"> • Perform the procedure in a well-lighted, private area of the home. • Instruct the client to observe the incision daily and call the health care provider if increased redness, drainage, or open areas are observed. | <ul style="list-style-type: none"> • Provide instructions and supplies for care of the incision, and tell the client when to shower for the first time. • Assess the client's ability to keep the incision clean and protected at home. |
|---|---|

people. Teaching should focus on actions to maintain comfort, to promote healing and restore wellness, and to make use of appropriate community agencies and other sources of help.

Maintaining Comfort

- Instruct the client to use pain medications as ordered, not allowing pain to become severe before taking the prescribed dose.
- If not contraindicated, discuss the use of OTC analgesics such as aspirin or acetaminophen as postoperative pain becomes less severe or if the client is reluctant to use prescription drugs due to side effects.
- Teach the client to avoid using alcohol or other central nervous system depressants while taking narcotic analgesics.
- Discuss the importance of gradually resuming activities, avoiding overexertion.
- Emphasize the importance of paying attention to increasing pain or discomfort. Instruct the client to contact the primary care provider if pain increases after a period of decreasing discomfort.
- Teach the client to use nonpharmacologic measures to help manage pain, such as conscious relaxation, distraction, meditation, or visualization.

Promoting Healing

- If indicated, teach the client how to change wound dressings and perform wound care.
- Emphasize the importance of hygiene and hand washing to prevent infections.
- Instruct the client to report promptly to the primary care provider any increasing redness, swelling, pain, or discharge from the incision or drain sites.
- Discuss any prescribed activity restrictions such as avoiding lifting.
- Discuss the importance of keeping follow-up appointments to monitor healing and recovery after surgery.

Restoring Wellness

- Discuss the relationship of increasing activities to restoring wellness and promoting a sense of well-being.
- Teach the client that surgery and stressors can depress immune function and to avoid exposure to illness (e.g., crowded areas and people with upper respiratory illnesses) whenever possible.
- Emphasize the importance of adequate rest for healing and immune function.

- If appropriate, discuss lifestyle changes to promote wellness, such as smoking cessation, increasing activity level, reducing stress, and consuming a healthy diet high in fruits, vegetables, and whole grains with adequate protein to promote healing.

Community Agencies and Other Sources of Help

- Provide information about where durable medical equipment can be purchased, rented, or obtained free of charge; how to access home health and other services; and where to obtain supplies such as dressings or nutritional supplements.
- Suggest additional sources of information, such as the National Rehabilitation Information Center, Reach to Recovery, and United Ostomy Association.

Referrals

The nurse needs to consider appropriate referrals for the client, such as:

- Home health agencies for wound care and assessment and for assistance with ADLs if necessary
- Community social services for assistance in obtaining medical and assistive equipment
- Respiratory, physical, or occupational therapy services as indicated.

Evaluating

Using the goals developed during the planning stage, the nurse collects data to evaluate whether the identified goals and desired outcomes have been achieved. If the desired outcomes are not achieved, the nurse and client, and support people, if appropriate, need to explore the reasons before modifying the care plan. For example, if the outcome "Pain control" is not met, questions to be considered include:

- What is the client's perception of the problem?
- Does the client understand how to use PCA?
- Is the prescribed analgesic dose adequate for the client?
- Is the client allowing pain to become intense prior to requesting medication or using PCA?
- Where is the client's pain? Could it be due to a problem unrelated to surgery (e.g., chronic arthritis, anginal pain)?
- Is there evidence of a complication that could cause increased pain (an infection, abscess, or hematoma)?

Critical Thinking Checkpoint

Mr. Teng is a 77-year-old client with a history of chronic obstructive pulmonary disease. Currently his respiratory condition is being controlled with medications and he is free of infection. He has just been transferred to the postanesthesia care unit following a hernia repair performed under spinal anesthesia. His blood pressure is 132/88 mmHg, pulse 84 beats/min, respirations 28/min, and tympanic temperature 36.5°C (97.8°F). He is awake and stable.

1. What factors place Mr. Teng at increased risk for the development of complications during and after surgery?
2. Speculate about why Mr. Teng's surgeon and anesthesiologist decided to perform Mr. Teng's surgery under regional anesthesia as opposed to general anesthesia.

3. What preparations were taken during the preoperative period to protect Mr. Teng from possible complications during and after his surgery?
4. How will Mr. Teng's postoperative assessments differ from those of a person who received general anesthesia?
5. What postoperative precautions are especially important to Mr. Teng in view of his chronic lung condition?

See Critical Thinking Possibilities on student resource website.

Chapter 37 Review

CHAPTER HIGHLIGHTS

- Surgery is a unique experience that creates stress and necessitates physical and psychological changes.
- The perioperative period includes three phases: preoperative, intraoperative, and postoperative.
- Surgical procedures are categorized by purpose, degree of urgency, and degree of risk.
- Factors such as age, general health, nutritional status, presence of sleep apnea, medication use, and mental status affect a client's risk during surgery.
- Clients must agree to surgery via informed consent and sign a consent form.
- Nursing history and physical assessment data are important sources for planning preoperative and postoperative care.
- The overall goal of nursing care during the preoperative phase is to prepare the client mentally and physically for surgery.
- Preoperative teaching includes situational information such as expected sensations and discomfort, psychosocial support, the role of the client throughout the perioperative period, and training for the postoperative period. Many aspects of preoperative teaching are intended to prevent postoperative complications.
- Preoperative teaching should include moving, leg exercises, and deep-breathing and coughing exercises.
- Physical preparation includes the following areas: nutrition and fluids, elimination, hygiene, medications, sleep, care of valuables and prostheses, special orders, and surgical skin preparation.
- A preoperative checklist provides a guide to and documentation of a client's preparation before surgery.
- Antiemboli stockings or sequential compression devices may be ordered for some clients to facilitate venous return.
- Maintaining the client's safety and homeostasis are the overall goals of nursing care during the intraoperative phase.
- Anesthesia may be general or regional. Regional anesthesia includes topical, local, nerve block, spinal anesthesia (subarachnoid block), and epidural.
- A surgical skin preparation should be carried out as close to the time of surgery as possible and is commonly performed during the intraoperative phase.
- Positioning of the client during surgery is important to reduce the risk of tissue and nerve damage.
- Immediate postanesthetic care focuses on assessment and monitoring parameters to prevent complications from anesthesia or surgery.
- Initial and ongoing assessment of the postoperative client includes level of consciousness; vital signs, including oxygen saturation; skin color and temperature; comfort; fluid balance; and dressings, bedclothes, drains, and tubes.
- Ongoing postoperative nursing interventions include (a) managing pain, (b) appropriate positioning, (c) encouraging incentive spirometry and deep-breathing and coughing exercises, (d) promoting leg exercises and early ambulation, (e) maintaining adequate hydration and nutritional status, (f) promoting urinary elimination, (g) continuing gastrointestinal suction, and (h) providing wound care.
- Surgical aseptic technique (sterile technique) is used when changing dressings on surgical wounds to promote healing and reduce the risk of infection.
- Hemovac and Jackson-Pratt drainage systems are examples of drains that may be placed in or near surgical wounds to promote drainage of excess serosanguineous or purulent exudate.
- Sutures, wire clips, or staples are used to approximate skin and underlying tissues after surgery. These are generally removed 7 to 10 days after surgery.

TEST YOUR KNOWLEDGE

- Which test is the best resource for determining the preoperative status of a client's liver function?
 - Serum electrolytes
 - Blood urea nitrogen (BUN), creatinine
 - Alanine aminotransferase (ALT), aspartate aminotransferase (AST), bilirubin
 - Serum albumin
- A client who is having a mastectomy expresses sadness about losing her breast. Based on this information, the nurse would identify that the client is at risk for which nursing diagnosis?
 - Disturbed Body Image*
 - Grieving*
 - Fear*
 - Ineffective Coping*
- Which statement by the client indicates that the preoperative teaching regarding gallbladder surgery has been effective?
 - "I cannot eat or drink anything after midnight."
 - "I'm not going to cough after surgery because it might open my incision."
 - "I might have a stroke if I stop taking my anticoagulant."
 - "The nurse showed me how to contract and relax my calf muscles."
- The nurse assesses a postoperative client who has a rapid, weak pulse; urine output of less than 30 mL/h; and decreased blood pressure. The client's skin is cool and clammy. What complication should the nurse suspect?
 - Thrombophlebitis
 - Hypovolemic shock
 - Pneumonia
 - Wound dehiscence
- The client is most likely to require the greatest amount of analgesia for pain during which period?
 - Immediately after surgery
 - 4 hours after surgery
 - 12 to 36 hours after surgery
 - 48 to 60 hours after surgery
- A postop client who had abdominal surgery is holding a pillow against his abdomen during deep-breathing and coughing exercises. What term does the nurse use to describe this technique? _____
- A semiconscious client in the postanesthesia care unit (PACU) is experiencing dyspnea (difficulty breathing). Which action should the nurse perform first?
 - Place a pillow under the client's head.
 - Remove the oropharyngeal airway.
 - Administer oxygen by mask.
 - Reposition the client to keep the tongue forward.
- The client's postoperative orders state "diet as tolerated." The client has been NPO. The nurse will advance the client's diet to clear liquids based on which assessment? Select all that apply.
 - Does not complain of nausea or vomiting
 - Pain level is maintained at a rating of 2–3 out of 10
 - States passing flatus
 - Ambulates with minimal assistance
 - Expresses feeling "hungry"
- The overall goal of nursing care during the intraoperative phase is the client's _____.
- The nurse plans to remove the client's sutures. Which action demonstrates appropriate standards of care? Select all that apply.
 - Use clean technique.
 - Grasp the suture at the knot with a pair of forceps.
 - Place the curved tip of the suture scissors under the suture as close to the skin as possible.
 - Pull the suture material that is visible beneath the skin during removal.
 - Remove alternate sutures first.

Meeting the Standards

This unit discusses the integral components of client care including asepsis, safety, hygiene, diagnostic testing, and medications, as well as skin and wound care, and care of the perioperative client. Knowledge of safety and asepsis guides every action taken by the nurse when providing client care, including administration of medications, diagnostic testing, wound care, and perioperative care.

CLIENT: Fairuz AGE: 36 CURRENT MEDICAL DIAGNOSES: Fractured Right Arm and Left Leg, Multiple Abrasions

Medical History: Fairuz was involved in a motor vehicle crash resulting in a fractured right arm, fractured left leg, and multiple abrasions and lacerations. Her right arm was set by closed reduction, and a synthetic cast was applied with a window cut over the forearm to monitor healing of a laceration requiring multiple sutures. She is taken to surgery where pins are placed in her left femur, and she is placed in traction. She has no other significant health conditions. The prognosis is that she will remain in traction for 5 to 6 weeks and will require physical therapy to regain the ability to walk.

Personal and Social History: Fairuz's family emigrated from India and she was born in the United States. She lives alone, has no children, and her parents died more than 10 years ago. She has no siblings. She is employed as a high school mathematics teacher and lives in a third-floor walk-up apartment. She is right-hand dominant and concerned about how she will function with her right arm in a cast. She has many friends who visit throughout the day and receives many phone calls from her students and coworkers.

Questions

American Nurses Association Standard of Professional

Performance #1 is Assessment: The registered nurse collects comprehensive data pertinent to the client's health and/or situation demonstrated by eliciting the client's values, preferences, expressed needs, and knowledge of the health care situation.

1. To assist Fairuz in meeting her hygiene needs, what questions will you want to ask in order to collect appropriate data for planning her care?
2. What important assessment data related to her risk for infection will be required to serve as baseline data for comparison purposes throughout her admission?
3. What are the nurse's priority assessments during the immediate postoperative period when Fairuz first returns to the unit after open reduction of her left leg fracture?

American Nurses Association Standard of Professional

Performance #2 is Diagnosis: The registered nurse analyzes the assessment data to determine the diagnoses or issues. The competent nurse derives the diagnosis or issues from assessment data.

4. Identify one actual and one "risk for" nursing diagnosis from NANDA International (Herdman & Kamitsuru, 2014) for Fairuz related to wound care, safety, and asepsis.
5. How do treatments, including medications, typically used with clients who have fractures influence your choice of diagnoses?

American Nurses Association. (2010). *Nursing: Scope and standards of practice* (2nd ed.). Silver Spring, MD: Author.

Herdman, T. H., & Kamitsuru, S. (Eds.). (2014). *NANDA International nursing diagnoses: Definitions and classification, 2015–2017*. Oxford, United Kingdom: Wiley-Blackwell.

38 Sensory Perception

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Discuss the components of the sensory-perception process.
2. Describe factors that influence sensory function.
3. Identify clinical signs and symptoms of sensory deprivation and overload.
4. Describe essential components in assessing a client's sensory-perception function.
5. Discuss factors that place a client at risk for sensory disturbances.
6. Develop nursing diagnoses and outcome criteria for clients with impaired sensory function.
7. Discuss nursing interventions to promote and maintain sensory function.
8. Identify strategies to promote a therapeutic environment for the client with acute confusion/delirium.

KEY TERMS

acute confusion, 915

visual, 904

INTRODUCTION

An individual's senses are essential for growth, development, and survival. Sensory stimuli give meaning to events in the environment. Any alteration in people's sensory functions can affect their ability to function within the environment. For example, many clients have impaired sensory functions that put them at risk in the health care setting; nurses can help them find ways to function safely in this often confusing environment.

COMPONENTS OF THE SENSORY EXPERIENCE

The sensory process involves two components: reception and perception. **Sensory reception** is the process of receiving stimuli or data. These stimuli are either external or internal to the body. External stimuli are **visual** (sight), **auditory** (hearing), **olfactory** (smell), **tactile** (touch), and **gustatory** (taste). Gustatory stimuli can be internal as well. Other types of internal stimuli are kinesthetic or visceral. **Kinesthetic** refers to awareness of the position and movement of body parts. For example, a person walking is aware of which leg is forward. A related sense is **stereognosis**, the ability to perceive and understand an object through touch by its size, shape, and texture. For example, a person holding a tennis ball is aware of its size, round shape, and soft surface without seeing it. **Visceral** refers to any large organ within the body. Visceral organs may produce stimuli that make a person aware of them (e.g., a full stomach). **Sensory perception** involves the conscious organization and translation of the data or stimuli into meaningful information.

For an individual to be aware of the surroundings, four aspects of the sensory process must be present:

- **Stimulus.** This is an agent or act that stimulates a nerve receptor.
- **Receptor.** A nerve cell acts as a receptor by converting the stimulus to a nerve impulse. Most receptors are specific, that is, sensitive to only one type of stimulus, such as visual, auditory, or touch.
- **Impulse conduction.** The impulse travels along nerve pathways either to the spinal cord or directly to the brain (Figure 38-1 ■). For example, auditory impulses travel to the organ of Corti in the inner ear. From there the impulses travel along the eighth cranial nerve to the temporal lobe of the brain.
- **Perception.** Perception, or awareness and interpretation of stimuli, takes place in the brain, where specialized brain cells interpret the nature and quality of the sensory stimuli. The client's level of consciousness affects the perception of the stimuli.

Arousal Mechanism

For the person to receive and interpret stimuli, the brain must be alert, also referred to as arousal. The reticular activating system (RAS) in the brainstem is thought to mediate the arousal mechanism. The RAS has two components: the reticular excitatory area (REA) and the reticular inhibitory area (RIA). The REA is responsible for arousal and wakefulness.

People have their own zone of optimum arousal, the level at which the person feels comfortable. **Sensoristasis** is the term used to describe the state in which a person is in optimal arousal. Beyond this comfort zone people must adapt to the increase or decrease in sensory stimulation. An absence of stimuli from the RAS to the cerebrum results in the brain becoming inactive or useless. The brain has

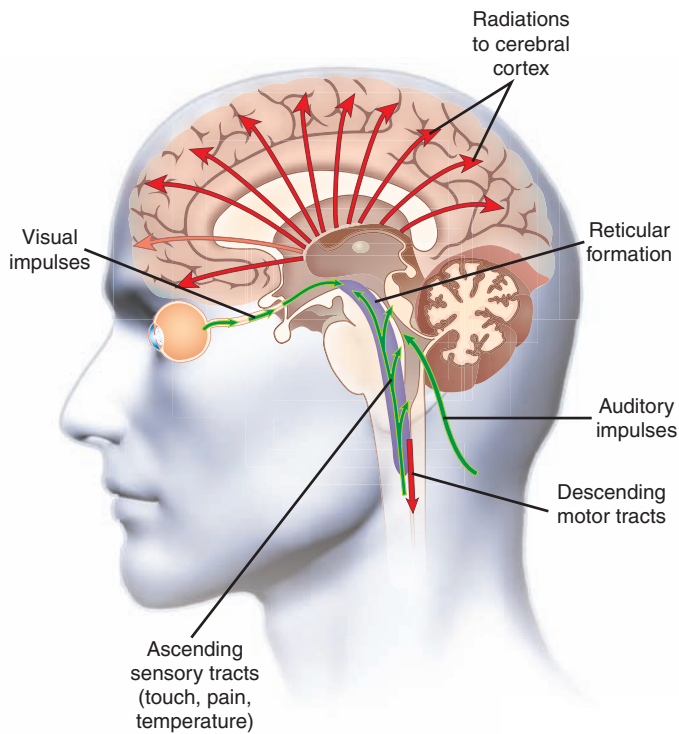

Figure 38-1 ■ The nerve impulses run along the ascending sensory tracts to reach the reticular activating system (RAS); then certain impulses reach the cerebral cortex where they are perceived.

the capacity to adapt to sensory stimuli. For example, a person living in a city may not notice traffic noise that someone from a rural area finds loud and disturbing. Not all sensory stimuli are acted on; some are stored by the memory to be used at a later date.

Awareness is the ability to perceive internal and external stimuli, and to respond appropriately through thought and action. There are several states of awareness (Table 38-1). A normal, alert person can assimilate many kinds of stimuli at one time.

FACTORS AFFECTING SENSORY FUNCTION

A number of factors affect sensory reception and perception, including a person’s developmental stage, culture, level of stress, medications and illness, and lifestyle and personality.

TABLE 38-1 States of Awareness

State	Description
Full consciousness	Alert; oriented to time, place, person; understands verbal and written words
Disoriented	Not oriented to time, place, or person
Confused	Reduced awareness, easily bewildered; poor memory, misinterprets stimuli; impaired judgment
Somnolent	Extreme drowsiness but will respond to stimuli
Semicomatose	Can be aroused by extreme or repeated stimuli
Coma*	Will not respond to verbal stimuli

*See Glasgow Coma Scale, Table 30-10 in Chapter 30.

Developmental Stage

Perception of sensation is critical to the intellectual, social, and physical development of infants and children. Infants learn to recognize the face of their mother or caregiver and establish bonding essential to later emotional development. Young children respond to music by singing and dancing as they begin to interact with their peers in groups. As children grow, they learn to interpret visual and auditory signals when preparing to cross the street. Adults have many learned responses to sensory stimuli. The sudden loss or impairment of any sense, therefore, has a profound effect on a person of any age.

Normal physiological changes in older adults put them at higher risk for altered sensory function. The diminishing of sensory perception that may come with chronic disease or aging is generally gradual. Hearing loss is common in older adults. “Approximately 314 people in 1,000 over age 65 and 50% of those over age 75 have hearing loss” (Tabloski, 2014, p. 345).

Culture

An individual’s culture often determines the amount of stimulation that a person considers usual or “normal.” For example, a child reared in a big-city Latino neighborhood where extended families share responsibilities for all the children may be accustomed to more stimulation than a child reared in a European-American suburb of scattered single-family homes. In addition, the normal amount of stimulation associated with ethnic origin, religious affiliation, and income level, for example, also affects the amount of stimulation an individual desires and believes to be meaningful. The sudden change in cultural surroundings experienced by immigrants or visitors to a new country, especially where there are differences in language, dress, and cultural behaviors, may also result in sensory overload or cultural shock.

Cultural deprivation, or **cultural care deprivation**, is a lack of culturally assistive, supportive, or facilitative acts. It is important that nurses be sensitive to what stimulation is culturally acceptable to a client. For example, in some cultures touching is comforting, whereas in others it is offensive. Some clients find the presence of cultural or religious symbols reassuring, and their absence a source of anxiety. Nurses should encourage clients who want to have such symbols present to do so, and to follow practices with which they are comfortable, provided that these practices do not endanger their health.

Stress

During times of increased stress, people may find their senses already overloaded and thus seek to decrease sensory stimulation. For example, a client dealing with physical illness, pain, hospitalization, and diagnostic tests may wish to have only close support people visit. In addition, a client may need the nurse’s help to decrease unnecessary stimuli (e.g., noise) as much as possible. On the other hand, clients may seek sensory stimulation during times of low stress.

Medications and Illness

Certain medications can alter an individual’s awareness of environmental stimuli. Narcotics, antiepileptic agents, and sedatives, for example, can decrease awareness of stimuli. Some antidepressants can also alter perceptions of stimuli. When administering these medications the nurse is responsible for protecting the client from injury that can result from impaired sensory perception. The nurse should

educate clients and their families on the effect medications produce that alter sensory perception. Anyone taking several medications concurrently may show alterations in sensory function. Older adults are at greatest risk for such alterations because they may have conditions that alter perception and spatial orientation.

Some medications, if taken in large doses or over a long period of time, become ototoxic, injuring the auditory nerve and causing hearing loss that may be irreversible. Some of these medications are aspirin, furosemide (Lasix), the aminoglycosides, and certain drugs given for cancer chemotherapy.

Certain diseases, such as atherosclerosis, restrict blood flow to the receptor organs and the brain, thereby decreasing awareness and slowing responses. Uncontrolled diabetes mellitus can impair vision and is a leading cause of blindness in the United States; diabetic neuropathy can cause changes in the tactile sense as well. Some central nervous system diseases cause varying degrees of paralysis and sensory loss. Diseases of the inner ear can affect the kinesthetic sense.

Lifestyle and Personality

Lifestyle influences the quality and quantity of stimulation to which an individual is accustomed. A client who is employed in a large company may be accustomed to many diverse stimuli, whereas a client who is self-employed and works in the home is exposed to fewer, less diverse stimuli. People's personalities also differ in terms of the quantity and quality of stimuli with which they are comfortable. Some people delight in constantly changing stimuli and excitement, whereas others prefer a more structured life with few changes.

SENSORY ALTERATIONS

People become accustomed to certain sensory stimuli, and when these change markedly an individual may experience discomfort. For example, when clients enter a hospital they usually experience stimuli that differ in quantity and quality from those to which they are accustomed. These changes may cause clients to become confused and disoriented (see Table 38–1). Some clients may experience excessive changes in mental alertness including delusions and hallucinations.

Nurses have become increasingly aware of the behaviors that may result from different stimuli. They now pay more attention to color, sound, privacy, and social interaction for clients so that the stimuli more closely resemble those in the home environment. Factors that contribute to alterations in behavior include sensory deprivation, sensory overload, and sensory deficits.

CLINICAL MANIFESTATIONS

Sensory Deprivation

- Excessive yawning, drowsiness, sleeping
- Decreased attention span, difficulty concentrating, decreased problem solving
- Impaired memory
- Periodic disorientation, general confusion, or nocturnal confusion
- Preoccupation with somatic complaints, such as palpitations
- Hallucinations or delusions
- Crying, annoyance over small matters, depression
- Apathy, emotional lability

Sensory Deprivation

Sensory deprivation is generally thought of as a decrease in or lack of meaningful stimuli. When a person experiences sensory deprivation, the balance in the reticular activating system is disturbed. The RAS is unable to maintain normal stimulation to the cerebral cortex. Because of this reduced stimulation, a person becomes more acutely aware of the remaining stimuli and often perceives these in a distorted manner. The person often experiences alterations in perception, cognition, and emotion. Clinical Manifestations lists clinical signs of sensory deprivation.

Sensory Overload

Sensory overload generally occurs when a person is unable to process or manage the amount or intensity of sensory stimuli. Three factors contribute to sensory overload:

- Increased quantity or quality of internal stimuli, such as pain, dyspnea, or anxiety
- Increased quantity or quality of external stimuli, such as a noisy health care setting, intrusive diagnostic studies, or contacts with many strangers
- Inability to disregard stimuli selectively, perhaps as a result of nervous system disturbances or medications that stimulate the arousal mechanism.

Sensory overload can prevent the brain from ignoring or responding to specific stimuli. Because of the many stimuli, the individual has difficulty perceiving the environment in a way that makes sense. As a result the individual's thoughts race in many directions, causing restlessness and anxiety. The person usually feels overwhelmed and does not feel in control. It is important for nurses to remember that sights and sounds that are familiar to them often represent overload to clients. People who have sensory overload may appear fatigued. They often cannot internalize new information and they experience cognitive overload. Factors such as pain, lack of sleep, and worry can also contribute to sensory overload. See Clinical Manifestations for common signs of sensory overload.

Sensory Deficits

A **sensory deficit** is impaired reception, perception, or both, of one or more of the senses. Blindness and deafness are sensory deficits. When the loss of sensory function is gradual, individuals often develop behaviors to compensate for the loss; sometimes these behaviors are unconscious. For example, a person with gradual hearing loss in the right ear may unconsciously turn the left ear toward a speaker. However, sudden loss of one of the senses can result in disorientation, and compensatory behavior often takes days or weeks to develop.

CLINICAL MANIFESTATIONS

Sensory Overload

- Complaints of fatigue, sleeplessness
- Irritability, anxiety, restlessness
- Periodic or general disorientation
- Reduced problem-solving ability and task performance
- Increased muscle tension
- Scattered attention and racing thoughts

Clients with sensory deficits are at risk for both sensory deprivation and sensory overload. For example, individuals with visual problems may be unable to read, watch television, or recognize nurses by sight, which could lead to sensory deprivation. On the other hand, blind people often have highly structured home environments, and the diversity and unfamiliarity of the hospital environment can create sensory overload. At the same time, impaired vision often results in an inability to move around readily or socialize with others.

●○○ NURSING MANAGEMENT

Assessing

Nursing assessment of sensory-perceptual functioning includes six components: (1) nursing history, (2) mental status examination, (3) physical examination, (4) identification of clients at risk, (5) the client's environment, and (6) the client's social support network.

Nursing History

During the nursing history the nurse assesses the client's current sensory perceptions, usual functioning, sensory deficits, and potential problems. In some instances, significant others can provide data the client cannot. For example, the client's significant others may provide evidence of recent changes in the client's hearing ability, such as inattention to others, mood swings, difficulty following clear instructions, frequent requests to have something repeated, and unusually loud radio or television volumes. Examples of interview questions to elicit data about the client's sensory-perceptual functioning are shown in the accompanying Assessment Interview.

Mental Status Examination

Mental status is critical to any evaluation of the sensory-perceptual process. Data on mental status, including level of consciousness, orientation, memory, and attention span, are usually obtained during the nursing history (see Chapter 30 ∞). It is important to note that sensory alterations can cause changes in cognitive functioning and vice versa.

Physical Examination

Physical assessment determines whether the senses are impaired. During the physical examination the nurse assesses vision and hearing and the olfactory, gustatory, tactile, and kinesthetic senses. The examination should reveal the client's specific visual and hearing abilities; perception of heat, cold, light touch, and pain in the limbs; and awareness of the position of the body parts. Specific sensory tests include the following:

- Visual acuity, using a Snellen chart or other reading material such as a newspaper, and visual fields
- Hearing acuity, by observing the client's conversation with others and by performing the whisper test and the Weber and Rinne tuning fork tests
- Olfactory sense, by asking the client to identify specific aromas
- Gustatory sense, by asking the client to identify three tastes such as lemon, salt, and sugar
- Tactile sense, by testing light touch, sharp and dull sensation, two-point discrimination, hot and cold sensation, vibration sense, position sense, and stereognosis.

These tests are described in detail in Chapter 30 ∞. The nurse should also determine whether sensory adaptive devices that the client uses, such as eyeglasses or hearing aids, are adequate and functioning properly.

Clients at Risk for Sensory Deprivation or Overload

Clients at risk for sensory-perceptual alterations need to be identified to ensure that preventive measures can be initiated. Box 38–1 describes clients at risk.

Client Environment

A nurse should assess the client's environment for quantity, quality, and type of stimuli. The environment may produce insufficient stimuli, placing the client at risk for sensory deprivation, or excessive stimuli, placing the client at risk for sensory overload. Nonstimulating

ASSESSMENT INTERVIEW Sensory-Perceptual Functioning

VISUAL

- How would you rate your vision (excellent, good, fair, or poor)?
- Do you wear eyeglasses or contact lenses?
- Describe any recent changes in your vision.
- Do you have any difficulty seeing near or far objects?
- Do you have any difficulty seeing at night? Have you ever experienced blurred vision, double vision, spots moving in front of your eyes, blind spots, light sensitivity, flashing lights, or halos around objects?
- When did you last visit an eye doctor?

AUDITORY

- How would you rate your hearing (excellent, good, fair, or poor)?
- Do you wear a hearing aid?
- Describe any recent changes in your hearing.
- Can you locate the direction of sounds and distinguish various voices?
- Do you experience any dizziness or vertigo? Do you experience any ringing, buzzing, humming, crackling noises, or fullness in the ears?

GUSTATORY

- Have you experienced any changes in taste (e.g., difficulty in differentiating sweet, sour, salty, and bitter tastes)?
- Do you enjoy the taste of foods as you did previously?

OLFACTORY

- Have you experienced any changes in smell?
- Do things (foods, flowers, perfumes, and so on) smell the same as previously?
- Can you distinguish foods by their odors and tell when something is burning?
- Have you experienced any changes in appetite? (Changes in appetite may be related to an impaired sense of smell.)

TACTILE

- Are you experiencing any pain or discomfort?
- Have you experienced any decrease in your ability to perceive heat, cold, or pain in your limbs?
- Do you have any numbness or tingling in your extremities?

KINESTHETIC

- Have you noticed any difficulty in perceiving the position of parts of your body?

BOX 38-1 Clients at Risk for Sensory Deprivation and Overload**Sensory Deprivation: Clients Who**

- are confined in a nonstimulating or monotonous environment in the home or health care agency
- have impaired vision or hearing
- have mobility restrictions such as quadriplegia or paraplegia with bed rest, traction apparatus
- are unable to process stimuli (e.g., clients who have brain damage or who are taking medications that affect the central nervous system)
- have emotional disorders (e.g., depression) and withdraw within themselves
- have limited social contact with family and friends (e.g., clients from a different culture).

Sensory Overload: Clients Who

- have pain or discomfort
- are acutely ill and have been admitted to an acute care facility
- are being closely monitored in an intensive care unit (ICU) (Figure 38-2 ■) and have intrusive tubes such as IVs, catheters, or nasogastric or endotracheal tubes
- have decreased cognitive ability (e.g., head injury).

Figure 38-2 ■ A client in an ICU may experience sensory overload.
David Joel/Getty Images.

environments include those that (a) severely restrict physical activity and (b) limit social contact with family and friends. Because appropriate or meaningful stimuli decrease the incidence of sensory deprivation, the nurse must consider the client's health care environment for the presence of the following stimuli:

- Electronic devices (computers, DVD/CD players, television, smart phones)
- Clock or calendar
- Reading material (or toys for children)
- Number and compatibility of roommates
- Number of visitors.

To assess a health care environment that produces excessive stimuli, the nurse considers, for example, bright lights, noise, therapeutic measures, and frequency of assessments and procedures. In the client's home, the nurse may also note the presence of a video/DVD recorder, pets, bright colors, adequate lighting, and so on.

CLINICAL ALERT!

Are you aware of the noise level around you or the noise level you create while providing nursing care? The standard of 45 decibels (dB) for rest and sleep is often not met. For example, studies have shown that sounds in critical care units range from 60 to 83 dB, thereby suggesting sensory overload.

Social Support Network

The degree of isolation a person feels is significantly influenced by the quality and quantity of support from family members and friends. A nurse should assess (a) whether the client lives alone, (b) who visits and when, and (c) any signs indicating social deprivation, such as withdrawal from contact with others to avoid embarrassment or dependence on others, negative self-image, reports of lack of meaningful communication with others, and absence

of opportunities to discuss fears or concerns that facilitate coping mechanisms.

Diagnosing

Disturbed sensory perception is no longer an approved NANDA International diagnosis for alterations in the sensory responses such as diminished sight, hearing, taste, smell, touch or kinesthetic sense. The approved NANDA (Herdman & Kamitsuru, 2014) diagnostic labels for perception and cognition are:

- **Acute Confusion:** abrupt onset of reversible disturbances of consciousness, attention, cognition, and perception that develop over a short period of time (p. 252)
- **Chronic Confusion:** irreversible, long-standing, and/or progressive deterioration of intellect and personality characterized by decreased ability to interpret environmental stimuli; decreased capacity for intellectual thought processes; and manifested by disturbances of memory, orientation, and behavior (p. 254)
- **Impaired Memory:** inability to remember or recall bits of information or behavior skills (p. 259)
- **Risk for Acute Confusion:** at risk for alterations in consciousness, attention, cognition, and perception that develops over a short time period (p. 253).

Sensory-Perception Problem as the Etiology

Depending on the data obtained, alterations in sensory-perception function may affect other areas of human functioning and indicate other diagnoses. In these instances the sensory-perception problem becomes the etiology.

Examples of nursing diagnoses for which sensory-perception disturbances are the etiology include the following:

- **Impaired Home Maintenance** related to sensory-perception disturbance (declining visual abilities)

- *Impaired Verbal Communication* related to sensory-perception disturbance (specify). For example:
 - Altered level of consciousness
 - Hearing impairment
 - Sensory overload
 - Sensory deprivation
- *Risk for Impaired Skin Integrity* related to sensory-perception disturbance (altered tactile sensation)
- *Risk for Injury* related to sensory-perception disturbance (specify). For example:
 - Visual impairment (e.g., decreased depth perception)
 - Reduced tactile sensation secondary to neurologic or circulatory alterations
 - Decreased sense of smell
 - Hearing impairment
 - Decreased kinesthetic sense
- *Social Isolation* related to sensory-perception disturbance (specify). For example:
 - Impaired vision
 - Impaired hearing

Planning

Planning includes goals associated with the care of clients independent of setting and those specific to the home environment.

Planning Independent of Setting

The overall outcome criteria for clients with sensory-perception alterations are to:

- Prevent injury.
- Maintain the function of existing senses.
- Develop an effective communication mechanism.
- Prevent sensory overload or deprivation.
- Reduce social isolation.
- Perform activities of daily living (ADLs) independently and safely.

The *Nursing Interventions Classification* (NIC) publication can be a guide when planning care (Bulechek, Butcher, Dochterman, & Wagner, 2013). Appropriate nursing activities may be selected from the following nursing interventions:

- Cognitive Stimulation
- Communication Enhancement: Hearing Deficit
- Communication Enhancement: Speech Deficit
- Communication Enhancement: Visual Deficit
- Nutrition Management
- Environmental Management: Safety
- Fall Prevention

- Body Mechanics Promotion
- Peripheral Sensation Management
- Emotional Support
- Surveillance: Remote Electronic.

Planning for Home Care

To provide for continuity of care, a nurse must consider a client's needs for assistance with care in the home or residential treatment setting. Some clients with severe alterations in sensory-perception functioning may be discharged to an assisted living facility that provides the specific support the client requires. Discharge planning incorporates a reassessment of the client's abilities for self-care, the availability and skills of support people, financial resources, and the need for referrals and home health services. See the accompanying Home Care Assessment for sensory-perception alterations and confusion. A major aspect of discharge planning involves the instructional needs of the client and family. The next section provides strategies to support visual and auditory function and maintain a safe environment for clients.

Implementing

Nurses can assist clients with sensory alterations by promoting healthy sensory function, helping clients manage acute sensory deficits, and adjusting environmental stimuli.

Promoting Healthy Sensory Function

Detecting sensory problems early is one step toward preventing serious problems. The arousal mechanism for sensation is normally present at birth; however, it is undifferentiated. The special senses are also present at birth, although some changes in function occur during the growth process.

The Early Hearing Detection and Intervention (EHDI) Tracking and Surveillance System goals have been established by the Centers for Disease Control and Prevention (CDC) (2014). The seven goals are:

- **Goal 1:** All newborns will be screened for hearing loss before 1 month of age.
- **Goal 2:** All infants who screen positive will require a diagnostic audiologic examination before the age of 3 months.
- **Goal 3:** All infants identified with hearing loss will receive early intervention services prior to age 36 months.
- **Goal 4:** Infants with late, progressive, or acquired hearing loss will be identified early.
- **Goal 5:** Infants with hearing loss will have a primary care provider who will collaborate and coordinate care with the EHDI Tracking and Surveillance System at the CDC.
- **Goal 6:** Each state is responsible for completing the EHDI Tracking and Surveillance System.

Home Care Assessment Sensory Perception Disturbances

PATIENT-CENTERED CARE

CLIENT AND ENVIRONMENT

- *Self-care abilities:* ability to care for self while adapting to sensory impairment
- *Safety:* physical safety of client's environment including lighting, noise, access, lack of clutter or obstructions, use of stairs, and assistive devices with respect to sensory impairment, such as flashing fire alarms or telephones for hearing impaired

- *Level of knowledge:* assistive devices available; ways to maximize use of other senses; local, regional, or national organizations that may provide education, training, support, or other assistance, such as the National Braille Association, Guide Dogs for the Blind, the National Association of the Deaf
- *Resources:* availability of family, friends, community assistance such as senior centers, transportation, and religious or cultural organizations

CLIENT TEACHING

Preventing Sensory Disturbances

- Have regular health examinations.
- Have regular eye examinations as recommended by the primary care provider to screen for eye problems. For clients ages 40 and over, a medical eye examination is generally recommended every 3 to 5 years, or every 1 to 2 years if there is a family history of glaucoma.
- Seek early medical attention (a) if signs suggesting visual impairment arise, for example, failure to react to light, or reduced eye contact from an infant; (b) if the child complains of an ear-ache or has an ear infection; and (c) for persistent eye redness, discharge or increased tearing, growths on or near the eye, pupil asymmetry or other irregularity, or any pain or discomfort.
- Obtain regular immunizations of children against diseases capable of causing hearing loss (e.g., rubella, mumps, and measles).
- Avoid giving infants and toddlers toys with long pointed handles and keep pointed instruments (e.g., scissors and screwdrivers) out of reach. Supervise preschoolers when they use scissors.
- Make sure that toddlers do not walk or run with a pointed object in hand; teach preschoolers to walk carefully when carrying such objects as sticks or toy weapons.
- Teach school-age children and adolescents the proper use of sports equipment (e.g., hockey sticks) and power tools.
- Wear protective eye goggles when using power tools, riding motorcycles, spraying chemicals, and so on.
- Wear ear protectors when working in an environment with high noise levels or brief loud impulse noises (e.g., blasting).
- Wear dark glasses with UV protection to avoid damage from ultraviolet rays and never look directly into the sun.

- **Goal 7:** Every state will have a complete EHDI Tracking and Surveillance System to minimize loss of clients and to maintain current information on every infant identified as having a hearing loss.

Early screening to detect problems in vision and hearing is essential. As previously stated, infants should be screened for hearing loss by 1 month of age, and preferably before hospital discharge. In addition, children with chronic ear infections and people who live or work in an environment where there are high noise levels should receive routine auditory testing. Women who are considering pregnancy should be advised of the importance of prenatal testing for syphilis and confirmation of a positive rubella titer, because maternal syphilis and rubella infection can both cause hearing impairments in newborns. Periodic vision screening of all newborns and children is recommended to detect congenital blindness, strabismus, and refractive errors. A child's visual acuity develops during early childhood. Children often have 20/20 vision by 6 to 7 years of age (Ball, Bindler, & Cowen, 2012, p. 512). Healthy sensory function can be promoted with environmental stimuli that provide appropriate sensory input. This input should vary and be neither excessive nor too limited. As many senses as possible should be stimulated. Various colors, sounds, textures, smells, and body positions can provide various sensations. Nurses can teach parents to stimulate infants and children, and teach family members to stimulate an older person and others in the home with sensory deficits. Social activities often help stimulate the mind and the senses.

Nurses should also teach clients at risk of sensory loss how to prevent or reduce the loss and should teach general health measures, such as getting regular eye examinations and controlling chronic diseases such as diabetes (Client Teaching).

Impaired Vision

For clients with impaired vision, nurses need to do the following in a health care setting:

- Orient the client to the arrangement of room furnishings and maintain an uncluttered environment.
- Keep pathways clear and do not rearrange furniture without orienting the client. Ensure that housekeeping personnel are informed about this.

- Organize self-care articles within the client's reach and orient the client to his or her location.
- Keep the call light within easy reach and place the bed in the low position.
- Assist with ambulation by standing at the client's side, walking about 1 foot ahead, and allowing the person to grasp your arm. Confirm whether the client prefers grasping your arm with the dominant or nondominant hand.

The most common vision diseases affecting older adults are macular degeneration, cataract, glaucoma, and diabetic retinopathy. Age-related macular degeneration (ARMD) is the leading cause of blindness in adults older than age 65. Cataracts are opacities of the lenses. Development is slow and painless and may be unilateral or bilateral. They are the leading cause of blindness in the world. Glaucoma is associated with optic nerve damage due to an increase in intraocular pressure and leads to vision loss. It is the second most common cause of blindness in the United States. Diabetic retinopathy is a microvascular disease of the eye occurring in both type 1 and type 2 diabetes (Tabloski, 2014, pp. 339–344).

Research has established an association between visual impairment and greater disability in performing ADLs (e.g., bathing, dressing, eating) and instrumental tasks (e.g., shopping, housekeeping). Studies have also shown that impaired vision increases the risk of depression among older adults. Explanations for this relationship vary. One explanation is that vision loss leads to increased disability, which leads to depression. Another explanation states that loss of vision causes fear—fear of losing one's autonomy and becoming dependent on another or others. Impaired vision also affects how a person obtains information, such as reading the newspaper. In addition, reading is often a leisure activity and its loss can affect a person's quality of life. It is important for the nurse to be aware of and assess for signs of depression and intervene as appropriate if an older adult is experiencing depression as a result of impaired vision (Watkinson, 2011).

Impaired Hearing

Clients with hearing impairments who are unable to hear the alarms of IV pumps and cardiac monitors need to be assessed frequently. They can be taught to use their visual sense to identify

DRUG CAPSULE**Client Taking Medication for Glaucoma *travoprost* (Travatan)**

Norman Daniels is 68 years old and has been diagnosed with open-angle glaucoma. His intraocular pressure is 44 mmHg. The normal intraocular pressure is 10 to 21 mmHg. His ophthalmologist has prescribed travoprost (Travatan), one drop in each eye at bedtime.

Travoprost is a prostaglandin analog medication that decreases intraocular pressure in open-angle glaucoma.

NURSING RESPONSIBILITIES

- Assess eye for inflammation, exudate, and pain.
- Note iris color.

CLIENT AND FAMILY TEACHING

- Use once daily as directed.
- Do not let the tip of the dropper touch any part of the eye.

- It may be used with other eye products to lower intraocular pressure. If more than one medication is being used, administer 5 minutes apart.
- Inform of risk of darkening of the iris, eyelashes, or skin around the eye.
- Do not administer while wearing contact lenses. Remove contact lenses and wait 15 minutes after instilling one eyedrop in each eye before reinserting contact lenses.
- Discard the container within 6 weeks of removing it from the sealed pouch.
- It should not be administered by women who are pregnant or plan to become pregnant (Frandsen & Pennington, 2014).

Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

kinks in the IV tubing or a loose ECG lead, and so on. For home safety, clients with impaired hearing need to obtain devices that either amplify sounds or respond with flashing lights to sounds such as a doorbell, phone, smoke detector, crying baby, or burglar alarm. The sounds of doorbells and alarm clocks may be amplified or changed to a lower frequency or buzzer-like sound. These devices can be obtained from hearing aid dealers, telephone companies, and appliance stores.

An important consequence of a decline in hearing as a person ages is difficulty understanding speech. Factors that influence this difficulty are the environment, rate of speech, and presence of an accent. Environments that are noisy and reverberant (echoing, hollow sounds) can cause difficulty for the older adult. Older adults with a hearing loss have difficulty understanding fast speech. Research indicates that an older adult's ability to process verbal information is slower than that of a younger adult, and that rapid speech allows less time for the older adult to recognize acoustic or auditory cues. A person who speaks with an accent can also affect speech understanding by an older person. Non-native English speakers may vary their pronunciation of syllables and words, making it challenging for the older adult to understand.

Impaired Olfactory Sense

Clients with an impaired sense of smell need to be taught about the dangers of cleaning and working with chemicals. Strong chemicals such as ammonia used in confined spaces such as a bathroom may affect the client before they are smelled. Because a gas leak can go undetected, clients need to keep gas stoves and heaters in good working order. Food poisoning is a concern with clients who have difficulty detecting spoiled meat or dairy products. These clients need to carefully inspect food for freshness (check its color and texture) and check expiration dates on food packages.

Impaired Tactile Sense

Clients with an impaired sense of touch may not be aware of hot temperatures, which can cause burns, or pressure on bony prominences, which can produce pressure ulcers. Clients with decreased sensation to temperature should have the temperature adjusted on their hot water heater and test water temperature with a thermometer before

bathing. Clients with decreased sensation to pressure must change their position frequently.

Managing Acute Sensory Impairments

When assisting clients who have a sensory impairment, a nurse needs to (a) encourage the use of sensory aids to support residual sensory function, (b) promote the use of other senses, (c) communicate effectively, and (d) ensure client safety.

Encouraging the Use of Sensory Aids

Many sensory aids are available for clients who have visual and hearing deficits. Examples are listed in Box 38–2. Sensory aids can be used in the health care setting as well as in the home. In all situations, the assistance of support people needs to be enlisted whenever possible to help the client deal with the deficit.

Promoting the Use of Other Senses

When one sense is lost, a nurse can teach the client to use other senses to supplement the loss. However, the type of stimulation needs to be adapted in accordance with the client's specific deficit. For example, for the client with a visual impairment, stimulation of hearing, taste, smell, and touch can be encouraged. A radio, audiotapes of music or books, clocks that chime, music boxes, and wind chimes provide auditory stimulation. Diets that include a variety of flavors, temperatures, and textures stimulate the gustatory sense. Taking sips of water between foods and eating foods separately can also emphasize the taste sensation. Fresh flowers, scented candles (safely used), room fragrances, brewing coffee, and baking can stimulate the olfactory sense. Clients can also be encouraged to remember pleasant or familiar odors such as the smell of a favorite flower or food. Measures such as providing a hug, massage, hair brushing, grooming, different textures in clothing and upholstery fabrics, and pets can stimulate tactile receptors.

Communicating Effectively

Communication with clients who have sensory impairments should convey respect, enhance the person's self-esteem, and ensure the exchange of correct information. A person with a hearing impairment has to concentrate more than other people do and therefore tires more readily. Fatigue compounded by an illness can further reduce the person's ability to hear. A person with a visual impairment is

ANATOMY & PHYSIOLOGY REVIEW

Glaucoma

Glaucoma is a group of diseases of the eye caused by increased intraocular pressure that can lead to optic nerve damage and eventual vision loss (see Figure D). Review Figure A for the normal anatomy of the eye.

A clear liquid, the aqueous humor, circulates inside the front portion of the eye, nourishing the lens and cornea. To maintain a normal level of pressure in the eye, the body constantly produces a small amount of aqueous humor and an equal amount flows out of the eye through a drainage system at the junction of the iris and the cornea. It is at this angle that the fluid passes through a trabecular meshwork,

drains into the canal of Schlemm, and enters the bloodstream in the back of the eye.

In acute open-angle glaucoma, the anterior chamber angle remains open but drainage of the aqueous humor through the canal of Schlemm is impaired. This causes a slow rise of the intraocular pressure. The eye's drainage angle becomes less efficient as a person ages and the risk of developing chronic open-angle glaucoma increases. The cause is unknown.

In acute closed-angle glaucoma, the drainage angle narrows and closes or becomes blocked by the iris. The intraocular pressure can rise quickly and cause an acute attack.

A, The normal anatomy of the eye. B, Open-angle (chronic) glaucoma. C, Closed-angle (acute) glaucoma.

ANATOMY & PHYSIOLOGY REVIEW

Glaucoma—continued

D

D, Narrowing of the optical fields is a typical symptom of untreated glaucoma.

QUESTIONS

1. Review Figure B. Describe the angle between the iris and the cornea:
2. Review Figure C. Describe the angle between the iris and the cornea:
3. Open-angle glaucoma is represented by which figure?

4. Closed-angle glaucoma is represented by which figure?
5. The increasing fluid pressure pushes against what important part of the eye with the resulting damage leading to vision loss?

See student resource website for answers.

Evidence-Based Practice How Does Depression Affect Reading Rehabilitation for People with Central Vision Loss?

EVIDENCE-BASED PRACTICE

The goal of this study by Grant, Seiple, and Szlyk (2011) was to investigate the relationship between depression and the numeric measures of visual function. Eighteen subjects were enrolled in a reading rehabilitation program. The subjects were diagnosed with central scotomas from macular degeneration. The researchers conducted psychological testing batteries and reading assessments prior to beginning the rehabilitation. The study revealed that clients who had greater depressive symptoms had a decreased response to reading rehabilitation, but were better adapted to their loss of vision after rehabilitation ended.

IMPLICATIONS

Nurses must understand that vision loss late in life will affect the client's independence and ability to socialize. These factors will

promote the client's sense of isolation, increasing symptoms of depression. Nurses should encourage the use of rehabilitation services that will allow an older adult with a visual impairment to adjust to life's new challenges. Providing clients with hands-on activities and social support will also enhance adaptation. Nurses are also instrumental in teaching clients adaptive strategies, helping them explore alternative activities, and referring them to appropriate community resources. Nurses working with this population should be mindful of the fact that clients may experience vision loss as a psychological, rather than a physical event, and tailor interventions to meet these needs.

LIFESPAN CONSIDERATIONS Sensory Perception

CHILDREN

Newborns should be screened for hearing loss before 1 month of age. The guidelines for collecting data on hearing loss have set a benchmark that a minimum of 90% of all children in each state will have access to early intervention including education and treatment. Infants with hearing impairment will begin treatment before 6 months of age. The development of a child with a hearing impairment should be monitored annually. Universal screening of all newborns is mandated in all states (American Academy of Pediatrics, 2013).

OLDER ADULTS

Normal changes of aging often result in varying degrees of impairments in sensory perception of the senses—hearing, vision, smell,

taste, and touch. Diseases and conditions that are more common in older adults are diabetes, strokes, and other neurologic disorders such as Parkinson's disease. Each of these conditions and others will alter the client's sensory perception. Nursing interventions need to be very specific and individualized. The interventions are directed to either increase or decrease sensory stimuli.

The goals of nursing care should be focused on maintaining safety and communication with clients who have these impairments. Clients with dementia may have problems that fit more appropriately under "altered thought processes," but the goals should be similar: to maximize their potential, maintain their quality of life and dignity, and at the same time, be aware of safety and communication issues.

BOX 38-2 Sensory Aids for Visual and Hearing Deficits**VISUAL**

- Eyeglasses of the correct prescription, clean and in good repair
- Adequate room lighting, including night-lights
- Sunglasses or shades on windows to reduce glare
- Bright contrasting colors in the environment
- Magnifying glass
- Phone dialer with large numbers
- Clock and wristwatch with large numbers
- Color code or texture code on stoves, washer, medicine containers, and so on
- Colored or raised rims on dishes
- Reading material with large print

- Braille or recorded books
- Service dog

HEARING

- Hearing aid in good order
- Lip reading
- Sign language
- Amplified telephones
- Telecommunication device for the deaf (TDD)
- Amplified telephone ringers and doorbells
- Flashing alarm clocks
- Flashing smoke detectors

unable to observe most nonverbal cues during communication and relies largely on the spoken word and tone of voice. Guidelines for communicating with people who have visual or hearing impairments are shown in Box 38-3.

Ensuring Client Safety

Nurses must implement safety precautions in health care settings for clients with sensory deficits. Examples of precautions include keeping the bed in the lowest position and placing the call light within reach.

Adjusting Environmental Stimuli

A hospitalized client functions best when the environment is somewhat similar to that of the individual's ordinary daily life. Sometimes nurses need to take steps to adjust the client's environment to prevent either sensory overload or sensory deprivation.

Preventing Sensory Overload

For clients who are at risk of overstimulation, nurses should reduce the number and type of environmental stimuli. The nurse can counteract sensory overload by blocking unnecessary stimuli and by helping the client organize and alter responses to the stimuli that cannot be blocked.

Dark glasses with UV protection can partially block lights, and a window shade or drape can reduce visual stimulation. Earplugs reduce auditory stimuli, as do soft background music and earphones. The odor from a draining wound can be minimized by keeping the dressing dry and clean.

Other methods of blocking stimuli are to reduce novelty and surprise, and to cluster care activities to provide rest intervals free of interruptions. Sometimes the number of visitors and the length of visits must be restricted.

By explaining sounds in the environment, the nurse can help the client organize them mentally, for example, a beep indicates an IV alarm. When clients understand their meaning, stimuli may be less confusing and more easily ignored. People can also learn through practice and feedback to alter their responses to the stimuli. Clients can employ relaxation techniques to reduce anxiety and stress despite continual sensory stimulation (see Chapter 42 ∞). Box 38-4 provides nursing measures for clients with sensory overload.

Preventing Sensory Deprivation

For clients who are at risk for sensory deprivation, nurses can increase environmental stimuli in a number of ways. For example, newspapers, books, music, and television can stimulate the visual and auditory senses. Providing objects that are pleasant to touch, such as a pet to stroke, can provide tactile and interactive stimulation. Clocks that differentiate night from day by color can help orient a client to time. The olfactory sense can be stimulated by the presence of fresh flowers or plants.

Arrangements should also be made for people to visit and talk with the client regularly. Many church and community groups provide visitors to "shut-ins," that is, people who are confined to their homes or who reside in nursing homes. Box 38-5 provides measures to prevent sensory deprivation.

Evidence-Based Practice How Does Hearing Impairment and Presence of Distracters Affect Driving in Older Adult Clients?**EVIDENCE-BASED PRACTICE**

The purpose of this study by Hickson, Wood, Chaparro, Lacherez, and Marszalek (2010) was to investigate the effect that hearing impairment and distractions have on the older adult's ability to drive. This was a cross-sectional study in a university laboratory and with a driving test. A total of 107 adults ages 62 to 88 were assessed. Of the participants, 26% had mild hearing impairment and 19% had moderate or greater impairment. Each client's hearing was assessed utilizing pure tone audiometry, speech prescription test, and self-reports with the Hearing Handicap Inventory for the Elderly. The driving skills of the participants were assessed on closed-circuit television. During the driving assessment, the participants experienced no distracters and both auditory and visual distracters.

The study results indicated that older adults with hearing impairment have increased difficulty driving when distracters are present.

IMPLICATIONS

In this study, the implementation of distracters increased the risk for driving difficulties experienced by older adults with hearing impairments. These results can be applied to nursing care and safety when clients with hearing impairments are performing ADLs. Community health nurses must assess the client's safety in their homes and their ability to drive safely. If distracters increase the risk for unsafe driving, they can also increase the risk of injury in the home environment.

BOX 38–3 Communicating with Clients Who Have a Visual or Hearing Impairment**VISUAL IMPAIRMENT**

- Always announce your presence when entering the client's room and identify yourself by name.
- Stay in the client's field of vision if the client has a partial vision loss.
- Speak in a warm and pleasant tone of voice. Some people tend to speak louder than necessary when talking to a person who is blind.
- Always explain what you are about to do before touching the person.
- Explain the sounds in the environment.
- Indicate when the conversation has ended and when you are leaving the room.

HEARING IMPAIRMENT

- Before initiating conversation, convey your presence by moving to a position where you can be seen or by gently touching the person.
- Decrease background noises (e.g., television) before speaking.
- Talk at a moderate rate and in a normal tone of voice. Shouting does not make your voice more distinct and in some instances makes understanding more difficult.
- Address the person directly. Do not turn away in the middle of a remark or story. Make sure the person can see your face easily and that it is well lighted.

- Avoid talking when you have something in your mouth, such as chewing gum. Avoid covering your mouth with your hand.
- Keep your voice at about the same volume throughout each sentence, without dropping the voice at the end of each sentence.
- Always speak as clearly and accurately as possible. Articulate consonants with particular care.
- Do not "overarticulate"; mouthing or overdoing articulation is just as troublesome as mumbling. Pantomime or write ideas, or use sign language or finger spelling as appropriate.
- Use longer phrases, which tend to be easier to understand than short ones. For example, "Would you like a drink of water?" presents much less difficulty than "Would you like a drink?" Word choice is important: "Fifteen cents" and "fifty cents" may be confused, but "half a dollar" is clear.
- Pronounce every name with care. Make a reference to the name for easier understanding, for example, "Joan, the girl from the office" or "Sears, the big downtown store."
- Change to a new subject at a slower rate, making sure that the person follows the change to the new subject. A key word or two at the beginning of a new topic is a good indicator.

The Confused Client

Confusion can occur in clients of all ages, but it is most commonly seen in older people. Confusion often presents with subtle symptoms, but it is important for the nurse to differentiate between **acute confusion (delirium)** and **chronic confusion (dementia)**. Delirium has an abrupt onset and a cause that, when treated, reverses the confusion. Dementia, often called chronic confusion, has symptoms

that are gradual and irreversible (e.g., Alzheimer's disease). It is important to differentiate between the two (Table 38–2).

The terms *acute confusion* and *delirium* are often used interchangeably by most health professionals, with nurses tending to favor the use of *acute confusion* and physicians using the term *delirium*. Acute confusion, however, is a *nursing* diagnosis that stems

BOX 38–4 Preventing Sensory Overload

- Minimize unnecessary light, noise, and distraction. Provide dark glasses and earplugs as needed.
- Control pain as indicated at the level desired by the client, on a scale of 0 to 10.
- Introduce yourself by name, and address the client by name.
- Provide orienting cues, such as clocks, calendars, equipment, and furniture in the room.
- Provide a private room.
- Limit visitors.
- Plan care to allow for uninterrupted periods of rest or sleep.
- Schedule a routine of care so the client knows when and what to expect (post the schedule for the client wherever possible).
- Speak in a low tone of voice and in an unhurried manner.
- Provide new information gradually to enable the client to process the meaning. When providing information, ask the client to repeat it so that there are no misunderstandings.
- Describe any tests and procedures to the client beforehand.
- Reduce noxious odors. Empty a commode or bedpan immediately after use, keep wounds clean and covered, use a room deodorizer when indicated, and provide good ventilation.
- Take time to discuss the client's problems and to correct misinterpretations.
- Assist the client with stress-reducing techniques.

BOX 38–5 Preventing Sensory Deprivation

- Encourage the client to use eyeglasses and hearing aids.
- Address the client by name and touch the client while speaking if this is not culturally offensive.
- Communicate frequently with the client and maintain meaningful interactions (e.g., discuss current events).
- Provide a telephone, radio and/or TV, clock, and calendar.
- Provide murals, pictures, sculptures, and wall hangings. Many libraries and museums will lend artwork free of charge, or a local school may provide art projects developed by their students.
- Have family and friends bring freshly cut flowers and plants.
- Consider having a resident pet such as fish, a cat, or a bird or make arrangements for pets to visit on a regular basis.
- Include different textured objects to feel such as a sheepskin pillow, silk scarf, soft blanket, or other inanimate object.
- Increase tactile stimulation through physical care measures such as back massages, hair care, and foot soaks.
- Encourage social interaction through activity groups or visits by family and friends.
- Encourage the use of crossword puzzles or games to stimulate mental function.
- Encourage environment changes such as a walk through a mall, or for an immobilized client, sitting near a window or at a place on the nursing unit where the client can watch local traffic.
- Encourage the use of self-stimulation techniques such as singing, humming, whistling, or reciting.

TABLE 38–2 Differentiating Between Delirium and Dementia

Characteristic	Delirium	Dementia
Distinguishing feature	Acute, fluctuating change in mental status	Memory impairment
Onset	Sudden, acute onset	Slow, insidious
Duration	Temporary; may last hours to days	Chronic, gradual, irreversible
Time of day	Worsens at night	No change with time of day
Sleep/wake cycles	Disturbed; cycles often reversed	Disturbed Fragmented Awakens often during the night
Alertness	Fluctuates; may be alert and oriented during the day but become confused and disoriented at night	Generally normal
Thinking	Disorganized, distorted; impaired attention; alterations in memory	Judgment impaired Difficulty with abstraction and word finding
Delusions/hallucinations	May have visual, auditory, and tactile hallucinations; misinterpretation of real sensory experiences	Delusions; usually no hallucinations
Causative And Risk Factors	Cerebral and cardiovascular disease, infections, reduced hearing and vision, environmental change, stress, sleep deprivation, polypharmacy, dehydration	Alzheimer's disease Multiple infarct dementia

from the clients' experience and behavioral response to their health condition. Acute confusion can result from drug or alcohol intoxication in all ages, but is more common in young adults. Older adults may experience acute confusion related to worsening dementia or acute systemic infection (Matata, Defres, Jones, Gummery, & Solomon, 2013).

Delirium occurs in 40% of older hospitalized clients following surgery. Factors that contribute to the development of delirium are increased age, cognitive impairment, sensory impairment, other comorbidities, impaired nutritional status, depression, and lowered educational level (Smith, 2012). The components of delirium include the following:

- The client has a reduced ability to focus, sustain, or shift attention.
- The client exhibits a change in cognition that may include memory impairment, disorientation, or development of a perceptual disturbance. This change varies from the initial baseline assessment of the client.
- The change or disturbance develops over a short period of time and fluctuates during a 24-hour period.

There are also clinical subtypes of delirium based on psychomotor activity and levels of alertness:

- With hyperactive delirium, the client can be restless, agitated, and disoriented.
- With hypoactive delirium, the client is quiet, confused, disoriented, and displays apathy. This may be incorrectly assessed as depression or dementia.
- In mixed delirium, the client has symptoms of both hyperactive and hypoactive delirium. The client will present with symptoms of one type of delirium that will be resolved and then present with the opposite type. Approximately 54.9% of delirium episodes are mixed-type delirium (Olson, 2012).

Older adults are often at risk for delirium when hospitalized for numerous reasons. Recognizing those clients at risk for delirium and the

symptoms of delirium when they occur is a critical first step in managing care. Unfortunately, delirium is often unrecognized or misdiagnosed by both the primary care provider and the nurse. A large number of intensive care unit clients present with symptoms of delirium. According to Olson (2012) critical care nurses are important in preventing and recognizing delirium. Clients who present with symptoms of delirium have higher mortality and morbidity rates than those who do not. Also, older adults often have other chronic medical problems (e.g., dementia, chronic obstructive pulmonary disease, hypertension, stroke) that place them at risk. Many older adults take numerous medications, with anticholinergics, narcotics, and sedatives often increasing the risk for delirium. Many older adults have a vision or hearing impairment. In addition to these predisposing factors, the nurse must also assess for *precipitating* factors that can occur while hospitalized. For example, undertreating of pain, the unfamiliar surroundings and routine of a hospital, possible sleep deprivation, stress, and sensory overload all compound the older adult's risk for developing delirium.

CLINICAL ALERT!

It is best to *describe* behaviors rather than use the word *confusion* or *confused* when documenting cognitive changes in older adults who may be experiencing delirium. The description of the actual behaviors provides better information.

Standardized tools can also be included in addition to the previously described assessments. The Confusion Assessment Method (CAM) is considered the gold standard in identifying clients with delirium. In addition, the Family CAM or FAM-CAM is a screening tool in which family members are interviewed to maximize the detection of delirium in clients. The tool was adapted from the CAM instrument to identify acute onset, fluctuations in the delirium course, inattention, disorganized thought processes, diminished level of consciousness, disorientation, perceptual changes, and hallucinations (Steis et al., 2012). Other tools include the Mini-Mental State

BOX 38-6 Promoting a Therapeutic Environment for a Client with Acute Confusion/Delirium

- Wear a readable name tag.
- If possible, consistent caregivers should be assigned.
- Address the person by name and introduce yourself frequently: “Good morning, Mr. Richards. I am Barbara Barcivik. I will be your nurse today.”
- Identify time and place as indicated: “Today is December 5, and it is 8:00 in the morning.”
- Ask the client, “Where are you?” and orient the client to place (e.g., nursing home) if indicated.
- Place a calendar and clock in the client’s room. Mark holidays with ribbons, pins, or other means.
- Speak clearly and calmly to the client, allowing time for your words to be processed and for the client to give a response.
- Encourage family to visit frequently except if this activity causes the client to become hyperactive.
- Provide clear, concise explanations of each treatment procedure or task.
- Eliminate unnecessary noise.
- Reinforce reality by interpreting unfamiliar sounds, sights, and smells; correct any misconceptions of events or situations.
- Schedule activities (e.g., meals, bath, activity and rest periods, treatments) at the same time each day to provide a sense of security.
- Provide adequate sleep.
- Keep eyeglasses and hearing aid within reach.
- Ensure adequate pain management.
- Keep familiar items in the client’s environment (e.g., photographs), and keep the environment uncluttered. A disorganized, cluttered environment increases confusion.
- Keep room well lit during waking hours.
- Eliminate unnecessary medications.

Examination (MMSE), the Delirium Index (DI), and the NEECHAM Confusion Scale.

Older adults at risk for delirium require interventions that eliminate or decrease the effects of the previously mentioned precipitating factors. Delirium can be prevented or interventions instituted to reverse the condition. Clients who have acute confusion/delirium often know something is wrong and want help. Box 38-6 lists nursing interventions to help promote a therapeutic environment for the client with acute confusion/delirium (Figure 38-3 ■).

Evaluating

Using the measurable and desired outcomes developed during the planning stage as a guide, the nurse collects the data needed to judge whether client goals and outcomes have been achieved. Examples of client outcomes and related indicators are shown in the Nursing Care Plan. If the desired outcomes are not achieved, the nurse and client, and support people, if appropriate, need to explore the reasons before modifying the care plan.

Figure 38-3 ■ Promoting orientation to time and date is essential for clients who are confused or have a memory loss.

NURSING CARE PLAN Sensory-Perception Disturbance

Assessment Data

Nursing Assessment

Julia Hagstrom is an 80-year-old widow who has recently become a resident of an extended care facility. Just prior to her admission she underwent surgery for the removal of cataracts and also experienced more difficulty with hearing. Her children were concerned about her physical safety and lack of socialization and urged her to enter a nursing home. Mrs. Hagstrom had cared for herself independently for 15 years in her own home. One day after admission the nurse finds the client somewhat confused and disoriented to place and time. She appears restless and withdrawn. She states, “I’m afraid of all of these strange creatures in this orphanage.”

Physical Examination

Height: 160 cm (5’3”)
 Weight: 55.3 kg (122 lb)
 Temperature: 37°C (98.6°F)
 Pulse: 72 beats/min
 Respirations: 18/min
 Blood pressure: 128/74 mmHg
 Rinne test: negative

Diagnostic Data

Chest x-ray, CBC, and urinalysis all negative

Nursing Diagnosis

Acute Confusion related to change in environment and hearing loss (as evidenced by disorientation to time and place; restlessness; and altered behavior)

Desired Outcomes*

Cognitive Orientation [0901] as evidenced by:

- Identifies significant other(s).
- Identifies current place.
- Identifies correct season.

Hearing Compensation Behavior [1610] as evidenced by consistently demonstrated:

- Positions self to advantage hearing.
- Reminds others to use techniques that advantage hearing.
- Eliminates background noise.
- Uses hearing supportive devices.

NURSING CARE PLAN Sensory-Perception Disturbance—continued

NURSING INTERVENTIONS*/SELECTED ACTIVITIES

RATIONALE

Reality Orientation [4820]

Provide a consistent physical environment and a daily routine.

Routine eliminates the element of surprise, overstimulation, and further confusion.

Provide access to familiar objects, when possible.

Familiarity helps reduce confusion.

Provide a low-stimulation environment for Mrs. Hagstrom because disorientation may be increased by overstimulation.

A disruption in the quality or quantity of incoming stimuli can affect a person's cognitive status. Sensory overload blocks out meaningful stimuli.

Provide for adequate rest, sleep, and daytime naps.

Reduces overstimulation and fatigue, which may be contributing factors to confusion.

Use a calm and unhurried approach when interacting with Mrs. Hagstrom.

Promotes communication that enhances the person's sense of dignity.

Speak to the client in a slow, distinct manner with appropriate volume.

The client who has difficulty hearing will be better able to lip read and comprehend speech.

Engage Mrs. Hagstrom in "here and now" activities (i.e., ADLs) that require her to focus on something other than herself that is concrete and reality oriented.

Assists the individual to differentiate between own thoughts and reality.

NURSING INTERVENTIONS*/SELECTED ACTIVITIES

RATIONALE

Communication Enhancement: Hearing Deficit [4974]

- Facilitate use of hearing aids, as appropriate.

Hearing can be enhanced if the volume is appropriate and the hearing aid is consistently used.

- Listen attentively.

Effective listening is essential in a nurse–client relationship. Poor listening skills can undermine trust and block therapeutic communication.

- Use simple words and short sentences, as appropriate.

Using simple terms and short sentences facilitates understanding and minimizes anxiety.

- Obtain Mrs. Hagstrom's attention through touch.

Gaining the attention of a client with a hearing impairment is an essential first step toward effective communication. However, the client's personal space should be respected and permission to touch should be obtained.

Evaluation

Outcomes met. Mrs. Hagstrom identifies her primary nurse by sight and name on the third day. She is aware that Christmas is 3 weeks away and is anxious to go shopping with the group. Her daughter has brought new batteries for her hearing aid, which she wears during the day.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

Critical Thinking Checkpoint

Mrs. Dodd is a 51-year-old client who is being cared for in the critical care unit following an automobile crash in which she suffered extensive traumatic injuries. Mrs. Dodd is connected to several monitoring devices, has an intubation tube and ventilator to assist her with respirations, and is receiving various pain and other medications.

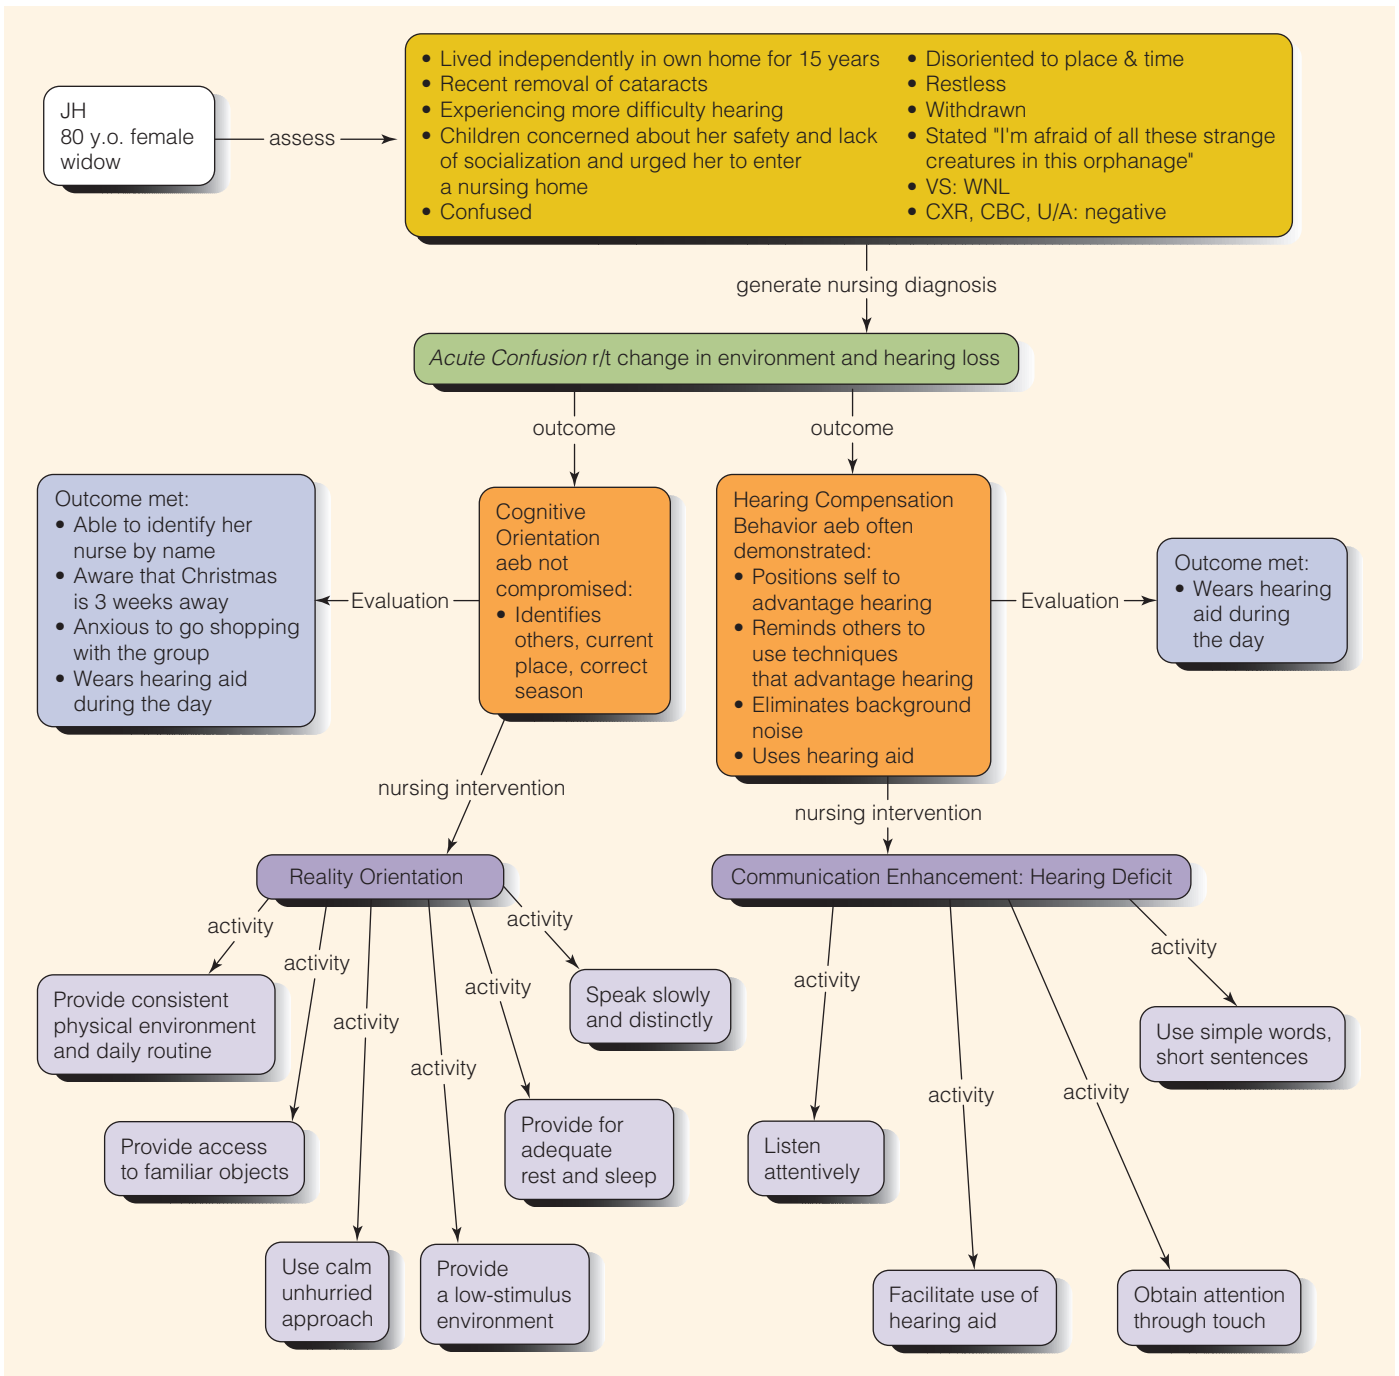

1. Identify factors that place Mrs. Dodd at risk for the development of sensory deprivation or overload.

2. What assessment findings would alert you to Mrs. Dodd's experiencing sensory overload as opposed to sensory deprivation?
3. How can you intervene to help Mrs. Dodd during this stressful event?
4. How might the care of a client in the home setting differ from the care of a client such as Mrs. Dodd who is receiving care in a critical care unit?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Sensory-Perception Disturbance

Chapter 38 Review

CHAPTER HIGHLIGHTS

- The sensory experience consists of two components: sensory reception and sensory perception.
- Sensory stimuli can be either external or internal. Visual, auditory, olfactory, tactile, and gustatory stimuli orient a person to the external environment. Kinesthetic and visceral stimuli orient the person to the internal environment. Kinesthetic stimuli make the person aware of the position and movement of body parts.
- Sensory perception involves the awareness and interpretation of stimuli into meaningful information. This process occurs in the cerebral cortex.
- The reticular activating system (RAS), with its many ascending and descending connections to other areas of the brain, monitors and regulates incoming stimuli. The RAS maintains, enhances, or inhibits cortical arousal.
- The normal, alert person can assimilate many kinds of information at one time and respond appropriately through thought and action.
- Factors affecting sensory stimulation include developmental stage, culture, stress, medications, illness, and lifestyle and personality.
- Sensory deprivation occurs when a person receives decreased sensory input or monotonous or meaningless sensory input.
- Sensory overload occurs when a person experiences excessive sensory input and is unable to process or manage the stimuli. The person feels overwhelmed and not in control.
- Responses to both sensory deprivation and sensory overload include perceptual changes (e.g., mild distortions or hallucinations), cognitive changes (e.g., decreased concentration and problem-solving ability), and affective changes (e.g., apathy, anxiety, anger, depression, and rapid mood swings).
- Clients at risk for sensory deprivation include (a) those who are homebound or institutionalized, (b) those on bed rest or isolation precautions, (c) those with sensory impairments, (d) those who come from a different culture, (e) those with certain affective disorders or disturbances of the nervous system, and (f) those on certain medications that affect the central nervous system.
- Clients at risk for sensory overload include (a) those in pain, (b) those in intensive care units, (c) those with intrusive and uncomfortable monitoring or treatment equipment, and (d) those with decreased cognitive ability (e.g., head injury).
- Assessment for sensory-perception disturbances includes (a) a nursing history to identify sensory impairments, (b) mental status examination, (c) physical examination, (d) identification of clients at risk, (e) the client's environment, and (f) the client's social support network.
- NANDA nursing diagnoses related to a client's sensory-perception impairments are *Acute Confusion*; *Chronic Confusion*; *Impaired Memory*; *Risk for Injury*; *Impaired Home Maintenance*; *Risk for Impaired Skin Integrity*; *Impaired Verbal Communication*; *Self-Care Deficit*; and *Social Isolation*.
- Goals for clients with sensory-perception disturbances include (a) preventing injury, (b) maintaining the function of existing senses, (c) developing an effective communication mechanism, (d) preventing sensory deprivation or overload, (e) reducing social isolation, and (f) performing ADLs independently and safely.
- Interventions to prevent or modify sensory deprivation, sensory overload, and sensory impairments include promoting healthy sensory function, helping clients manage sensory impairments, and adjusting environmental stimuli.
- Clients with sensory impairments need instruction about sensory aids available to support residual sensory function, ways to promote the use of other senses, and methods to ensure safety from bodily harm.
- Nurses and support people need to devise and implement effective communication mechanisms for clients who have visual and hearing impairments.
- Clients with acute confusion/delirium need care directed toward promoting their orientation to time, place, person, and situation.

TEST YOUR KNOWLEDGE

1. Which client is at greatest risk for experiencing sensory overload?
 1. A 40-year-old client in isolation with no family
 2. A 28-year-old quadriplegic client in a private room
 3. A 16-year-old listening to loud music
 4. An 80-year-old client admitted for emergency surgery
2. An alert 80-year-old client is transferred to a long-term care facility. On the second night, he becomes restless and agitated. What is the most appropriate nursing diagnosis?
 1. *Chronic Confusion*
 2. *Impaired Memory*
 3. *Acute Confusion*
 4. *Disturbed Thought Processes*
3. The nursing diagnosis *Risk for Impaired Skin Integrity* related to sensory-perception disturbance would best fit a client who:
 1. Cut a foot by stepping on broken glass.
 2. Uses a wheelchair due to paraplegia.
 3. Wears glasses because of poor vision.
 4. Is legally blind and smokes in bed.
4. Which statement indicates the client needs a sensory aid in the home?
 1. "I tripped over that throw rug again."
 2. "I can't hear the doorbell."
 3. "My eyesight is good if I wear my glasses."
 4. "I can hear the TV if I turn it up high."
5. A hospitalized client is disoriented and believes she is in a train station. Which response from the nurse is the most appropriate?
 1. "You wouldn't be getting a bath at the train station."
 2. "Let's finish your bath before the train arrives."
 3. "Don't you know where you are?"
 4. "It may seem like a train station sometimes, but this is Valley Hospital."
6. A client with impaired vision is admitted to the hospital. Which interventions are most appropriate to meet the client's needs? Select all that apply.
 1. Identify yourself by name.
 2. Decrease background noise before speaking.
 3. Stay in the client's field of vision.
 4. Explain the sounds in the environment.
 5. Keep your voice at the same level throughout the conversation.

7. A client is exhibiting signs and symptoms of acute confusion/delirium. Which strategy should the nurse implement to promote a therapeutic environment?
1. Keep lights in the room dimmed during the day to decrease stimulation.
 2. Keep the environmental noise level high to increase stimulation.
 3. Keep the room organized and clean.
 4. Use restraints for client safety.
8. A client is at risk for sensory deprivation. Which of the following clinical signs would the nurse observe? Select all that apply.
1. Sleeplessness
 2. Decreased attention span
 3. Irritability
 4. Excessive sleeping
 5. Crying, depression
9. The nurse is assessing for sensory function. Match the assessment tool to the specific sense it will be testing.
- | | |
|--------------------|--------------|
| Identifying taste | 1. Visual |
| Stereognosis | 2. Hearing |
| Snellen chart | 3. Tactile |
| Identifying aromas | 4. Olfactory |
| Tuning fork | 5. Gustatory |
10. An 85-year-old client has impaired hearing. When creating the care plan, which intervention should have the highest priority?
1. Obtaining an amplified telephone
 2. Teaching the importance of changing his position
 3. Providing reading material with large print
 4. Checking expiration dates on food packages

READINGS AND REFERENCES

Suggested Readings

- Newton, M., & Sanderson, A. (2013). The effect of visual impairment on patients' falls risk. *Nursing Older People*, 25(8), 16–21. doi:10.7748/nop2013.10.25.8.16.e489
- An older adult who is visually impaired can be seven times more likely to fall than one without visual impairment. When providing care to clients with visual impairment, it is very important to communicate effectively and ensure that all their needs have been met. When providing information related to changes in position or mobility it is important to be very specific so falls are prevented. In addition, if the client uses hearing aids make sure that they are functioning well.
- Worley, J. A., Matson, J. L., & Kozlowski, A. M. (2011). The effects of hearing impairment on symptoms of autism in toddlers. *Developmental Neurorehabilitation*, 14, 171–176. doi:10.3109/17518423.2011.564600
- Toddlers with hearing impairments are often misdiagnosed with autism spectrum disorder. In this research study the authors utilized a screening tool call the Baby and Infant Screen for Children with aUtism Traits (BISCUIT). The BISCUIT effectively identified children who suffered from hearing impairment rather than autism spectrum disorder.

39 Self-Concept

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Summarize the development of self-concept and self-esteem, including the framework described by Erikson.
2. Describe the dimensions and components of self-concept.
3. Identify common stressors affecting self-concept and coping strategies.
4. Describe the essential aspects of assessing role relationships.
5. Identify nursing diagnoses related to altered self-concept.
6. Describe nursing interventions designed to achieve identified outcomes for clients with altered self-concept.
7. Describe ways to enhance client self-esteem.

INTRODUCTION

Self-concept is one's mental image of oneself. A positive self-concept is essential to a person's mental and physical health. Individuals with a positive self-concept are better able to develop and maintain interpersonal relationships and resist psychological and physical illness. An individual possessing a strong self-concept should be better able to accept or adapt to changes that may occur over the life span. How one views oneself affects one's interaction with others.

Nurses have a responsibility to assess clients for a negative self-concept and to identify the possible causes in order to help them develop a more positive view of themselves. Individuals who have a poor self-concept may express feelings of worthlessness, self-dislike, or even self-hatred. They may feel sad or hopeless, and may state they lack energy to perform even the simplest of tasks.

SELF-CONCEPT

Self-concept involves all of the self-perceptions—appearance, values, and beliefs—that influence behavior and are referred to when using the words *I* or *me*. Self-concept influences the following:

- How one thinks, talks, and acts
- How one sees and treats another person
- Choices one makes
- Ability to give and receive love
- Ability to take action and to change things.

There are four dimensions of self-concept:

- **Self-knowledge:** insight into one's own abilities, nature, and limitations
- **Self-expectation:** what one expects of oneself; may be realistic or unrealistic expectations
- **Social self:** how a person is perceived by others and society

- **Social evaluation:** the appraisal of oneself in relationship to others, events, or situations.

People who value “how I perceive me” above “how others perceive me” can be termed *me-centered*. They try hard to live up to their own expectations and compete only with themselves, not others. In contrast, strongly *other-centered* people have a high need for approval from others and try hard to live up to the expectations of others, comparing, competing, and evaluating themselves in relation to others. They tend to have difficulty asserting themselves, and fear disapproval. The positive self-concept, therefore, is me-centered and is formed with limited reference to others' opinions.

In addition to assessing and promoting a positive self-concept with clients, a nurse's own self-concept is important. Nurses who understand the different dimensions of themselves are better able to understand the needs, desires, feelings, and conflicts of their clients. Nurses who feel positive about themselves are more likely to help clients meet their needs.

Self-awareness refers to the relationship between one's perception of himself or herself and others' perceptions of him or her. Thus, a nurse who is very self-aware has perceptions that are very congruent. Becoming more self-aware is a process that requires time and energy and is never complete. One important component of the process is introspection, which involves the nurse reflecting on his or her own beliefs, attitudes, motivations, strengths, and limitations. The nurse also gains insight into the self through working with other nurses who serve as mentors and by taking feedback obtained during regular performance reviews seriously and acting on it.

Once the nurse has developed a clear understanding and awareness of self, the nurse can respect and avoid projecting his or her own beliefs onto others. While in the caregiver role, the self-aware nurse is able to suspend judgment and focus on the needs of the client, even if they differ from those of the nurse. When conflicts arise, the nurse can

analyze his or her reactions through introspection and by asking these questions:

- “Why do I react this way (fear, anger, anxiety, annoyance, worry)?”
- “Can I change the way I respond to this situation to affect the client’s reaction in a helpful way?”

FORMATION OF SELF-CONCEPT

A person is not born with a self-concept; rather, it develops as a result of social interactions with others. Chapter 20 ∞ discusses various theories of growth and development, including Erikson’s stages of development, Piaget’s cognitive developmental phases, and Havighurst’s developmental tasks.

According to Erikson (1963), throughout life people face developmental tasks associated with eight psychosocial stages that provide a theoretical framework. The success with which a person copes with these developmental tasks largely determines the development of self-concept. Difficulty coping can result in self-concept problems at the time and, often, later in life. Table 39–1 lists examples of behaviors

indicating successful and unsuccessful resolution of these developmental tasks.

The development of one’s self-concept consists of three broad steps:

- The infant learns that the physical self is separate and different from the environment.
- The child internalizes others’ attitudes toward self.
- The child and adult internalize the standards of society.

The term **global self** refers to the collective beliefs and images one holds about oneself. It is the most complete description that individuals can give of themselves at any one time. It is also a person’s frame of reference for experiencing and viewing the world. Some of these beliefs and images represent statements of fact, for example, “I am a woman,” “I am a father,” or “I am short.” Others refer to less tangible aspects of self, for instance, “I am competent” or “I am shy.”

Each separate image and belief one holds about oneself has a bearing on self-concept. However, self-concept is not simply a sum of its parts. The various images and beliefs people hold about

TABLE 39–1 Examples of Behaviors Associated with Erikson’s Stages of Psychosocial Development

Stage: Developmental Tasks	Behaviors Indicating Positive Resolution	Behaviors Indicating Negative Resolution
Infancy: trust vs. mistrust	Requesting assistance and expecting to receive it Expressing belief of another person Sharing time, opinions, and experiences	Restricting conversation to superficialities Refusing to provide a person with personal information Being unable to accept assistance
Toddlerhood: autonomy vs. shame and doubt	Accepting the rules of a group but also expressing disagreement when it is felt Expressing one’s own opinion Easily accepting deferment of a wish fulfillment	Failing to express needs Not expressing one’s own opinion when opposed Overly concerned about being clean
Early childhood: initiative vs. guilt	Starting projects eagerly Expressing curiosity about many things Demonstrating original thought	Imitating others rather than developing independent ideas Apologizing and being very embarrassed over small mistakes Verbalizing fear about starting a new project
Early school years: industry vs. inferiority	Completing a task once it has been started Working well with others Using time effectively	Not completing tasks started Not assisting with the work of others Not organizing work
Adolescence: identity vs. role confusion	Asserting independence Planning realistically for future roles Establishing close interpersonal relationships	Failing to assume responsibility for directing one’s own behavior Accepting the values of others without question Failing to set goals in life
Early adulthood: intimacy vs. isolation	Establishing a close, intimate relationship with another person Making a commitment to that relationship, even in times of stress and sacrifice Accepting sexual behavior as desirable	Remaining alone Avoiding close interpersonal relationships
Middle-aged adults: generativity vs. stagnation	Being willing to share with another person Guiding others Establishing a priority of needs, recognizing both self and others	Talking about oneself instead of listening to others Showing concern for oneself in spite of the needs of others Being unable to accept interdependence
Older adults: integrity vs. despair	Using past experience to assist others Maintaining productivity in some areas Accepting limitations	Crying and being apathetic Not accepting changes Demanding unnecessary assistance and attention from others

themselves are not given equal weight and prominence. Each person's self-concept is like a piece of art. At the center of the art are the beliefs and images that are most vital to the person's identity. They constitute **core self-concept**. For example, "I am very smart/of average intelligence" or "I am male/female." Images and beliefs that are less important to the person are on the periphery. For example, "I am left-/right-handed" or "I am athletic/unathletic."

People are thought to base their self-concept on how they perceive and evaluate themselves in these areas:

- Vocational performance
- Intellectual functioning
- Personal appearance and physical attractiveness
- Sexual attractiveness and performance
- Being liked by others
- Ability to cope with and resolve problems
- Independence
- Particular talents.

Self-concept in these areas also extends to the choices people make and perceptions they have about their health. Individuals with strong positive self-concept about appearance are likely to value healthy behaviors and take action to maintain the health of their skin, hair, and body tone, for example. Individuals with negative self-concepts may be less proactive about health promotion and illness prevention activities.

Maintaining and evaluating one's self-concept is an ongoing process. Events or situations may change the level of self-concept over time. Having a basic self-concept includes how we see ourselves and how we are seen by others. There is also the **ideal self**, which is how we should be or would prefer to be. The ideal self is the individual's perception of how one should behave based on certain personal standards, aspirations, goals, and values. Sometimes this ideal self is realistic; sometimes it is not. When the perceived self is close to the ideal self, people do not wish to be much different from what they believe they already are. A discrepancy between the ideal self and perceived self can be an incentive to self-improvement. However, when the discrepancy is great, low self-esteem can result.

Nurses, like other adults, view themselves based on both internal and external inputs acquired over many years. The ability to appraise one's own strengths, the desire to follow in the steps of role models, and the feedback received from colleagues and clients are some of the influences on the nurse's self-concept.

COMPONENTS OF SELF-CONCEPT

The four components of self-concept are personal identity, body image, role performance, and self-esteem.

Personal Identity

Personal identity is the conscious sense of individuality and uniqueness that is continually evolving throughout life. People often view their identity in terms of name, gender, age, race, ethnic origin or culture, occupation or roles, talents, and other situational characteristics (e.g., marital status and education).

Personal identity also includes beliefs and values, personality, and character. For instance, is the person outgoing, friendly, reserved, generous, selfish? Personal identity thus encompasses both the tangible and factual, such as name and sex, and the

intangible, such as values and beliefs. Identity is what distinguishes self from others.

A person with a strong sense of identity has integrated body image, role performance, and self-esteem into a complete self-concept. This sense of identity provides a person with a feeling of continuity and a unity of personality. Furthermore, the individual sees himself or herself as a unique person.

Body Image

The image of physical self, or **body image**, is how a person perceives the size, appearance, and functioning of the body and its parts. Body image has both cognitive and affective aspects. The cognitive is the knowledge of the material body; the affective includes the sensations of the body, such as pain, pleasure, fatigue, and physical movement. Body image is the sum of these attitudes, conscious and unconscious, that a person has toward his or her body.

Body image includes clothing, makeup, hairstyle, jewelry, and other things intimately connected to the person (Figure 39–1 ■). It also includes body prostheses, such as artificial limbs, dentures, and hairpieces, as well as devices required for functioning, such as wheelchairs, canes, and eyeglasses. Past as well as present perceptions and how the body has evolved over time are part of one's body image.

Figure 39–1 ■ Body image is the sum of a person's conscious and unconscious attitudes about his or her body.

JGI/Jamie Grill/Getty Images.

A person's body image develops partly from others' attitudes and responses to that person's body and partly from the individual's own exploration of the body. For example, body image develops in infancy as the parents or caregivers respond to the child with smiles, holding, and touching, and as the child explores its own body sensations during breast-feeding, thumb sucking, and the bath. Cultural and societal values also influence a person's body image.

The various information and entertainment media have played a part over the years in how individuals view themselves and others. During adolescence, concerns related to body image are of paramount concern. The "ideal" person portrayed by the media is really an unrealistic goal for many.

If a person's body image closely resembles one's body ideal, the individual is more likely to think positively about the physical and nonphysical components of the self. The body ideal is greatly influenced by cultural standards. For example, currently in North America the fit, well-toned body is admired.

Another aspect of body image is the understanding that different parts of the body have different values for different people. For example, large breasts may be highly important to one woman and unimportant to another, or the occurrence of gray hair may be traumatic to one person and barely noticed by another.

A person with a healthy body image will normally show concern for both health and appearance. This person will seek help if ill and will include health-promoting practices in daily activities. A person who has an unhealthy body image is likely to be overly concerned about minor illness and to neglect activities like sleep and a healthy diet, both of which are important to health.

The individual who has a body image disturbance may hide or not look at or touch a body part that is significantly changed in structure by illness or trauma. Some individuals may also express feelings of helplessness, hopelessness, powerlessness, and vulnerability, and may exhibit self-destructive behavior such as over- or undereating or suicide attempts.

Role Performance

Throughout life, people undergo numerous role changes. A **role** is a set of expectations about how the person occupying a particular position behaves. **Role performance** is how a person in a particular role behaves in comparison to the behaviors expected of that role. **Role mastery** means that the person's behaviors meet role expectations. Expectations, or standards of behavior of a role, are set by society, a cultural group, or a smaller group to which a person belongs. Each person usually has several roles, such as husband, parent, brother, son, employee, friend, nurse, and church member. Some roles are assumed for only limited periods, such as client, student, and ill person. **Role development** involves socialization into a particular role. For example, nursing students are socialized into nursing through exposure to their instructors, clinical experience, classes, laboratory simulations, and seminars.

To act appropriately, people need to know who they are in relation to others and what society expects for the positions they hold. **Role ambiguity** occurs when expectations are unclear, and people do not know what to do or how to do it and are unable to predict the reactions of others to their behavior. Failure to master a role creates frustration and feelings of inadequacy, often with consequent lowered self-esteem.

Self-concept is also affected by role strain and role conflicts. People undergoing **role strain** are frustrated because they feel or are made to feel inadequate or unsuited to a role. Role strain is often associated with sex role stereotypes. For example, women in occupations traditionally held by men might be treated as having less knowledge and competence than men in the same roles.

Role conflicts arise from opposing or incompatible expectations. In an interpersonal conflict, people have different expectations about a particular role. For example, a grandparent may have different expectations than the mother about how she should care for her children. One person's or group's role expectations may differ from the expectations of another person or group. For example, a woman who has little flexibility in her full-time job schedule has a role conflict if her husband expects her to handle all childcare problems. Sometimes role expectations violate the beliefs or values of the role occupant. For example, a nurse in a family planning clinic may be expected to advise couples about birth control methods that are not consistent with the nurse's belief system regarding prevention or management of unwanted pregnancy. Role conflict can lead to tension, a decrease in self-esteem, and embarrassment.

Self-Esteem

Self-esteem is one's judgment of one's own worth, that is, how that person's standards and performances compare to others' standards and to one's ideal self. If a person's self-esteem does not match with the ideal self, then low self-concept results.

The two types of self-esteem are global and specific. **Global self-esteem** is how much one likes oneself as a whole. **Specific self-esteem** is how much one approves of a certain part of oneself. Global self-esteem is influenced by specific self-esteem. For example, if a man values his looks, then how he looks will strongly affect his global self-esteem. By contrast, if a man places little value on his cooking skills, then how well or badly he cooks will have little influence on his global self-esteem.

Self-esteem is derived from self and others. In infancy, self-esteem is related to the caregiver's evaluations and acceptances. Later the child's self-esteem is affected by competition with others. As an adult, a person who has high self-esteem has feelings of significance, of competence, of the ability to cope with life, and of control over one's destiny.

The foundation for self-esteem is established during early life experiences, usually within the family structure. However, an adult's level of overall self-esteem may change markedly from day to day and moment to moment. Severe stress—for example, stress related to prolonged illness or unemployment—can substantially lower a person's self-esteem. In health care, individuals who believe that their condition is viewed negatively by society may have lower self-esteem. People frequently focus on their negative aspects and spend less time on their positive aspects. It is important for both strengths and weaknesses to be identified.

SELF-CARE ALERT

If Maslow's level of love and belonging needs are met, the needs for self-esteem are next higher on the hierarchy. When the need for self-esteem is satisfied, the individual strives for self-actualization (see Chapter 16 ∞).

Evidence-Based Practice Do African American Grandmothers Raising Their Grandchildren Experience Role Strain?

EVIDENCE-BASED PRACTICE

Millions of American children are being raised primarily by their grandparents. African Americans are disproportionately represented in this number. Using role strain theory and socioemotional selectivity theory, Conway, Jones, and Speakes-Lewis (2011) studied how older grandmothers managed their grandchild-raising role compared to younger grandmothers. Eighty-five African American grandmothers, ages 33 to 88 years old (with the majority being 40 to 64), who were caring for their grandchildren at least 5 days each week completed demographic questionnaires and scales of role demand, emotional strain, caregiving strain index, and level of care.

Although being a parent at any age is stressful, being responsible for the process again at a time when most women are focused on a child-free lifestyle could be extraordinarily stressful and in conflict with the woman's role—from her own view as well as that of others. Results of this study showed that older grandmothers experienced less emotional and caregiving strain relative to younger

grandmothers. Although married grandmothers experienced less caregiving strain than younger ones, their age did not prevent the strain associated with the level of care.

IMPLICATIONS

Nurses should never assume that a child being parented by a caregiving grandparent is in a better or worse situation than being parented by the child's mother or father. Nurses should also never assume that the older age of the caregiver makes for a more difficult caregiving situation. This research suggests that older grandmothers may feel less role strain than younger grandmothers because of their more robust experiences. All grandmothers experienced less role strain if they, themselves, were married. Nurses must assess each situation and provide resources and support as indicated. The researchers acknowledged that other ethnic groups must be studied to determine if the findings are unique to African Americans.

FACTORS THAT AFFECT SELF-CONCEPT

Many factors affect a person's self-concept. Major factors are stage of development, family and culture, stressors, resources, history of success and failure, and illness.

Stage of Development

As an individual develops, the conditions that affect the self-concept change. For example, an infant requires a supportive, caring environment, whereas a child requires freedom to explore and learn. Older adults' self-concept is based on their experiences in progressing through life's stages.

Family and Culture

A young child's values are largely influenced by the family and culture. Later on, peers influence the child and thereby affect the sense of self. When the child is confronted by differing expectations from family, culture, and peers, the child's sense of self is often confused (Figure 39-2 ■). For example, a child may realize that his parents expect he will not drink alcohol and that he will attend religious services each Saturday. At the same time, his peers drink beer and encourage him to spend Saturday with them.

Figure 39-2 ■ A child is often pulled in opposite directions by family and peer expectations.
Jonathan Nourak/PhotoEdit Inc.

Stressors

Stressors can strengthen the self-concept as an individual copes successfully with problems. On the other hand, overwhelming stressors can cause maladaptive responses including substance abuse, withdrawal, and anxiety. The ability of a person to handle stressors will largely depend on personal resources. It is important for the nurse to identify any stressors that may affect aspects of the self-concept. See Box 39-1 for examples of stressors that may place a client at risk for problems with self-concept.

BOX 39-1 Stressors Affecting Self-Concept

IDENTITY STRESSORS

- Change in physical appearance (e.g., facial wrinkles)
- Declining physical, mental, or sensory abilities
- Inability to achieve goals
- Relationship concerns
- Sexuality concerns
- Unrealistic ideal self

BODY IMAGE STRESSORS

- Loss of body parts (e.g., amputation, mastectomy, hysterectomy)
- Loss of body functions (e.g., from stroke, spinal cord injury, neuromuscular disease, arthritis, declining mental or sensory abilities)
- Disfigurement (e.g., through pregnancy, severe burns, facial blemishes, colostomy, tracheostomy)
- Unrealistic body ideal (e.g., a muscular configuration that cannot be achieved)

ROLE STRESSORS

- Loss of parent, spouse, child, or close friend
- Change or loss of job or other significant role
- Divorce
- Illness of self or others that affects role performance
- Ambiguous or conflicting role expectations
- Inability to meet role expectations

SELF-ESTEEM STRESSORS

- Lack of positive feedback from significant others
- Repeated failures
- Unrealistic expectations
- Abusive relationship
- Loss of financial security

Resources

An individual's resources are internal and external. Examples of internal resources include confidence and values, whereas external resources include support network, sufficient finances, and organizations. Generally the greater the number of resources a person has and uses, the more positive the effect on the self-concept.

History of Success and Failure

People who have a history of failures come to see themselves as failures, whereas people with a history of successes will have a more positive self-concept. Likewise, individuals with a positive self-concept tend to find contentment in their level of success, whereas a negative self-concept can lead to viewing one's life situation as negative.

Illness

Illness and trauma can also affect an individual's self-concept. A woman who has had a mastectomy may see herself as less attractive, and the loss may affect how she acts and values herself. People respond to stressors such as illness and alterations in function related to aging in a variety of ways. Acceptance, denial, withdrawal, and depression are common reactions.

●○○ NURSING MANAGEMENT

Assessing

A thorough assessment includes a psychosocial assessment of the client and the family or support person because this provides clues to actual or potential problems. The nurse assessing self-concept focuses on its four components: (1) personal identity, (2) body image, (3) role performance, and (4) self-esteem.

Before conducting a psychosocial assessment, the nurse must establish trust and a working relationship with the client. Guidelines for conducting a psychosocial assessment include the following:

- Create a quiet, private environment.
- Minimize interruptions if possible.
- Maintain appropriate eye contact.
- Sit at eye level with the client.
- Demonstrate an interest in the client's concerns.
- Indicate acceptance of the client by not criticizing, frowning, or demonstrating shock.
- Ask open-ended questions to encourage the client to talk rather than close-ended questions that tend to block free sharing.
- Avoid asking more personal questions than are actually needed.
- Minimize writing detailed notes during the interview because this can create client concern that confidential material is being "recorded" as well as interfere with your ability to focus on what the client is saying.
- Determine whether the family can provide additional information.
- Maintain confidentiality.
- Be aware of your own biases and discomforts that could influence the assessment.
- Consider how the client's behavior is influenced by culture (see Culturally Responsive Care).

When stressors are identified, the nurse needs to determine how the client perceives the stressor. A positive, growth-oriented perception of stressful events reinforces self-worth; a negative, hopeless, defeatist perception leads to decreased self-esteem. The nurse should

Culturally Responsive Care

PATIENT-CENTERED CARE

Assessing Self-Concept

It is the nurse's responsibility to use therapeutic communication and to remain sensitive to the effect that cultural influences will have on a client's behaviors and needs. Cultural background is not only assessed directly but is also considered as a factor in the areas of self-perception, role relationships, major stressors, and coping strategies. In the area of behaviors that may suggest low self-esteem, nurses need to ask themselves the following question: Is this really a behavior that would suggest low self-esteem or is it part of the cultural behavior(s) of the client? In addition, might the client be experiencing cultural dissonance, a situation in which there are conflicting beliefs and attitudes between the client's culture and the one in which the client is living?

also identify the client's coping style and determine whether this style is effective by asking the client such questions as these:

- When you have a problem or face a stressful situation, how do you usually deal with it?
- Do these methods work?

CLINICAL ALERT!

The degree to which a stressor is perceived to affect self-concept varies from person to person. For example, some people may respond to repeated failures by trying harder, whereas others may give up.

Personal Identity

When assessing self-concept, the information the nurse first needs is about the client's personal identity. This involves who the client believes he or she is. See the accompanying Assessment Interview for examples of questions to ask.

Body Image

If there are indications of a body image disturbance (Figure 39-3 ■), the nurse should assess the client carefully for possible functional or physical problems. The disturbance may be a result of a present deformity or malfunction or an anticipated one. In addition to the stated responses about the problem, it is important to assess related behavior. See the accompanying Assessment Interview for examples of questions to ask about body image.

Role Performance

The nurse assesses the client's satisfactions and dissatisfactions associated with role responsibilities and relationships: family roles, work roles, student roles, and social roles. Family roles are especially

ASSESSMENT INTERVIEW Personal Identity

- How would you describe your personal characteristics? or How do you see yourself as a person?
- How do others describe you as a person?
- What do you like about yourself?
- What do you do well?
- What are your personal strengths, talents, and abilities?
- What would you change about yourself if you could?
- How do you feel if you think someone does not like you?

Figure 39-3 ■ People do not always appear to themselves as they appear to others.
Gusto/Science Source.

ASSESSMENT INTERVIEW Body Image

- Is there any part of your body you would like to change?
- Do you feel different or inferior to others?
- How do you feel about your appearance?
- What changes in your body do you expect following your surgery/treatment/illness?
- How have significant others in your life reacted to changes in your body?

important to people because family relationships are particularly close. Relationships can be supportive and growth producing or, at the opposite extreme, highly stressful if there is violence or abuse. Assessment of family role relationships may begin with structural aspects such as the number in the family group, ages, and residence location. To obtain data related to the client's family relationships and satisfaction or dissatisfaction with work roles and social roles, the nurse might ask some of the questions shown in the accompanying Assessment Interview. Keep in mind, however, that questions need to be tailored to the individuals and their culture, age, and situation.

ASSESSMENT INTERVIEW Role Performance

<p>FAMILY RELATIONSHIPS</p> <ul style="list-style-type: none"> • Tell me about your family. • What is home like? • How is your relationship with your spouse/partner/significant other (if appropriate)? • What are your relationships like with your other relatives? • How are important decisions made in your family? • What are your responsibilities in the family? • How well do you feel you accomplish what is expected of you? • What about your role or responsibilities would you like to change? • Are you proud of your family members? • Do you feel your family members are proud of you? 	<p>WORK ROLES AND SOCIAL ROLES</p> <ul style="list-style-type: none"> • Do you like your work? • How do you get along at work? • What about your work would you like to change if you could? • How do you spend your free time? • Are you involved in any community groups? • Are you most comfortable alone, with one other person, or in a group? • Who is most important to you? • Whom do you seek out for help?
--	---

Self-Esteem

A nurse can ask the following questions to determine a client's self-esteem:

- Are you satisfied with your life?
- How do you feel about yourself?
- Are you accomplishing what you want?
- What goals in life are important to you?

It is important for the nurse to determine the client's cultural background first in order to not misinterpret specific behaviors. The following behaviors might reflect low self-esteem or may be misinterpreted due to the client's cultural background:

- Avoids eye contact.
- Stoops in posture and moves slowly.
- Is poorly groomed and has an unkempt appearance.
- Is hesitant or halting in speech.
- Is overly critical of self (e.g., "I'm no good," "I'm ugly," or "People don't like me.").
- May be overly critical of others.
- Is unable to accept positive remarks about self.
- Apologizes frequently.
- Verbalizes feelings of hopelessness, helplessness, and powerlessness, such as "I really don't care what happens," "I'll do whatever anyone wants," or "Whatever is destined will happen."

Diagnosing

A positive self-concept can serve as a resource to a client when facing health challenges. Sometimes, as supported by data, the client has a problem in the area of self-perception and the classes of self-concept, self-esteem, and body image. Three of the NANDA International (Herdman & Kamitsuru, 2014) nursing diagnostic labels relating specifically to this domain:

- *Disturbed Body Image*
- *Ineffective Role Performance*
- *Chronic Low Self-Esteem* (and *Risk for*).

Additional nursing diagnoses that may apply to clients with problems of self-concept include the following:

- *Disturbed Personal Identity* (and *Risk for*)
- *Anxiety* related to changed physical appearance (e.g., amputation, mastectomy)

- *Ineffective Coping* with role change related to death of spouse
- *Grieving or Complicated Grieving* related to change in physical appearance
- *Hopelessness*
- *Powerlessness (and Risk for)*
- *Parental Role Conflict*
- *Readiness for Enhanced Self-Concept*
- *Disturbed Sleep Pattern*
- *Social Isolation*
- *Spiritual Distress*

Planning

The nurse develops plans in collaboration with the client and support people when possible, according to the client's state of health, level of anxiety, resources, coping mechanisms, and sociocultural and religious affiliation. The nurse who has little experience in caring for clients with altered self-concept may wish to consult with a more experienced nurse to develop effective plans. The nurse and client set goals to enhance the client's self-concept.

The goals or desired outcomes established will vary according to the diagnoses and defining characteristics related to each individual. Specific nursing interventions can be selected to meet the individual needs of the client.

Implementing

Nursing interventions to promote or enhance a positive self-concept include helping a client to identify areas of strength. In addition, for clients who have an altered self-concept, nurses should establish a therapeutic relationship and assist clients to evaluate themselves and make behavioral changes.

Identifying Areas of Strength

People often perceive their problems and weaknesses more easily than their assets and strengths. People with low self-esteem tend to focus even more on their limitations and to be aware of fewer strengths and many more problems. When a client has difficulty identifying personality strengths and assets, the nurse provides the client with a set of guidelines or a framework for identifying personality strengths (Box 39–2).

Nurses can employ the following specific strategies to reinforce strengths:

- Stress positive thinking rather than self-negation.
- Notice and verbally reinforce client strengths.
- Encourage the setting of attainable goals.
- Acknowledge goals that have been attained.
- Provide honest, positive feedback.

Enhancing Self-Esteem

Nurses assisting clients who have an altered self-concept or self-esteem must establish a therapeutic relationship. To do this the nurse must have self-awareness and effective communication skills. The following nursing techniques may help clients analyze the problem and enhance their self-esteem:

- Encourage clients to appraise the situation and express their feelings.
- Encourage clients to ask questions.
- Provide accurate information.

BOX 39–2 Framework for Identifying Personality Strengths

Note past, present, and anticipated future participation in:

- Hobbies and crafts
- Expressive arts such as writing, painting, dance, or music
- Sports and outdoor activities, including spectator sports
- Education, training, reading, technology, and related areas
- Work, vocation, job, or position.

In addition, determine:

- Sense of humor and the ability to laugh at oneself and take kidding
- Health status including healthy aspects of body function and good health maintenance practices
- Special aptitudes such as sales or mechanical ability; a “green thumb”; ability to recognize and enjoy beauty; ability to solve problems; a liking for adventure or pioneering; having perseverance and the drive needed to get things done
- Relationship strengths including the ability to make people feel comfortable, the capacity to enjoy being with people, being aware of people's needs and feelings, and being able to listen
- Emotional strengths including the capacity to give and receive warmth, affection, and love; the ability to “take” anger and to feel and express a wide range of emotions; and the capacity for empathy
- Spiritual strengths such as religious faith or love of God, and membership and participation in church and related activities.

- Become aware of distortions, inappropriate or unrealistic standards, and faulty labels in clients' speech.
- Explore clients' positive qualities and strengths.
- Encourage clients to express positive self-evaluation more than negative self-evaluation.
- Avoid criticism.
- Teach clients to substitute negative self-talk (“I can't walk to the store anymore”) with positive self-talk (“I can walk half a block each morning”). Negative self-talk reinforces a negative self-concept.

Certain strategies vary depending on the age of the client (see Lifespan Considerations).

Evaluating

To determine whether client goals or desired outcomes have been achieved, the nurse uses data collected during interactions with the client and significant others. If outcomes are not achieved, the nurse should explore the reasons, considering questions such as the following:

- Have old situations recurred, triggering feelings or behaviors associated with low self-esteem?
- Have new stressful situations occurred with which the client feels unable to cope, resulting in continuing or recurrent low self-esteem (see Chapter 42 ∞)?
- Are new or additional roles causing increased stress in adapting?
- Are significant others supporting the client adequately in attempts to improve self-esteem?
- Did the client follow through on referrals to appropriate agencies? Did the agencies provide the expected services?
- Were the client's expectations too high in relation to the time needed for successful resolution of self-esteem problems?

LIFESPAN CONSIDERATIONS Enhancing Self-Esteem

CHILDREN

- Children build strong self-esteem if they develop five basic attitudes: (1) security and trust, (2) identity, (3) belonging, (4) purpose, and (5) personal competence.
- Security and trust are developed early in life; infants should learn that they can rely on their parents to meet their needs promptly and consistently. With older children, trust and security are strengthened when adults spend time with them: listening, playing, reading, or just being there. Both emotional and physical contact, such as a hug, convey warmth and caring.
- Identity is developed when children are allowed to explore and experiment with the world around them and to express themselves as unique individuals in that world. They should be given opportunities to “practice” who they are. Preschoolers, for example, love to dress themselves and should be allowed to wear outlandish outfits (within limits of weather and safety) if they choose. Teenagers who try new hair colors and styles, some of which may “offend” their parents, are engaging in a crucial developmental step (Figure 39–4 ■).
- Belonging is essential for all humans, and having a sense that others in your social network care about you, want you there, and benefit by your contribution is important to healthy self-esteem. Children gain this sense of belonging by being included in activities, by being praised for their efforts and achievements, and by being valued by parents, siblings, caregivers, and other adults. Parents should make an effort to “catch their children doing well” and praise them for it (e.g., “I like the way you share with your brother.”). Children should also hear that they are valued just for being themselves (e.g., “I like doing things with you. Remember when we went to the park? Wasn’t that fun?”).
- Purpose and belonging are closely related. Children need opportunities to participate in the family and their community in order to discover what they can best contribute based on their strengths and skills. One mother, for example, stated

Figure 39–4 ■ Exploring different styles is a healthy and normal step in developing one’s identity.
Nancy Pastor/Getty Images.

“Leo (age 4) is our actor. He is wonderful with costumes and can make any of us smile when he starts his routine.” Leo may never become an actor, but he knows he makes a significant contribution to his family’s well-being. He brings them joy.

- Personal competence grows as children identify and refine their skill sets. Children develop competence as they confront and solve problems, face challenges, expand their thinking, and are asked to do more than they think they can do. Adults must, however, provide children with support, guidance, appropriate assistance, and constructive feedback (including praise) in order to prevent the child from being overwhelmed. Too much frustration or uncertainty can lead to giving up, avoidance, lying, bullying, and other antisocial behaviors. If adults help children to accomplish goals that are important to them, children are more likely to develop a sense of personal competence and independence.
- Key ingredients for helping children develop high self-esteem are love, acceptance, firmness, consistency, and the establishment of expectations. Such qualities provide children with a safe, loving, supportive, and predictable world in which to live.

ADOLESCENTS

- Provide increasing levels of responsibility. Adolescents need to experience successes and failures and the consequences of their own behavior.
- Encourage discussion about issues including problems and mistakes.
- Show appreciation for effort and contributions (Figure 39–5 ■). Emphasize the process, not just the result.
- Ask for their opinions and suggestions.
- Encourage participation in decision making in areas that affect the adolescent. Show confidence in the teen’s judgments.
- Avoid comparison with or ridicule or punishment in front of others.
- Assist in the creation of realistic goals and standards.
- Adolescents often engage in volunteer activities in their schools or communities, helping them to identify their strengths and find meaning in their activities. Knowing that they have a purpose and make a difference gives children strong self-esteem.

ADULTS

- Explore the meaning of self-esteem and how his or her self-esteem has influenced past behaviors and actions (and can influence present and future plans and decisions).

Figure 39–5 ■ Public praise for achievements enhances self-esteem.
Tom & Dee Ann McCarthy/Glow Images.

LIFESPAN CONSIDERATIONS Enhancing Self-Esteem—continued

- Assist the client in assessing the internal and external forces contributing to or retarding his or her self-esteem.
- Act in ways that demonstrate belief that the person can cope with the realities and demands of life and is worthy of experiencing joy and happiness.
- Avoid comparisons with other people.
- Discourage statements about the self that are negative.
- Encourage the use of affirmations to enhance self-esteem, including statements such as “I like myself” or “I am a valuable person.”
- Encourage associations with positive, supportive people.
- Make positive statements about the person's past successes (major or minor).
- Assist the person to make a list of his or her positive qualities and to review this list often.
- Suggest the person do things for others. Making a positive contribution enhances positive feelings of self-worth.

OLDER ADULTS

Older adults who become increasingly dependent can develop low self-esteem. Old age is frequently accompanied by changes such as reduced income, decline in physical health, loss of friends and family, and retirement. In addition to those actions listed above for use with adults, nurses can use the following techniques to help older adults enhance their self-esteem:

- Encourage clients to participate in planning their own care.
- Listen carefully to their concerns.
- Assist clients to identify and use their own strengths.
- Encourage them to participate in activities in which they can be successful.
- Communicate that the client is valued. Use the client's name and ask for advice.
- Encourage older adults to stay connected with their memories (Figure 39–6 ■). Reminiscing by writing or recording an autobiography or storytelling are excellent ways to do this.
- For older adults who are in hospitals or nursing homes, make sure that they are always shown respect and dignity and are provided privacy.
- Encourage creative activities to tap their resources. Examples are music, art, storytelling, quilting, and photography.
- Work with clients to establish goals in small steps that are achievable—this, in itself, can bolster self-esteem.

WEAVING THE TAPESTRY OF LIFE

The mainstays of the tapestry of life are the powers in one's life—self-esteem, love of life and humanity, and closeness to and recognition of the Godlife in oneself and others.

The weavings that form the patterns in one's life are experiences, knowledge, and dreams. Beauty can be seen throughout, but the strength of the fabric increases with age as the tapestry displays interweavings and integration of these special qualities.

Figure 39–6 ■ Sharing memories with others can enhance seniors' self-esteem and general feelings of well-being.
Art Montes De Oca/Getty Images.

As time goes on, aging is often accompanied by a fragileness of the physical body and an increased number of inevitable losses—emotional and social, as well as physical. This is when the integration of those special fibers—strengthening qualities—becomes so crucial to the overall quality of life of the individual.

When these strengths are displayed in the tapestry of life, the individual is not only given a feeling of self-worth and self-love, but the tapestry is a beautiful gift for all who behold it and are somehow touched by it. *Grace Miller*

The nurse, client, and significant others need to understand that to change beliefs, feelings, and behaviors affecting self-esteem requires time and ongoing effort. Unlike many physical problems (e.g., wounds) where healing can be quickly observed, improving one's

self-concept can be a continuing concern and is not so easily evaluated. New crises can cause clients to doubt themselves and revert to former feelings of inadequacy. People can learn from each new situation and gain new strategies for feeling satisfied with themselves.

Critical Thinking Checkpoint

Craig is a 20-year-old male college student who was involved in an automobile crash 3 days ago, suffering a traumatic amputation of his left lower leg. Craig's mother has remained with him since the crash and is very supportive. His father is grief stricken and having difficulty dealing with Craig's condition because Craig was captain of his college basketball team and had aspirations of becoming a professional athlete. Craig's condition is stable and he is being placed into a rehabilitation program immediately. Soon, he will be fitted for a leg prosthesis. Usually an outgoing individual, Craig is somber and nontalkative. He does not look at his leg when dressings are being changed and he refuses to discuss his rehabilitation program.

1. Given Craig's age, speculate about whether Craig's self-concept is at risk for being adversely affected by his disability.
2. What data suggest that Craig's self-esteem is, or is at risk for being, negatively affected by his amputation?
3. What factors are likely to affect Craig's adaptation to his amputation and rehabilitation?
4. How would your interventions differ for a client with the same condition who was 70 years old?
5. What other groups of clients, in addition to those with amputations, are at risk for the development of altered self-esteem or body image?

See Critical Thinking Possibilities on student resource website.

Chapter 39 Review

CHAPTER HIGHLIGHTS

- A positive self-concept is essential to a person's mental and physical health.
- A person's self-perception can differ from the person's perception of how others see him or her and from the ideal self, that is, how the person would like to be.
- Factors affecting self-concept include stage of development, family and culture, stressors, resources, history of success and failure, and illnesses that affect role performance.
- The nurse assesses four areas of self-concept: personal identity, body image, role performance and relationships, and self-esteem.
- Because a positive self-concept is basic to health, one of the nurse's major responsibilities is to assist clients whose self-concept is disturbed to develop a more positive and realistic image of themselves.
- A trusting client–nurse relationship is essential for the effective assessment of a client's self-concept, for providing help and support, and for motivating client behavior change.

TEST YOUR KNOWLEDGE

1. Sally is 5'7", weighs 105 lb, and believes that she is fat. Which of the following most represents this perception?
 1. Altered body image
 2. Altered personal identity
 3. Excessive self-expectation
 4. Altered core self-concept
2. Students juggling the responsibilities of work, school, and family are most likely to experience which of the following?
 1. Role ambiguity
 2. Role strain
 3. Role conflict
 4. Role enhancement
3. An appropriate desired outcome for clients with *Situational Low Self-Esteem* includes which of the following?
 1. Restored self-esteem
 2. Consistently verbalizes self-acceptance
 3. Teaches adaptive skills
 4. Describes preoccupation with altered self
4. An 89-year-old client states, "I'm a lost cause. I can't even stand long enough to cook my own meals anymore." Which is the most appropriate response?
 1. "That must be difficult. What things are you still able to do?"
 2. "Well, that is to be expected at your age."
 3. "Do you have someone else who can cook for you?"
 4. "Are you a good cook?"
5. An adult who has failed to satisfactorily resolve the developmental task of adolescence—identity versus confusion—is most likely to show which behavior?
 1. Asserts independence
 2. Is unable to express personal desires
 3. Has difficulty working as a member of a team
 4. Goes along with the crowd in all activities
6. During an annual performance review, which statement by the nurse indicates the area of self-awareness?
 1. "I rarely make any medication errors."
 2. "I am willing to mentor new nurses."
 3. "My client satisfaction reports agree that I am friendly and helpful."
 4. "All of my clients have recovered quickly from their health problems."

7. When asked to describe herself, a client newly diagnosed with a chronic illness describes only those roles involving others (e.g., wife, mother, medical assistant) and no personal hobbies or interests. What should the nurse include when planning her care?
 1. How her treatment will affect her ability to perform those roles
 2. How to set goals for her to develop personal hobbies or interests
 3. That the family must be present while the treatment plan is being developed
 4. That she will need psychological counseling for role performance in addition to her medical treatment
8. You are caring for a client who has a nursing diagnosis of *Chronic Low Self-Esteem*. Which behaviors are consistent with this diagnosis? Select all that apply.
 1. Confronts authority
 2. Verbalizes own weaknesses
 3. Is unable to perform consistent with his/her family role (e.g., mother, father)
 4. Sets unrealistically high goals
 5. Has difficulty making positive observations about self
 6. Has difficulty sleeping
9. Which interventions are appropriate for a client with low/poor self-concept? Select all that apply.
 1. Encourage the client to compare self with others.
 2. Suggest the client not say negative things about self.
 3. Suggest the client say positive things about self.
 4. Recommend the client avoid situations of having to care for others.
 5. Communicate very low-level expectations of the client's behavior.
10. Self-concept may vary according to a variety of conditions affecting the individual. The nurse recognizes that even appropriate nursing interventions are least likely to alter which of the following?
 1. Resources
 2. Self-knowledge
 3. Core self-concept
 4. Social self

Levant, R. F. (2011). Research in the psychology of men and masculinity using the gender role strain paradigm as a framework. *American Psychologist*, *66*, 765–776. doi:10.1037/a0025034
This article discusses the specialty area of the psychology of men and masculinity, focusing on research conducted using the gender role strain paradigm. It presents three types of masculine gender role strain (discrepancy, dysfunction, and trauma) and the normative male alexithymia (difficulty with experiencing, expressing, and describing emotional responses) hypothesis. It also presents future research directions.

40 Sexuality

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe sexual development and concerns across the life span.
2. Define sexual health.
3. Discuss the varieties of sexuality.
4. Give examples of how the family, culture, religion, and personal expectations and ethics influence one's sexuality.
5. Describe physiological changes during the sexual response cycle.
6. Identify the forms of altered sexual function.
7. Identify basic sexual questions the nurse should ask during client assessment.
8. Formulate nursing diagnoses and interventions for the client experiencing sexual problems.
9. Recognize health promotion teaching related to reproductive structures.

INTRODUCTION

All humans are sexual beings. Regardless of gender, age, race, socioeconomic status, religious beliefs, physical and mental health, or other demographic factors, we express our sexuality in a variety of ways throughout our lives.

Human sexuality is difficult to define. Sexuality is an individually expressed and highly personal phenomenon that evolves from life experiences. Physiological, psychosocial, and cultural factors influence a person's sexuality and lead to the wide range of attitudes and behaviors seen in humans. Satisfying or "normal" sexual expression can be described as whatever behaviors give pleasure and satisfaction to those adults involved, without threat of coercion or injury to self or others. What constitutes normal sexual expression, however, varies among cultures and religions.

DEVELOPMENT OF SEXUALITY

The development of sexuality begins with conception and continues throughout the life span. Table 40–1 outlines characteristics of sexual development typically seen throughout the life span, with nursing interventions and teaching guidelines for each developmental stage.

Birth to 12 Years

The ability of the human body to experience a sexual response is present before birth. As evidenced by ultrasound, males have erections several months before birth. They continue to experience

erections after birth. Females have vaginal lubrication at birth. When babies find their fingers and toes, they also find their genitals. They seem to experience a pleasurable sensation from the touch but one would not call this a sexual experience. By the age of 3, more purposeful **masturbation** (excitation of one's own or another's genital organs by means other than sexual intercourse) begins and the orgasmic response is quite common, although males do not ejaculate until after puberty. By age 2 1/2 or 3, children have beginning awareness of genital differences between males and females.

Around age 9 or 10, the first physical changes of puberty begin—the development of breast buds in girls and the growth of pubic hair. As the adrenal glands mature, they produce more testosterone and estradiol, which contributes to the first experiences of sexual attraction to another person. Girls need to be taught about **menstruation** (monthly uterine bleeding) and related self-care.

Adolescence

During early adolescence (12 to 13 years), primary and secondary sex characteristics continue to develop, necessitating more information about body changes. For boys, the testes and scrotum increase in size, the skin over the scrotum becomes darker, pubic hair grows, and axillary sweating begins. Development of the genitals to adult size takes about 5 to 6 years. For girls, the pelvis and hips broaden, the breast tissue develops (see page 573 in Chapter 30 ) , pubic hair grows, axillary sweating begins, and vaginal secretions become milky and change from an alkaline to an acid pH.

TABLE 40–1 Sexual Development Throughout Life

Stage	Characteristics	Nursing Interventions and Teaching Guidelines
INFANCY Birth–18 months	Given gender assignment of male or female. Differentiates self from others gradually. External genitals are sensitive to touch. Male infants have penile erections; females, vaginal lubrication.	Self-manipulation of the genitals is normal. Caregivers need to recognize these behaviors as common in children.
TODDLER 1–3 years	Continues to develop gender identity. Able to identify own gender.	Body exploration and genital fondling is normal. Use names for body parts. Children from single-parent homes should have contact with adults of both sexes.
PRESCHOOLER 4–5 years	Becomes increasingly aware of self. Explores own and playmates' body parts. Learns correct names for body parts. Learns to control feelings and behavior. Focuses love on parent of the other sex.	Answer questions about "where babies come from" honestly and simply. Parental overreaction to exploration of genitals and masturbation can lead to feelings that sex is "bad."
SCHOOL AGE 6–12 years	Has strong identification with parent of same gender. Tends to have friends of the same gender. Has increasing awareness of self. Increased modesty, desire for privacy. Continues self-stimulating behavior. Learns the role and concepts of own gender as part of the total self-concept. At about 8 or 9 years becomes concerned about specific sex behaviors and often approaches parents with explicit concerns about sexuality and reproduction.	Provide parents and children with opportunities to express their concerns and ask questions regarding sex. Answer all questions with factual data and perhaps follow up with appropriate books and other material. Advise parents to discuss basic information about sexual intercourse, menstruation, and reproduction with children at about 10 years of age. Give children reading material and then discuss it with them.
ADOLESCENCE 12–18 years	Primary and secondary sex characteristics develop. Menarche usually takes place. Develops relationships with interested partners. Masturbation is common. May participate in sexual activity. May experiment with homosexual relationships. Are at risk for pregnancy and sexually transmitted infections (STIs).	Adolescents require information about body changes. Peer groups have great importance at this time and assist in forming gender roles. Dating helps adolescents prepare for adult roles. Parents influence values and beliefs regarding behavior. Teenagers require information about contraceptive measures and precautions to take with regard to STIs.
YOUNG ADULTHOOD 18–40 years	Sexual activity is common. Establishes own lifestyle and values. Homosexual identity usually established by mid-20s. Many couples share financial obligations and household tasks.	Young adults often require information about measures to prevent unwanted pregnancies (i.e., abstinence or contraceptive devices). Require information to prevent STIs. Regular communication is required to understand partner's sexual needs and to work through problems and stresses.
MIDDLE ADULTHOOD 40–65 years	Men and women experience decreased hormone production. The menopause occurs in women usually anywhere between ages 40 and 55. The climacteric occurs gradually in men. The quality rather than the number of sexual experiences becomes important. Individuals establish independent moral and ethical standards.	Women and men may need help adjusting to new roles. People may require counseling to help them reevaluate and direct their energies. Encourage couples to look at the positive aspects of this time of life.
LATE ADULTHOOD 65 years and older	Interest in sexual activity often continues. Sexual activity may be less frequent. Women's vaginal secretions diminish, and breasts atrophy. Men produce fewer sperm and need more time to achieve an erection and to ejaculate.	Older adults often continue to be sexually active. Couples may require counseling about adapting their affection and sexual needs to physical limitations.

First-time sexual activity increases from less than 2% before age 12 to 6% by age 15, 33% by age 16, 48% at age 17, and 61% at age 18 (Finer & Philbin, 2013). The percent of teens who have never had sex has decreased for both males and females during the past 20 years (Martinez, Copen, & Abma, 2011).

Teenage girls may have irregular menstruation initially, which can lead to embarrassment because of stained clothing. They can be taught to be aware of subtle signs of impending menstruation, such as tender breasts, water retention or bloating, or the appearance of skin eruptions or pimples. Girls should also be counseled regarding the variety of feminine hygiene products available (e.g., sanitary pads and tampons) so they can make intelligent choices. Parents and nurses should advise teenage girls to wash their hands thoroughly before and after inserting a tampon, to change tampons frequently, to alternate them with sanitary pads, and to use pads at night. These measures will help to decrease infection, including the risk of “toxic shock,” a particular type of *Staphylococcus aureus* infection. Thorough cleaning of the genital area and wiping from front to back will also decrease infection and prevent odors.

Dysmenorrhea (painful menstruation) is prevalent among adolescent females. Cramping, lower abdominal pain radiating to the back and upper thighs, nausea, vomiting, diarrhea, and headaches may occur for a few hours up to 3 days. Dysmenorrhea results from powerful uterine contractions, which cause ischemia and cramping pain. The symptoms of dysmenorrhea are treated with administration of analgesics such as aspirin, application of heat to the abdomen, certain exercises such as abdominal muscle strengthening, biofeedback, and nonsteroidal anti-inflammatory medications, such as ibuprofen.

All adolescents want to know about sexual behaviors but are often uneasy about discussing these concerns with their parents. Nurses, the schools, and the family need to provide accurate information. During the nursing assessment, teenagers should be asked directly what they know about sex, contraception, and reproduction. Sometimes a lot of the teenager’s information is based on popular myths and little, if any, on fact. The nurse should discuss factual information about sex, sexual actions and their consequences, the individual’s right to decide regarding ways to express oneself sexually,

and the responsibilities of each person regarding sexual activity. See Table 40–2.

Sexually transmitted infections (STIs) are the most common bacterial infections among adolescents. Teens need education about these diseases, preventive measures, and early treatment. The common types and symptoms of STIs for which teenagers should seek medical care are listed in Clinical Manifestations. The nurse should also inform teens about the methods of birth control: abstinence, pills, timed-release transdermal patches and implants, diaphragms, intrauterine devices, the rhythm method, and condoms to prevent an unplanned pregnancy. These are discussed later in this chapter.

Young and Middle Adulthood

In young adulthood, many people form intimate relationships with long-term implications. These relationships may take the form of dating, cohabitation, or marriage. Note, however, that some people do not form intimate relationships until late adulthood and that some never form these types of relationships.

Young adult men and women are often concerned about normal sexual response, for both themselves and their partners. In heterosexual relationships, problems may arise because of basic differences in male and female expectations and responses. Gay and lesbian couples may fare better in this respect. Couples need to communicate their needs to one another early in their courtship so a successful intimate relationship can develop and grow. Young adults should also know that because sexual needs and responses may change, each partner should listen and respond to the needs of the other.

During middle adulthood both men and women experience decreased hormone production, causing the climacteric, usually called menopause in women. These events often affect the individual’s sexual self-concept, body image, and sexual identity. See Chapter 23 ∞ for further information on menopause.

Older Adulthood

Older adults may define sexuality far more broadly and include in their definition such things as touching, hugging, romantic gestures

TABLE 40–2 Common Sexual Misconceptions

Misconception	Fact
Nearly all men over 70 years old have erectile dysfunction.	Sexual ability is not lost due to age. Changes are commonly due to disease or medication.
Masturbation causes certain mental instabilities.	Masturbation is a common and healthy behavior.
Sexual activity weakens a person.	There is no evidence that sexual activity weakens a person.
Women who have experienced orgasm are more likely to become pregnant.	Conceiving is not related to experiencing orgasm.
Nice girls shouldn’t feel entitled to their own sexual satisfaction.	As women become more comfortable with their own sexuality, they advocate for their own sexual fulfillment.
A large penis provides greater sexual satisfaction to women than a small penis.	There is no evidence that a large penis provides greater satisfaction.
Alcohol is a sexual stimulant.	Alcohol is a relaxant and central nervous system depressant. Chronic alcoholism is associated with erectile dysfunction.
Intercourse during menstruation is dangerous (i.e., it will cause vaginal tissue damage).	There is no physiological basis for abstinence during menses.
The face-to-face coital position is the moral or proper one.	The position that offers the most pleasure and is acceptable to both partners is the correct one.

CLINICAL MANIFESTATIONS

Sexually Transmitted Infections

Infection	Male	Female
Gonorrhea	Painful urination; urethritis with watery white discharge, which may become purulent.	May be asymptomatic; or vaginal discharge, pain, and urinary frequency may be present.
Syphilis	Chancere, usually on glans penis, that is painless and heals in 4–6 weeks; secondary symptoms—skin eruptions, low-grade fever, inflammation of lymph glands—in 6 weeks to 6 months after chancere heals.	Chancere on cervix or other genital areas that heals in 4–6 weeks; symptoms same as for male.
Genital warts (condyloma acuminatum)	The infection is caused by the human papillomavirus (HPV). Single lesions or clusters of lesions growing beneath or on the foreskin, at the external meatus, or on the glans penis. On dry skin areas, lesions are hard and yellow-gray. On moist areas, lesions are pink or red and soft with a cauliflower-like appearance.	Certain strains of HPV have been linked to cervical cancer. Lesions appear at the bottom part of the vaginal opening and on the perineum, labia, inner walls of the vagina, and cervix.
Chlamydial urethritis	Urinary frequency; watery, mucoid urethral discharge.	Commonly a carrier; vaginal discharge, dysuria, urinary frequency.
Trichomoniasis	Slight itching; moisture on top of penis; slight, early morning urethral discharge. Many males are asymptomatic.	Itching and redness of vulva and skin inside thighs; copious watery, frothy vaginal discharge.
Candidiasis	Itching, irritation, discharge, plaque of cheesy material under foreskin.	Red and excoriated vulva; intense itching of vaginal and vulvar tissues; thick, white, cheesy or curd-like discharge.
Acquired immunodeficiency syndrome (AIDS)	Symptoms can appear anytime from several months to several years after acquiring the virus. The person has reduced immunity to other diseases. Symptoms include any of the following for which there is no other explanation: persistent heavy night sweats; extreme fatigue; severe weight loss; enlarged lymph glands in neck, axillae, or groin; persistent diarrhea; skin rashes; blurred vision or chronic headache; harsh, dry cough; thick gray-white coating on tongue or throat.	
Herpes genitalis (herpes simplex of the genitals)	Primary herpes involves the presence of painful sores or large, discrete vesicles that last for weeks; vesicles rupture. Recurrent herpes is itchy rather than painful; it lasts for a few hours to 10 days.	

Evidence-Based Practice Does Women's Attraction to Other Women Predict Their Feelings of Well-Being?

EVIDENCE-BASED PRACTICE

In this study, Johns, Zimmerman, and Bauermeister (2013) examined the relationship between sexual attraction, sexual identity, and psychosocial well-being in the 391 female subsample of a national sample of adults ages 18 to 24. Women in this study rated on a scale from 1 (not at all) to 5 (extremely) their degree of sexual attraction to males and females, respectively. From these scores, women were divided into four groups (low female/low male attraction, low female/high male attraction, high female/low male attraction, or high female/high male attraction). Then, the relationship between experiences of attraction, reported sexual identity, and psychosocial outcomes were explored. The results indicated *sexual attraction* to be predictive of women's psychosocial well-being as much as or more than sexual identity measures. While the identification of oneself as lesbian, gay, or bisexual may cause external stressors that negatively influence psychosocial well-being, the possession of same-sex attraction may be the internal mechanism that leads women of

this age group to feel different from their peers, regardless of how they identify their sexual orientation.

IMPLICATIONS

Currently, individuals who have sex with members of their same gender, whether exclusively or not, may be considered one of the sexual minorities. This study showed that the feelings of well-being in this sexual minority group of women were more influenced by how attracted they were to other women than how they demonstrated their sexual preference (sexual identity). Internal feelings of depression, anxiety, and low self-esteem can arise as much from thoughts and feelings as from actions. For the nurse, this finding reinforces the importance of not making any assumptions about a person's sexuality. A thorough assessment and a demonstration of openness to any preferences the client may express are critical to identifying and meet client needs.

(e.g., giving or receiving roses), comfort, warmth, dressing up, joy, spirituality, and beauty. Interest in sexual activity is not lost as people age. For men, however, more time is needed to achieve an erection and to ejaculate (the erection may last longer than at a younger age); more direct genital stimulation is required to achieve an erection; the volume of ejaculated fluid decreases; and the intensity of contractions with orgasm may decrease. The refractory period after orgasm is longer.

Older women remain capable of multiple orgasms and may experience an increase in sexual desire after menopause. Vaginal lubrication and elasticity decrease with menopause and decreased estrogen, and phases of the sexual response cycle may take longer to occur. There is a possibility of pain during sexual activity and intercourse (dyspareunia) related to vaginal dryness or chronic health conditions (e.g., diabetes or arthritis). Lack of privacy may be a concern for older adults who live with family or in a rehabilitation or nursing home facility.

Many products are available to assist older adults with enhancing their sexual experiences. These range from simple lubricants to medications and surgically implanted devices that enable penile erections. Although older adults' technique may require modification, the nurse should never assume that they are less interested in or less motivated to have an active sex life.

SEXUAL HEALTH

Sexual health is an individual and constantly changing phenomenon falling within the wide range of human sexual thoughts, feelings, needs, and desires. For most people, sexual health is not a concern until its absence or impairment is noticed. A person's degree of sexual health is best determined by that individual, sometimes with the assistance of a qualified professional.

The Centers for Disease Control and Prevention (CDC)/Health Resources and Services Administration (HRSA) Advisory Committee on HIV, Viral Hepatitis, and STD Prevention and Treatment (2012) defines sexual health in the United States as follows:

Sexual health is a state of well-being in relation to sexuality across the life span that involves physical, emotional, mental, social, and spiritual dimensions. Sexual health is an inextricable element of human health and is based on a positive, equitable, and respectful approach to sexuality, relationships, and reproduction, that is free of coercion, fear, discrimination, stigma, shame, and violence. Sexual health includes: the ability to understand the benefits, risks, and responsibilities of sexual behavior; the prevention and care of disease and other adverse outcomes; and the possibility of fulfilling sexual relationships. (p. 41)

Sexual health occurs when sexual relationships are respectful, safe, and pleasurable. Respect for sexual rights, which are essential for sexual health are listed in Box 40–1.

BOX 40–1 Sexual Rights

1. The right to equality and non-discrimination
2. The right to life, liberty, and security of the person
3. The right to autonomy and bodily integrity
4. The right to be free from torture and cruel, inhuman, or degrading treatment or punishment
5. The right to be free from all forms of violence and coercion
6. The right to privacy
7. The right to the highest attainable standard of health, including sexual health; with the possibility of pleasurable, satisfying, and safe sexual experiences
8. The right to enjoy the benefits of scientific progress and its application
9. The right to information
10. The right to education and the right to comprehensive sexuality education
11. The right to enter, form, and dissolve marriage and other similar types of relationships based on equality and full and free consent
12. The right to decide whether to have children, the number and spacing of children, and to have the information and the means to do so
13. The right to the freedom of thought, opinion, and expression
14. The right to freedom of association and peaceful assembly
15. The right to participation in public and political life
16. The right to access to justice, remedies, and redress

From *Declaration of Human Rights*, by the World Association for Sexual Health, 2014. Reprinted with permission. Retrieved from <http://www.worldsexology.org/resources/declaration-of-sexual-rights/>

Components of Sexual Health

Five critical components of sexual health are sexual self-concept, body image, gender identity, gender-role behavior, and freedoms and responsibilities. Also see Chapter 39 for further discussion of self-concept, role, image, and identity.

One's **sexual self-concept** (how one values oneself as a sexual being) determines with whom one will have sex, the gender and kinds of people a person is attracted to, and the values about when, where, with whom, and how one expresses sexuality. A positive sexual self-concept enables people to form intimate relationships throughout life. A negative sexual self-concept may impede the formation of relationships.

Body image, a central part of the sense of self, is constantly changing. Pregnancy, aging, trauma, disease, and therapies can alter an individual's appearance and function, which can affect body image. How a person feels about his or her body is related to one's sexuality. People who feel good about their bodies are likely to be comfortable with and enjoy sexual activity. People who have a poor body image may respond negatively to sexual arousal. A major influence on body image for women is the media focus on physical attractiveness and breast size. Likewise, many men worry about penis size. The myth that "larger is better," particularly if it stays erect for a substantial time, is pervasive in North America. A person's body image can suffer when unable to achieve these expectations.

Gender identity is one's self-image as a female or male. More than just the biologic component, it also includes social and cultural norms. Gender identity results from developmental events that may or may not conform to one's apparent biologic sex. Once gender identity is established, it cannot be easily changed.

Gender-role behavior is the outward expression of a person's sense of maleness or femaleness as well as the expression of what is perceived as gender-appropriate behavior. Each society defines its roles for males and females; boys are given reinforcement for behaving in a "masculine" way, and girls receive reinforcement for exhibiting "feminine" behaviors (Figure 40–1).

Physical structure, variations in the internal sense of what is male or female, family values, and cultural values all influence gender-role behavior. In North America, traditional adult male roles include breadwinner, lover, father, and athlete. Expected male behaviors include wearing trousers, demonstrating physical strength, and expressing feelings in a controlled fashion. Women traditionally express

Figure 40–1 ■ Children express gender-role behavior at an early age. Bill Aron/PhotoEdit.

their emotions more freely and are gentler in their physical responses; they also have a broader choice of clothing than men do.

Androgyny, or flexibility in gender roles, is the belief that most characteristics and behaviors are human qualities that should not be limited to one specific gender or the other. Being androgynous does not mean being sexually neutral or imply anything about one's sexual orientation. Rather, it describes the degree of flexibility a person has regarding gender-stereotypic behaviors. Adults who can behave flexibly regarding their sexual roles may adapt better than those who adopt rigid stereotyped gender roles.

Sexual health includes both freedoms and responsibilities. Sexually healthy people engage in activities that are freely chosen, including both self-pleasuring and shared-pleasuring activities. Individuals also have freedom of their sexual thoughts, feelings, and fantasies. Sexually healthy people are ethically motivated to exercise behavioral, emotional, economic, and social responsibility for themselves.

VARIETIES OF SEXUALITY

There is a tremendous range of variation in how people experience and express their sexuality. There are also many differences in the priority people place on sexuality in their lives. Sexual varieties include sexual orientation, gender identity, and erotic preferences.

Sexual Orientation

One's attraction to people of the same sex, other sex, or both sexes is referred to as **sexual orientation**. Sexual orientation lies along a continuum with a wide range between extremes of exclusive attraction. This is one reason why the number of terms used to describe sexuality is increasing. The term LGBTQQ is frequently used. It stands for lesbian, gay, bisexual, transgender, queer, and questioning. In general, same-sex attraction has been called *homosexuality*, women attracted only to women are referred to as *lesbians*, men attracted to men as *gay* (although gay is also a general term for homosexual), individuals attracted to people of both genders as *bisexuals*, someone who identifies with a different gender than their anatomic designation is a **transgender person**, someone who rejects gender stereotypes may be considered *queer*, and those who have not decided on their orientation may be *questioning*. Many other terms may also be used. The nurse should feel comfortable asking for the client's definition of a term if unsure of its meaning.

The origins of sexual orientation are still not well understood. Some biologic theories describe sexual orientation in terms of the genetic composition of the individual. Psychological theories stress the role of early learning experiences and cognitive processes. Other theories acknowledge the confluence of genetics and the environment in developing sexual orientation.

Estimates of the percentage of the population with a homosexual orientation vary. Because these individuals grow up acutely aware of the discrimination they face in North America, many do not disclose their sexual orientation; actual figures are not available. A 2012 survey of over 120,000 Americans demonstrated that 3.4% of adults self-identify as lesbian, gay, bisexual, or transgender (Gates & Newport, 2012).

Gender Identity

Western culture is deeply committed to the idea that there are only two sexes. Biologically speaking, however, there are many gradations running from female to male (Figure 40–2 ■). Sometimes gender

Figure 40–2 ■ Gender identity may not be a straightforward classification.

David Gifford/Science Source.

is clear, in other cases there is a blending of both genders within the same individual, and in some it is unclear.

INTERSEX

About 1 in every 4,500 babies is born with an **intersex** condition in which there are contradictions among chromosomal sex, gonadal sex, internal organs, and external genital appearance (Calleja-Agius, Mallia, Sapiano, & Schembri-Wismayer, 2012). The gender of such an infant is ambiguous. This means that an intersexed person has some parts usually associated with males and some parts usually associated with females. Intersex anatomy may not be apparent at birth. Sometimes it is undetected until puberty, until the person is identified as an infertile adult, or until the person dies and is autopsied. For more information, see the Intersex Society of North America website.

TRANSGENDERISM

The medical profession considers transgender individuals to have a condition called gender *dysphoria* (strong and persistent feelings of discomfort with one's assigned gender) or *gender identity disorder*. For the transgendered person, sexual anatomy contradicts gender identity. Those who are born physically male but are emotionally and psychologically female are called male-to-female (MtF) transgenders. Those who are born female but are emotionally and psychologically male are called female-to-male (FtM) transgenders.

Most transgendered people report that they have felt gender dysphoria since early childhood. They often suffer for many years and try to hide the situation from family and friends for fear of being considered “crazy.”

As self-understanding and acceptance have increased, many transgendered individuals have lived part or full time as members of the other sex. Their sexual orientation may be heterosexual, homosexual, or bisexual.

CROSS-DRESSERS

Cross-dressing (dressing in the clothing of the other sex) makes individuals' outward appearance consistent with their inner identity and gender role and increases their comfort with themselves.

Cross-dressers are typically males who cross-dress to express the feminine side of their personality. Usually, cross-dressers are not interested in permanently altering their bodies through surgical means, especially since the majority are comfortable with their original birth identity and behavior in their public and professional lives.

Cross-dressing is a conscious choice and may occur at home or in public settings. The frequency of the activity ranges from rarely to often. Cross-dressers may have a female name to go with the female personality and wardrobe. Cross-dressing occurs more frequently in cultures where males are expected to be strong, independent, and unemotional protectors. If the social climate is one with rigid gender roles, some men may need to express their gentleness and dependence by creating a separate world and female persona within that social climate.

Erotic Preferences

Over a lifetime, sexual fantasies and single-partner sex are the most common sexual outlets for women and men, single and coupled individuals, and heterosexual and LGBTQQ individuals. Masturbation is the ongoing love affair that each of us has with ourselves throughout our lifetime. It is the way we discover our erotic feelings and learn about our sexual response. Mutual masturbation can provide sexual pleasuring and intimacy without hurrying to genital interaction before both partners are ready. Masturbation shared with a partner is a safe alternative to unprotected genital sex.

Male-to-female or female-to-female **oral-genital sex** is known technically as cunnilingus. This involves kissing, licking, or sucking of the female genitals including the mons pubis, vulva, clitoris, labia, and vagina. Fellatio is oral stimulation of the penis by licking and sucking. The term “sixty-nine” refers to simultaneous oral-genital stimulation by two people. Preconceptions and myths are a major deterrent for those who have not tried oral sex. However, like most sexual practices, oral-genital sex is not completely free of the potential for STI transmission, and safe sex practices must be used.

Anal stimulation can be a source of sexual pleasure because the anus has a rich nerve supply. Stimulation may be applied with fingers, mouth, or sex toys such as vibrators. The anus is surrounded by strong muscles, and the rectum contains no natural lubrication. Thus inserting a finger or penis in the rectum requires relaxation and water-soluble lubricant.

A common form of sexual activity for heterosexual couples is **genital intercourse**. Penile-vaginal intercourse (**coitus**) can be both physically and emotionally satisfying. Various positions are used for this kind of intercourse; the most common is lying face to face (with female or male on top). Side-lying, standing, sitting, and rear-entry positions are also used. Side-lying, female-on-top, and rear-entry positions facilitate clitoral stimulation, either by penile or manual contact. The choice of intercourse positions and activities depends on physical comfort and beliefs, values, and attitudes about different practices.

During intercourse, the man moves the penis back and forth along the vaginal walls by rhythmic thrusting movements of his hips. The woman may move her own body to match the partner’s hip movements. Movements continue until orgasm is achieved by one or both partners. Simultaneous orgasm can be difficult to achieve. After coitus, caressing, hugging, and kissing can increase the shared intimacy and should be encouraged.

The other form of genital intercourse is anal intercourse, during which the penis is inserted into the anus and rectum of the partner. Anal intercourse is commonly practiced by gay men, but

heterosexual couples engage in it as well. Positions for anal intercourse are similar to those for penile-vaginal intercourse, with minor differences due to the position of the anus. Current practice dictates the use of a condom to prevent the transmission of infections. Because anorectal tissue is not self-lubricating, a lubricant must be used on the condom. Also, because normal bacterial flora from the bowel can produce infection in other parts of the body, the used condom should be removed and another applied before inserting the penis into other body orifices.

Many other varieties of sexuality are beyond the scope of this chapter. These include several or many partners, nudism, swinging, group sex, fetishism, sexual sadism, and sexual masochism.

FACTORS INFLUENCING SEXUALITY

Many factors influence a person’s sexuality. Discussed here are family, culture, religion, and personal expectations and ethics.

Family

For the majority of us, the family is the earliest and most enduring social relationship. Families are the fabric of our day-to-day lives and shape the quality of our lives by influencing our outlooks on life, our motivations, our strategies for achievement, and our styles for coping with adversity. Within our families we develop our gender identity, body image, sexual self-concept, and capacity for intimacy. Through family interactions we learn about relationships and gender roles and our expectations of others and ourselves (Figure 40–3 ■).

From earliest beginnings, children observe their parents and model themselves after these role models. If parents can share affection with one another and other family members, children will most likely become adults who can give and receive affection. If parents seldom hug, hold hands, or kiss each other, their children may become adults who are very uncomfortable with romantic touch. If family gender-role behavior is very rigid, arguments and hurt feelings will abound if a person from this system is partnered with a person who grew up in an androgynous family system. Family messages about sex range from “sex is so shameful it shouldn’t be talked about” to “sex is

Figure 40–3 ■ Children often imitate their parents’ roles. Sally and Richard Greenhill/Alamy.

a joyful part of adult relationships.” The following are common sexual messages children get from their families:

- Sex is dirty.
- Premarital sex is sinful.
- Good girls don’t do it.
- Masturbation is disgusting.
- Men should be the sexual experts.
- Sex is mainly for procreating.
- Bodies, including genitals, are beautiful.
- Sex should be fun for both women and men.
- Sexual thoughts and feelings are natural.
- Masturbation is a common, pleasurable activity.
- There is great variety in sexual behaviors.

Culture

Culture influences the sexual nature of dress, rules about marriage, expectations of role behavior and social responsibilities, and sex practices. Societal attitudes vary widely. Attitudes about childhood sexual play with self or children of the same gender or other gender may be restrictive or permissive. Premarital and extramarital sex and homosexuality may be culturally unacceptable or tolerated. Polygamy (several marriage partners) or monogamy (one marriage partner) may be the norm. Gender-role behavior also varies from culture to culture. Culture is so much a part of everyday life that it is taken for granted. We assume that others share our own views, including those for whom we provide care. It is impossible to provide sensitive nursing care if we believe that our own culture is more important than, and preferable to, any other culture.

Cultures differ regarding which body parts they find to be erotic. In some cultures, legs are erotic and breasts are not. Body weight may also be a determinant of sexual attractiveness. There is a great deal of pressure in American culture to be very thin. Women considered obese in America are found highly attractive in other countries. Public nudity ranges from women’s entire bodies and faces being covered in Islamic societies to complete nudity in some cultures in New Guinea and Australia.

Female circumcision, also known as female genital mutilation, female ritual cutting (FRC), or female genital cutting (FGC), is a practice in parts of Africa, the Middle East, and parts of Asia. Some of the cultural beliefs behind the practice include the following: Female genitals are offensive to men, if not removed the clitoris will become the size of a penis, the labia get in the way of intercourse, the cutting enhances fertility, and it prepares the woman for childbirth. Removal of the clitoris may or may not be accompanied by removal of the labia and closure of the vaginal entrance except for a small opening. Long-term medical complications include urinary incontinence, chronic urinary tract infections, vaginal scarring, pain syndromes, infertility, and sexual dysfunctions. FGC has been banned by the United Nations General Assembly (Hearst & Molnar, 2013).

Male circumcision is controversial. Some professional groups support newborn circumcision believing it will prevent the spread of HIV and other infections. Others say there is insufficient evidence of potential medical benefits (Wysong et al., 2011). In addition to the medical issues, there are also ethical concerns related to performing elective surgery on children too young to provide consent. In June 2013, Germany banned the circumcision of boys under the age of 18. However, circumcision is also a religious ritual among Jews and Muslims. Newborn circumcision rates vary according to geographic region in the United States.

Religion

Religion influences sexual expression. It provides guidelines for sexual behavior and acceptable circumstances for the behavior, as well as prohibited sexual behavior and the consequences of breaking the sexual rules. The guidelines or rules may be detailed and rigid or broad and flexible. Some religions view forms of sexual expression other than male–female intercourse as unnatural and hold virginity before marriage to be the rule.

Many religious values conflict with the more flexible values of society that have developed during the past few decades (often labeled the “sexual revolution”), such as the acceptance of premarital sex, unwed parenthood, homosexuality, and abortion. These conflicts create marked anxiety and potential sexual dysfunctions in some individuals. See Chapter 41  for additional information about religious values.

Personal Expectations and Ethics

Although ethics is integral to religion, ethical thought and ethical approaches to sexuality can be viewed separately from religion. Cultures have developed written or unwritten codes of conduct based on ethical principles. Personal expectations concerning sexual behavior come from these cultural norms. What one person or culture views as bizarre, perverted, or wrong may be natural and right to another. Examples include values regarding masturbation, oral or anal intercourse, and cross-dressing. Many people accept a variety of sexual expressions if they are performed by consenting adults, are practiced in private, and are not harmful. Couples need to explore and communicate clearly about various types of acceptable sexual expression to prevent domination of sexual decision making by one member of the couple. To assess a few of your personal values, complete the statements in Box 40–2.

SEXUAL RESPONSE CYCLE

Commonly occurring phases of the human sexual response follow a similar sequence in both females and males regardless of sexual orientation. It does not matter if the motive for being sexually active is true love or passionate lust. Table 40–3 provides a summary of the physiological changes associated with each phase of the cycle.

The response cycle starts in the brain, with conscious sexual desires called the **desire phase**. Sexually arousing stimuli, often called erotic stimuli, may be real or symbolic. Sight, hearing, smell, touch, and imagination (sexual fantasy) can all invoke sexual arousal. Sexual desire fluctuates within each person and varies from person to person. If people suppress or block out conscious sexual desires, they may experience no physiological response. Although psychological issues are the more common causes of lack of sexual desire, medications, drugs, and hormone imbalances can also interfere.

BOX 40–2 Assessing Personal Sexual Values

- I believe sexual satisfaction is . . .
- When I think of my parents having sex, I . . .
- If I cared for a transgendered client, I would . . .
- When I think about lesbians, gays, and bisexuals, I . . .
- Masturbation is . . .
- My beliefs about oral sex are . . .

TABLE 40–3 Physiological Changes Associated with the Sexual Response Cycle

Phase of the Sexual Response Cycle	Signs Present in Both Sexes	Signs Present in Males Only	Signs Present in Females Only
Excitement/plateau	Muscle tension increases as excitement increases. Sex flush, usually on chest. Nipple erection.	Penile erection; glans size increases as excitement increases. Appearance of a few drops of lubricant, which may contain sperm.	Erection of the clitoris. Vaginal lubrication. Labia may increase two to three times in size. Breasts enlarge. Inner two thirds of vagina widens and lengthens; outer third swells and narrows. Uterus elevates.
Orgasmic	Respirations may increase to 40 breaths/min. Involuntary spasms of muscle groups throughout the body. Diminished sensory awareness. Involuntary contractions of the anal sphincter. Peak heart rate (110–180 beats/min), respiratory rate (40/min or greater), and blood pressure (systolic 30–80 mmHg and diastolic 20–50 mmHg above normal).	Rhythmic, expulsive contractions of the penis at 0.8-sec intervals. Emission of seminal fluid into the prostatic urethra from contraction of the vas deferens and accessory organs (stage 1 of the expulsive process). Closing of the internal bladder sphincter just before ejaculation to prevent retrograde ejaculation into bladder. Orgasm may occur without ejaculation. Ejaculation of semen through the penile urethra and expulsion from the urethral meatus. The force of ejaculation varies from man to man and at different times but diminishes after the first two to three contractions (stage 2 of the expulsive process).	Approximately 5–12 contractions in the orgasmic platform at 0.8-sec intervals. Contraction of the muscles of the pelvic floor and the uterine muscles. Varied pattern of orgasms, including minor surges and contractions, multiple orgasms, or a simple intense orgasm similar to that of the male.
Resolution	Reversal of vasocongestion in 10–30 min; disappearance of all signs of myotonia within 5 min. Genitals and breasts return to their preexcitement states. Sex flush disappears in reverse order of appearance. Heart rate, respiratory rate, and blood pressure return to normal. Other reactions include sleepiness, relaxation, and emotional outbursts such as crying or laughing.	A refractory period during which the body will not respond to sexual stimulation; varies, depending on age and other factors, from a few moments to hours or days.	

The **excitement phase** involves two primary physiological changes (Figure 40–4 ■). Vasocongestion is an increase in the blood flow to various body parts resulting in erection of the penis and clitoris and swelling of the labia, testes, and breasts. Vasocongestion stimulates sensory receptors within these body parts that transmit messages to the conscious brain where they are usually interpreted as pleasurable sensations. When stimulation is continued, vasocongestion increases until it either is released by orgasm or fades away. Likewise, myotonia, an increase of tension in muscles, may increase until released by orgasm, or it may also fade away.

The **orgasmic phase** is the involuntary climax of sexual tension, accompanied by physiological and psychological release. This phase is the measurable peak of the sexual experience. Although the entire body is involved, the major focus of the orgasm is felt in the pelvic region. Male orgasms usually last 10 to 30 seconds, while

female orgasms last 10 to 50 seconds. Men usually have an ejaculation and expel semen as part of their orgasm. Before puberty and in later years, males experience orgasms without ejaculation.

The **resolution phase**, the period of return to the unaroused state, may last 10 to 15 minutes after orgasm, or longer if there is no orgasm. This phase in females is varied as some women experience multiple successive orgasms followed by a longer period of resolution.

ALTERED SEXUAL FUNCTION

The ability to engage in sexual behavior is of great importance to most people. Many individuals experience transient problems with their ability to respond to sexual stimulation or to maintain the response. A smaller percentage of people experience problems lifelong in duration. The problems may be generalized to all sexual interactions and

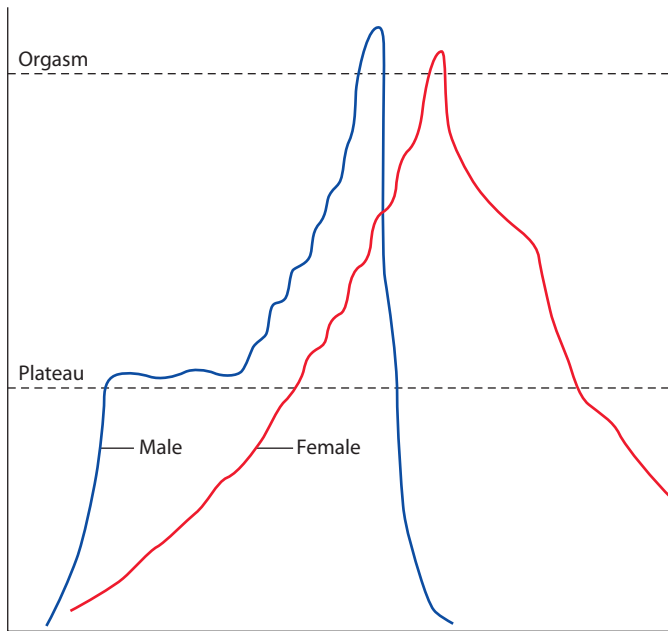

Figure 40-4 ■ Phases of the sexual response cycle.

settings, or they may be situational, occurring in a specific setting or with specific types of sexual activity. It is often difficult to sort out the multiple factors contributing to an individual's or a couple's sexual problems. A number of past and current factors are involved.

Past and Current Factors

Sociocultural factors interfering in sexual function include a very strict upbringing accompanied by inadequate sex education. Rigid gender-role socialization may inhibit exploration of sexual activities, positions, toys, and other lovemaking behaviors. If people's religious affiliations lead them to believe that sex is only for procreation, they may have great difficulty in celebrating the pleasure and fun of a loving sexual relationship. Another factor may be parental punishment for normally exploring one's genitals or for normal childhood sex play. In our current culture, the pressures of family and work often leave mature couples with too little time and not enough energy to enjoy sex.

Psychological factors may include negative feelings, such as guilt, anxiety, or fear that interfere with the ability to experience pleasure and joy. Some people experience guilt when they enjoy sex or when they participate in what they label "unusual" sexual activities, or regarding their choice of partner. Adults sexually abused at any time of their lives may experience overwhelming anxiety when faced with the decision to engage in sex. Fears may include pregnancy, STIs, or pain. Because vulnerability and intimacy are inherent in most sexual relationships, fear of these may lead to an avoidance of sex. Fear of failure in sexual performance often becomes a vicious cycle; that is, fear of failure creates actual failure, which produces more fear. Individuals may worry excessively: "Am I going to lose my erection?" "Am I going to have an orgasm this time?" "My stomach is too flabby." "When did his thighs get that fat?" Depressed people lose interest in sexual activity and often experience a complete loss of sexual desire and fulfillment.

Cognitive factors include the internalization of negative expectations and beliefs. Those with low self-esteem may not understand how another person could value and love them and also find them sexually attractive. For those who have not yet accepted their sexual

orientation or gender identity, this cognitive conflict may interfere with sexual relationships.

Sexual problems may also be symptomatic of relationship problems. Conflict and anger with one's partner are not conducive to positive sexual interaction. Some individuals lose the physical attraction to another or feel more attracted to someone else.

Lack of intimacy and feeling like a sex object inhibit the feeling of communion and connection that is an important part of making love. Another factor is expecting one's partner to read one's mind about sexual needs. Failure to communicate may cause one or both partners not knowing how to please the other. Unless the partners experiment, sex may, in time, become boring. Disagreements in sexual frequency and/or sexual activities may lead to further relationship conflict.

Health factors can interfere with people's expression of sexuality. Physical changes brought on by illness, injury, or surgery may inhibit full sexual expression. There may be sexual side effects from several conditions such as heart disease, diabetes mellitus, joint disease, cancer, and mental disorders. Surgeries such as hysterectomy, prostate surgery, and radical surgeries alter a person's body image. Spinal cord injuries, traumatic amputations, or disfiguring accidents negatively affect sexual functioning. The presence of an STI in one partner induces fear of transmission in the other, often resulting in abstinence from sexual contact. In some situations, an STI is unknown and transmission occurs.

Many prescription medications have side effects that affect sexual functioning beyond those intended for that purpose. Most frequently, the impact is negative, but sometimes there is a positive impact. Table 40-4 provides an overview of the effects of medications on sexual function. For example, antidepressants may slow ejaculation. This may be a problem for the man who suddenly finds himself unable to ejaculate. If the man is suffering from rapid ejaculation, however, the antidepressant may "cure" this problem. Some street drugs such as marijuana, amphetamines, and cocaine enhance sexual functioning. Others, such as opioids and anabolic steroids, interfere with sexual functioning.

Sexual Desire Disorders

For most people, sexual desire varies from day to day and over the years. Some people, however, report a deficiency in or absence of sexual fantasies and persistently low interest or a total lack of interest in sexual activity; these clients suffer from **hypoactive sexual desire disorder**. If both individuals in a relationship are similarly uninterested in sex, there really is no problem. More typically, there is a disparity of sexual needs, and the person with the greater desire becomes dissatisfied with the sexual relationship. The key issue in the relationship is not frequency but rather the dovetailing of partners' needs.

Sexual aversion disorder is a severe distaste for sexual activity or the thought of sexual activity, which then leads to a phobic avoidance of sex. It occurs in both women and men. Intense emotional dread of an impending sexual interaction also can trigger the physiological symptoms of anxiety: sweating, increased heart rate, and extreme muscle tension. The person then stops the sexual interaction or prevents it from even beginning.

Sexual Arousal Disorders

Sexual arousal refers to the physiological responses and subjective sense of excitement experienced during sexual activity. Lack of lubrication and failure to attain or maintain an erection are the major

TABLE 40–4 Effects of Medications on Sexual Function

Medication	Possible Effects*
Alcohol	Moderate amounts: increased sexual functioning; chronic use: decreased sexual desire, orgasmic dysfunction, and erectile dysfunction
Alpha-blockers	Inability to ejaculate
Amphetamines	Increased sex drive, delayed orgasm
Amyl nitrate	Reported enhanced orgasm; vasodilation, fainting
Anabolic steroids	Decreased sex drive, shrinking of testicles and infertility in men
Antianxiety agents	Decreased sexual desire; orgasmic dysfunction in women; delayed ejaculation
Anticonvulsants	Decreased sexual desire; reduced sexual response
Antidepressants	Decreased sexual desire; orgasmic delay or dysfunction in women; delayed or failed ejaculation; painful erection
Antihistamines	Decreased vaginal lubrication; decreased desire
Antihypertensives	Decreased sexual desire; erectile failure; ejaculation dysfunction
Antipsychotics	Decreased sexual desire; orgasmic dysfunction in women; delayed ejaculation; ejaculatory failure
Barbiturates	In low doses, increased sexual pleasure; in large doses, decreased sexual desire, orgasmic dysfunction, and erectile dysfunction
Beta-blockers	Decreased sexual desire
Cardiotonics	Decreased sexual desire
Cocaine	Increased intensity of sexual experience; with chronic use, decreased sexual desire and sexual dysfunction
Diuretics	Decreased vaginal lubrication; decreased sexual desire; erectile dysfunction
Marijuana	As above for cocaine, but prolonged use reduces testosterone levels and reduces sperm production
Narcotics	Inhibited sexual desire and response; erectile and ejaculatory dysfunctions

*Nurses and clients must familiarize themselves with the specific medication prescribed or used, because effects vary in each category of drug.

disorders of the arousal phase. In **female sexual arousal disorder**, the lack of vaginal lubrication causes discomfort or pain during sexual intercourse. The diagnosis of **male erectile disorder** is usually made when the man has erection problems during 25% or more of his sexual interactions. Some men cannot attain a full erection, and others lose their erection prior to orgasm. The term commonly applied to this condition, impotency, implies that the man is feeble, inadequate, and incompetent. The accurate term is erectile dysfunction (ED), which is objectively descriptive and not judgmental. Arousal disorder may also be diagnosed even when lubrication and erection are adequate if individuals report a persistent or recurring lack of subjective sexual excitement or pleasure.

Orgasmic Disorders

The term commonly applied in the past to women who did not experience orgasm, *frigid*, implied that the woman was totally incapable of responding sexually. The more accurate and objective term is **female orgasmic disorder**, which simply means that the sexual response stops before orgasm occurs. Preorgasmic women have never experienced an orgasm. Compounding the orgasmic difficulty is the associated anxiety. In the preoccupation with orgasm, the real goal of being sexual—mutual pleasuring and intimacy—is lost, and the interchange becomes one of anxiety, frustration, and anger.

Some men suffer from **male orgasmic disorder**. Men with this disorder can maintain an erection for long periods (an hour or more) but have extreme difficulty ejaculating, referred to as retarded ejaculation. In heterosexual intercourse, the difficulty may be limited

to ejaculation in the vagina. Some men ejaculate after self-stimulation or manual or oral stimulation by the partner, whereas others have great difficulty ejaculating with any type of stimulation. This disorder is much less common than rapid ejaculation.

Rapid ejaculation is one of the most common sexual dysfunctions among men. There are many definitions, with descriptions ranging from ejaculating before being touched, ejaculating before penetration, ejaculating with one internal thrust, to ejaculating within a minute or two of penetration. The problem is best self-defined as when a man is concerned about his ejaculatory control, or the couple agrees that ejaculation is too rapid for mutual satisfaction.

Sexual Pain Disorders

Both women and men can experience **dyspareunia**, pain during or immediately after intercourse. It is associated with many physiological causes, especially those that inhibit lubrication. Skin irritations, vaginal infections, estrogen deficiencies, and use of medications that dry vaginal secretions can cause women to experience discomfort with intercourse.

Pelvic disorders, such as infections, lesions, endometriosis, scar tissue, or tumors, can cause painful intercourse. Similarly, in males, infection or inflammation of the glans penis or other genitourinary organs can cause pain with intercourse. Also, some contraceptive foams, creams, sponges, or latex products can irritate either the vagina or penis.

Vaginismus is the involuntary spasm of the outer one third of the vaginal muscles, making penetration of the vagina painful and

DRUG CAPSULE

Phosphodiesterase Type 5 (PDE5) Inhibitor sildenafil citrate (Viagra); tadalafil (Cialis); vardenafil (Levitra)**THE CLIENT TAKING MEDICATION FOR ERECTILE DYSFUNCTION (ED)**

In erectile dysfunction (ED), the sexually stimulated penis does not achieve or maintain an erection, often due to restricted blood flow to the penis. These medications inhibit the breakdown of the enzymes and products that allow the muscle relaxation which facilitates adequate blood flow to the penis. The medications do not enhance sexual desire or cure the ED but allow the stimulated penis to obtain and sustain an erection.

NURSING RESPONSIBILITIES

- ED medications are contraindicated for men with uncontrolled high or low blood pressure, stroke, renal or liver problems, vision loss, or bleeding disorders.
- Men with an anatomically deformed penis should consult with the primary care provider prior to taking these medications.
- Medications come in different dose strengths and may require adjustment.

CLIENT AND FAMILY TEACHING

- General safety in using these medications is the same as for engaging in sexual activity overall. The risk of adverse outcomes of sexual activity after taking these medications is not increased.
- Explain that men who take medications that are nitrates—those that are prescribed (e.g., nitroglycerin) or those that are recreational (e.g., amyl nitrate—"poppers")—should not take these medications.
- The client should take the medication about 1 hour prior to sexual activity. Some formulations are taken once per day and others not more than once every 3 days.
- Teach side effects to immediately report to the primary care provider: loss of vision, or an erection that lasts more than 4 hours.
- Other common side effects may include headache, muscle pain, flushing, or stuffy nose.
- These medications do not prevent pregnancy or STIs.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

sometimes impossible. The woman often experiences desire, excitement, and orgasm with stimulation of the external sexual structures. Attempts at intercourse, however, elicit the involuntary spasm. She may have similar difficulty undergoing pelvic exams and inserting tampons or a diaphragm.

Vulvodynia is constant, unremitting burning that is localized to the vulva with an acute onset. The girl or woman has problems in sitting, standing, and sleeping related to the intensity of pain. **Vestibulitis** causes severe pain only on touch or attempted vaginal entry. Half of the women with vestibulitis report lifelong dyspareunia.

People with any of these disorders report a negative impact on their sexual functioning and partner relationship, as well as their self-esteem and mental health.

Problems with Satisfaction

Some people experience sexual desire, arousal, and orgasm and yet feel dissatisfied with their sexual relationships. These sexual problems are more commonly related to the emotional tone of the relationship than to the physiological response. Since giving and receiving pleasure in a mutually intimate relationship are the primary goals of sex for most people, dissatisfaction problems may be more disturbing than other types of sexual dysfunctions.

Satisfaction problems may be situational. For example, one partner may choose an inconvenient time, or a partner may feel anxious and therefore cannot experience much pleasure or joy. Some people describe their problems as related to the lack of touching and caressing of their earlier lovemaking experiences. Unfortunately, people relating sexually for a long time often become genitally focused and neglect the rest of the body. One or both partners may feel touch starved, long for more extragenital loving, and become dissatisfied with sex.

Satisfaction problems are often related to relationship difficulties. The inability to communicate effectively in other relationship areas frequently results in sexual frustration. Partners angry with

each other and make love without resolving the conflict may feel unhappy about the relationship despite having experienced arousal and orgasm. Couples who define their relationship in terms of rigid, unequal power and gender roles may have difficulty negotiating and compromising about sexual issues. Not infrequently, the person with the least power feels helpless and dissatisfied with the sexual interchanges.

Lack of intimacy or a feeling of connectedness is understandably related to satisfaction problems. If one has sex with a stranger, the body may function well, but there is often a sense of something missing after the sexual experience. Making love to one person while feeling more attracted to or in love with another person can cause feelings of emptiness or disconnection. Even couples in a committed relationship may complain of lack of intimacy. Dissatisfaction issues include lack of romance, love, tenderness, and nurturance. Fulfillment of sexuality depends on the ability to relate with a partner in an intimate and mutually pleasing manner compatible with values and chosen lifestyle.

●○○ NURSING MANAGEMENT**Assessing**

Because sexuality and sexual functioning are aspects of health and well-being, they are a part of nursing care and need to be assessed. Clients are often hesitant to introduce the topic of sex with their primary health care providers. They may be too embarrassed, they may think that they should not have sexual problems in our liberated times, or they may think they are too old or too young to have these problems. When health care professionals do not introduce the topic, these individuals are unrecognized and unserved.

Information about a client's sexual health status should always be an integral part of a nursing assessment. The amount and kind of data collected depend on the context of the assessment, that is, the client's reason for seeking health care and how the client's sexuality interacts with other problems.

The nurse conducts a sexual history on the following categories of clients:

- Those receiving care for pregnancy, infertility, contraception, or an STI
- Those whose illness or therapy will affect sexual functioning (e.g., clients with diabetes, gynecologic problems, or heart disease)
- Those experiencing a sexual problem.

Nursing History

Including a sexual history as part of the general nursing history is important for some clients and not important for others. It is critical, however, to introduce the topic of sexuality to all clients in order to give them permission to bring up any concerns or problems. All nursing histories should at least include a question such as “Have there been any changes in your sexual functioning that might be related to your illness or the medications you take?” Nurses might also facilitate communication by saying, “As a nurse, I’m concerned about all aspects of your health. People often have questions about sexual matters, both when they are well and when they are ill. When I take your history, sexual concerns are included to help plan a comprehensive treatment approach.”

It is critical that nurses not make assumptions about clients because assumptions interfere with accurate history taking. If you start from the belief that all people do all things, you will be more open to clients than if you make assumptions about who is and who is not sexually active and how. Presuming that your personal beliefs are shared by others is detrimental to the nurse–client relationship.

Interviewing a client regarding sexual health may be uncomfortable for some nurses (and for the client). Nurses must be aware of their own feelings and beliefs so that they can prepare approaches for gathering data and creating the nursing care plan. The nurse sets aside personal values about sexual practices and uses a culturally sensitive, nonjudgmental, nonthreatening, and reassuring approach. It is extremely important to create an atmosphere that facilitates open communication and comfort for the client. Remind the client that all personal health information is handled in a confidential manner. Also see Chapter 5 ∞ for a review of values clarification and Chapter 11 ∞ for more information on the health history.

The accompanying Assessment Interview provides questions that nurses may ask as part of the health history. These questions typically are asked in the assessment process after a rapport has been established.

Physical Examination

Physical examination of the female genitals and reproductive tract and the male genitals is part of a routine physical examination in

some agencies. Check agency protocol. See Chapter 30 ∞ for details of the examination. If the client has not been examined in the past year or if data from the recent nursing history indicate a need, the nurse performs a physical examination. Nursing history data indicating the need for a physical examination include the following:

- Suspicion of infertility, pregnancy, or an STI
- Reports of discharge, presence of a lump or sore, or change in color, size, and shape of a genital organ
- Changes in urinary function
- Need for Papanicolaou test
- Request for birth control.

Identifying Clients at Risk

Clients at risk for altered sexual patterns include those experiencing the following:

- Altered body structure or function due to trauma, pregnancy, recent childbirth, anatomic abnormalities of the genitals, or a variety of diseases
- Physical, psychosocial, emotional, or sexual abuse; sexual assault
- Disfiguring conditions, such as burns, skin conditions, birthmarks, scars (e.g., mastectomy), and ostomies
- Specific medication therapy that causes sexual problems (see Table 40–4)
- Temporary or long-term impaired physical ability to perform grooming and maintain sexual attractiveness
- Value conflicts between personal beliefs and religious doctrine
- Loss of a partner
- Lack of knowledge or misinformation about sexual functioning and expression.

Diagnosing

The NANDA International (Herdman & Kamitsuru, 2014) nursing diagnoses relating specifically to sexuality include the following:

- *Ineffective Sexuality Pattern*
- *Sexual Dysfunction*.

Sexual problems can also be the etiology of other diagnoses, including the following:

- *Deficient Knowledge* (e.g., about conception, STIs, contraception, or normal sexual changes over the life span) related to misinformation and sexual myths
- *Ineffective Relationship* related to unrealistic expectations
- *Pain* related to inadequate vaginal lubrication, or effects of genital surgery

ASSESSMENT INTERVIEW Sexual Health History

- Are you sexually active? With men, women, or both?
- Are you sexually active with one or more than one partner?
- Describe the positive and negative aspects of your sexual functioning.
- Do you have difficulty with sexual desire? Arousal? Orgasm? Satisfaction?
- Do you experience any pain during sex?
- If there are problems, how have they influenced how you feel about yourself? How have they affected your partner? How have they affected the relationship?
- Do you expect your sexual functioning to change because of your illness?
- What are your partner’s concerns about your future sexual functioning?
- Do you have any other sexual questions or concerns that I have not addressed?

- *Anxiety* related to loss of sexual desire or functioning
- *Fear* related to history of sexual abuse or dyspareunia
- *Disturbed Body Image* (e.g., mastectomy) related to perceived sexual rejection by spouse.

Planning

Overall goals to meet clients' sexual needs include the following:

- Maintain, restore, or improve sexual health.
- Increase knowledge of sexuality and sexual health.
- Prevent the occurrence or spread of STIs.
- Prevent unwanted pregnancy.
- Increase satisfaction with the level of sexual functioning.
- Improve sexual self-concept.

Nursing interventions to promote sexual health and function focus largely on the nurse's teaching role. Clients need to be taught about normal sexual function, the effects of medications on sexual function, preventing STIs, and performing breast and testicular self-examinations. Besides teaching, nurses can do the following to help clients maintain a healthy sexual self-concept:

- Provide privacy during intimate body care.
- Give attention to the client's appearance and dress.
- Give clients privacy to meet their sexual needs alone or with a partner within physically safe limits.

Remember that clients' comfort in discussing sex-related topics and being examined is culturally influenced. Planning for clients must include using culturally sensitive communication techniques implemented with both clients and culturally appropriate family members.

Implementing

The interventions the nurse selects are based on the data obtained from the client and the identified nursing diagnoses. Many interventions are directed at providing information about sexual health and counseling for altered sexual function.

Nurses require six basic skills to help clients in the area of sexuality:

- Self-knowledge and comfort with their own sexuality
- Acceptance of sexuality as an important area for nursing intervention and a willingness to work with clients who express their sexuality in a variety of ways
- Knowledge of sexual growth and development throughout the life cycle
- Knowledge of basic sexuality, including how certain health problems and treatments may affect sexuality and sexual function and which interventions facilitate sexual expression and functioning
- Therapeutic communication skills
- Ability to recognize the need for all clients and family members to have the topic of sexuality introduced not only in written or audiovisual materials but also in a verbal discussion.

CLINICAL ALERT!

As a result of culture, age, gender, and personal characteristics, not every nurse will be comfortable discussing sex with every client. However, it is the nurse's responsibility to ensure that *someone* introduces the topic with the client.

Providing Sexual Health Teaching

Educating about sexual health is an important component of nursing implementation. Many sexual problems exist because of sexual ignorance; many others can be prevented with effective sexual health teaching. Examples of important areas of teaching are sex education (including self-examination) and responsible sexual behavior.

Sex Education

Nurses can assist clients to understand their anatomy and how their body functions. Understanding the anatomy of the genitals may help women learn how their body responds to sexual stimulation. Both men and women need to learn the kind of stimulation that is pleasing and causes arousal. The importance of open communication between partners should also be encouraged. Women may also benefit from learning Kegel exercises. These exercises involve contraction and relaxation of the pubococcygeal muscle, the muscle that contracts when a person prevents urine flow. The benefits of Kegel exercises include increased pelvic floor muscle tone; increased vaginal lubrication during sexual arousal; increased sensation during intercourse; increased genital sensitivity; stronger gripping of the base of the penis; earlier postpartum recovery of the pelvic floor muscle; and increased flexibility of episiotomy scars (Modarres, Rahimikian, & Booriaie, 2012). The steps to perform Kegel exercises are discussed in Chapter 48 because these exercises are also used in bladder retraining.

Details about physiological changes that occur during major developmental crises should be provided as part of general health care. For example, the nurse needs to discuss the effects of puberty, pregnancy, menopause, and the male climacteric on sexual function. When clients experience illness or surgery that may alter sexual function, the nurse needs to discuss effects of treatment (e.g., medications) and any changes that need to be undertaken to ensure safe sex (e.g., position changes or a safe time to resume sexual intercourse after a heart attack).

Parents often need assistance to learn ways to answer questions about sexuality and what information to provide for their children starting in the preschool years. Parents need to be the primary educators of children at an early age; however, peers, teachers, media, and toys also teach about sexual issues.

Although there is an increasing awareness today of sexuality and sexual functioning, some people still hold certain myths and misconceptions about sexuality. Many of these are handed down in families and are part of the beliefs in a particular culture. Nurses must learn about the beliefs clients hold and provide up-to-date information. The website of the Sexuality Information and Education Council of the United States has a wealth of information on various aspects of sexuality.

Teaching Self-Examination

Breast self-examination (BSE) for women and testicular self-examination (TSE) for men can play an important role in early detection of disease, resulting in a greater chance of cure and less complex treatment. Clients need to be assured that most lumps discovered are not cancerous, but it is essential that all lumps or other detected abnormalities be checked by the client's primary care provider for accurate diagnosis. All nursing history assessments of clients need to include the client's understanding and practice of BSE or TSE. Self-examination involves both inspection and palpation procedures. Beginning in their early 20s, women should be told about the benefits and limitations of BSE and the importance of reporting breast symptoms to a health professional. Those who perform BSE should receive

instruction and have their technique reviewed regularly. Women may choose not to perform BSE or to perform BSE irregularly (Smith, Brooks, Cokkinides, Saslow, & Bradley, 2013). Some primary care providers recommend that men perform TSE monthly.

Although the vast majority of breast cancers in the United States each year occur in women, men with an increased risk of breast cancer due to high estrogen levels or a strong family history of breast cancer should also learn BSE. For BSE a regular time is best—such as 1 week following menstruation, when breast tenderness and fullness caused by fluid retention have subsided, or on the same day of the month for men or postmenopausal women. People who examine themselves regularly become familiar with the shape and texture of their breasts. The steps of BSE are very similar to those used when the nurse performs breast examination (see Skill 30-14 in the Chapter 30 ∞). For techniques of breast self-examination, see Client Teaching.

Testicular cancer tends to be a young male's cancer. Starting at age 15, monthly self-exams of the testicles are an effective way for men to get to know this area of their body and detect testicular

cancer at an early and very curable stage. The best time for TSE is after a warm bath or shower when the scrotal sac is relaxed. For techniques of self-examination, see Client Teaching.

CLINICAL ALERT!

It may be wise for both male and female nurses to request permission from a parent or guardian before teaching testicular self-examination to teenage boys. Although the nurse need not touch the boy during the teaching, the boy must touch himself during TSE and parents may prefer the nurse not instruct him to do so.

Responsible Sexual Behavior

Responsible sexual behavior involves the prevention of STIs, the prevention of unwanted pregnancy, and the avoidance of sexual harassment or abuse.

STI Prevention The prevention of STIs is an essential part of sexual health teaching (Figure 40-6 ■). Increases in these infections are

CLIENT TEACHING

Breast Self-Examination

INSPECTION BEFORE A MIRROR

Look for any change in size or shape; lumps or thickenings; any rashes or other skin irritations; dimpled or puckered skin; any discharge or change in the nipples (e.g., position or asymmetry). Inspect the breasts in all of the following positions:

- Stand and face the mirror with your arms relaxed at your sides or hands resting on the hips; then turn to the right and the left for a side view (look for any flattening in the side view).
- Bend forward from the waist with arms raised over the head.
- Stand straight with the arms raised over the head and move the arms slowly up and down at the sides. (Look for free movement of the breasts over the chest wall.)
- Press your hands firmly together at chin level while the elbows are raised to shoulder level.

PALPATION: LYING POSITION

- Place a pillow under your right shoulder and place the right hand behind your head. This position distributes the right breast tissue more evenly on the chest.
- Use the finger pads (tips) of the three middle fingers (held together) on your left hand to feel for lumps in the right breast.

- Press the breast tissue against the chest wall firmly enough to know how your breast feels. A ridge of firm tissue in the lower curve of each breast is normal.
- Use small circular motions systematically all the way around the breast as many times as necessary until the entire breast has been covered. (Review Figures 4 through 6 in Skill 30-14, page 570 in Chapter 30 ∞, for patterns that the client may use.)
- Bring your arm down to your side and feel under your armpit, where breast tissue is also located.
- Repeat the exam on your left breast, using the finger pads of your right hand.

PALPATION: STANDING OR SITTING

- Repeat the examination of both breasts while upright with one arm behind your head. This position makes it easier to check the area where a large percentage of breast cancers are found, the upper outer part of the breast and toward the armpit.
- *Optional:* Do the upright BSE in the shower. Soapy hands glide more easily over wet skin. Report any changes to your health care provider promptly.

CLIENT TEACHING

Testicular Self-Examination

- Choose one day of each month (e.g., the first or last day of each month) to examine yourself.
- Examine yourself when taking a warm shower or bath.
- Support the testicle underneath with one hand. Place the fingers of the other hand under the testicle and the thumb on top (this may be easier to do if the leg on that side is raised).
- Roll each testicle between the thumb and fingers of your hand, feeling for lumps, thickening, or a hardening in consistency (Figure 40-5 ■). The testes should feel smooth.
- Palpate the epididymis, a cordlike structure on the top and back of the testicle. The epididymis feels soft and not as smooth as a testicle.
- Locate the spermatic cord, or vas deferens, which extends upward from the scrotum toward the base of the penis. It should feel firm and smooth.

- Using a mirror, inspect your testicles for swelling, any enlargement, or lumps in the skin of the testicle.
- Report any lumps or other changes to your health care provider promptly.

Figure 40-5 ■ Rolling the testicle between the thumb and fingers.

Figure 40-6 ■ Adolescents require age-appropriate teaching about sexuality and sexually transmitted infections.
Image Source/Getty Images.

due to two factors: (1) changing sexual morality that has permitted increased sexual activity and (2) an increase in the number of sexual partners. Because STIs elicit feelings of guilt, shame, and fear, people frequently do not seek medical help as early as they should. Clients need education about these infections, preventive measures, and early treatment. Many STIs can be treated quickly and effectively. Others may have serious consequences. Women may develop pelvic inflammatory disease (PID) resulting in damage to the reproductive structures and possible infertility. AIDS, which may be acquired through sexual transmission, currently has no cure. The anxiety about AIDS transmission has caused many individuals to improve their safe-sexual behavior, such as using a condom during genital or anal sex.

The Clinical Manifestations feature earlier in this chapter lists common signs of STIs for which people should seek medical care. Methods for decreasing exposure to STIs are described in the Client Teaching feature.

Prevention of Unwanted Pregnancies Prevention of unwanted pregnancies must be addressed not only with adolescents but also with couples planning the time of births and want to space children and limit family size. Nurses need to be familiar with various contraceptive methods and their advantages, disadvantages,

Figure 40-7 ■ Methods of contraception.
Charles Thatcher/Getty.

contraindications, effectiveness, safety, and cost (Figure 40-7 ■). The various methods are outlined in Box 40-3. It is beyond the scope of this text to discuss contraceptives in detail.

Avoiding Sexual Harassment and Abuse Sexual harassment exists when someone in a position of power threatens another person's job or status in exchange for unwanted sexual acts. Such harassment can be severe enough to be considered abuse, but sexual abuse (also called molestation) is forced, unwanted sexual activity of any kind. Prevention is the most important role of the nurse and this can best be accomplished through educating adult clients and families of children about their rights and support services available if they believe sexual harassment or abuse is occurring. Assessing for, diagnosing, and intervening in possible situations of sexual harassment or abuse is a significant undertaking and not every nurse will be skilled in these roles. Sexual assault nurse examiners have specialized training in the role of assessing and treating victims of sexual assault (Wadsworth & Van Order, 2012). However, every nurse must know of the legal requirements and proper methods of reporting suspected abuse.

Counseling for Altered Sexual Function

One technique nurses can use to help clients with altered sexual function is the PLISSIT model, developed by Annon (1976) for this purpose. The model involves four progressive levels represented by the acronym PLISSIT:

P	Permission giving
LI	Limited information
SS	Specific suggestions
IT	Intensive therapy

CLIENT TEACHING

Preventing Transmission of STIs and HIV

- Limit the number of sexual partners.
- Talk openly with sexual partners about how to have “safer sex,” and be honest about any history of an STI.
- Abstain from high-risk sexual activity with a partner known to have or suspected of having an STI.
- Use condoms in relationships that have the potential for STI transmission.
- Follow safe sex practices during oral sex including the use of a dental dam during cunnilingus to prevent STI transmission.
- Report to a health care facility for examination whenever in doubt about possible exposure or when signs of an STI are evident.
- When an STI is diagnosed, notify all partners and encourage them to seek treatment.
- Discuss the use of preexposure prophylactic medications for high-risk individuals (U.S. Public Health Service, 2014).

BOX 40-3 Methods of Contraception

- Abstinence.
- Withdrawal of the penis before ejaculation (*coitus interruptus*).
- Fertility awareness (identification of the days of the month when conception is most likely to occur and abstaining during that time). Also referred to as *natural planning*.
- Mechanical barriers: vaginal diaphragm, vaginal ring, cervical cap, condom (*Note*: There are three types of condom materials: latex, lambskin, and polyurethane. All are equally effective at preventing pregnancy. Latex condoms are the least expensive. Lambskin pore size does not protect against STIs as well as the others. Polyurethane condoms are recommended if contact with latex should be avoided. Polyurethane is the material used in female condoms.)
- Chemical barriers: insertion of spermicidal foams, creams, jellies, or suppositories into the vagina before intercourse.
- Intrauterine devices (IUDs).
- Hormonal: oral contraceptives (birth control pills), subdermal implants of synthetic progestin, transdermal patches (*Note*: Certain antibiotics decrease the effectiveness of oral contraceptives and patches. Women on these antibiotics must use an alternative method of contraception until their antibiotic treatment is completed. Other drug interactions can occur with implants.)
- Emergency contraception: hormonal: levonorgestrel pill taken within 5 days (120 hours) of unprotected intercourse. Commonly referred to as Plan B or the morning-after pill.
- When inserted within 5 days of unprotected intercourse, a copper-bearing IUD is the most effective form of emergency contraception available (World Health Organization, 2012).
- Surgical sterilization: tubal ligation and vasectomy.
- Abortion.

At each level, the nurse provides additional guidance and information to the client and therefore requires more specialized and specific knowledge and skill. All professional nurses should be able to function at the first three levels. At the levels of limited information, specific suggestions, and intensive therapy, the nurse can also refer the client to a health care provider more skilled to assist the client with the particular issues identified during the first level.

Permission Giving

Clients may feel that they need permission to be sexual beings, to ask questions, to show affection, and to express themselves sexually. Giving permission means that the nurse by attitude or word lets the client know that sexual thoughts, fantasies, and behaviors between informed consenting adults are allowed. Giving permission begins when the nurse acknowledges the client's spoken and unspoken sexual concerns and conveys the attitude that sexual concerns and needs are important to health and recovery.

The nurse might ask a client recuperating from a heart attack the following questions:

“Now that you're recuperating and you've had some time to sort out your feelings, have you thought about how your heart attack might alter your sex life?”

“Have you and your partner discussed how you both feel about it?”

Limited Information

Clients need accurate but concise information. The nurse might explain what is normal; how some medical conditions, treatments,

injuries, or surgeries may affect sexuality and sexual functioning; or how aging may affect sexuality and functioning.

Continuing with the preceding example, the nurse shares information and informs the client about how the heart attack might affect the client's sex life, including the following:

“Your heart attack will not change your sexual responsiveness. Most people can resume intercourse in four to six weeks, but this should be confirmed by your doctor. If you can climb a flight of stairs without having chest pain you should be able to resume having sex since it takes about the same amount of energy.”

“Many clients fear sexual intercourse after a heart attack because of the physical exertion associated with it. However, your prescribed program of progressive physical activity will also increase your tolerance for sexual activity.”

Many clients recuperating from childbirth or illness or disease (e.g., heart attack) need instruction about safe sexual activities and the effects that therapy may have on sexual functioning. The following topics need to be considered:

- When sexual activity is safe
- Specific sexual activities that are unsafe, and why
- Adaptations needed for resuming a satisfactory sexual life
- The side effects of prescribed medications on sexual functioning, and the need to notify the primary care provider for possible dose or medication adjustment should problems develop.

Specific Suggestions

At this level, the nurse requires specialized knowledge and skill about how sexuality and functioning may be affected by a disease process or therapy and what interventions might be effective. The nurse offers suggestions to help the client adapt sexual activity to promote optimal functioning, such as what measures might alleviate vaginal dryness, safe positions for intercourse following a total hip replacement, safe and unsafe sexual practices following a heart attack, and ways to handle ostomy appliances, urinary catheters, casts, or other devices (e.g., prostheses) during sexual activity. Similarly, nurses who work on a cardiac unit need specialized knowledge about sexual readjustment during cardiac rehabilitation, and nurses working with clients with spinal cord injuries need information about the sexual consequences of spinal injuries at various levels.

Using the example of the client recuperating from a heart attack, the nurse may offer the following suggestion:

“Many people express concern about the stress of certain positions for intercourse, but you may use whatever position is comfortable for you and your partner, or try side-lying or partner-on-top positions.”

Intensive Therapy

At this level of intervention, nurses must have specialized preparation and knowledge of sexual and gender identity disorders. Nurses who function in the sex therapist role should meet the qualifications for practice identified by the American Association of Sexuality Educators, Counselors, and Therapists (AASECT), which differentiates sex counseling from sex therapy. Sex counseling helps clients incorporate their sexual knowledge into satisfying lifestyles and socially responsible behavior. Sex therapy is a highly specialized, in-depth treatment to help clients resolve serious sexual problems. AASECT publishes a national directory of professionals certified to provide sex education, counseling, or therapy.

Dealing with Inappropriate Sexual Behavior

Nurses, both male and female, may encounter a variety of sexually inappropriate behaviors for several reasons. The behavior may be aggressive or nonaggressive. Clients may act out sexually by

- Exposing themselves.
- Asking the nurse to provide intimate physical care, such as bathing genital areas, when they can do this themselves.
- Touching or grabbing the nurse's genitals or buttocks.
- Making blatant sexual statements to the nurse.
- Offering the nurse sex.
- Whistling; making comments about the nurse's attractiveness or desirability.
- Making sexual comments to another client in the same room or to visitors about the "hot" nurse or what they would like to do sexually with the nurse.

Possible reasons for this inappropriate behavior are

- Fear or anxiety over future ability to function sexually.
- Unmet needs for intimacy and sexual closeness because of hospitalization, injury, illness, treatment, lack of a partner, or lack of privacy.
- Misinterpretation of the nurse's behavior as sexual or provocative.
- Need for reassurance that they are still sexual beings and still sexually attractive.
- Need for attention.
- Confusion: Neurologic impairment or trauma can lead clients to use profane sexual language, engage in masturbation, expose themselves, or inappropriately touch or grab at the nurse.

- Need to control: Clients may experience loss of control over their lives because of hospitalization, injury, or illness.
- Need for power.
- Belief that flirtatious behavior is expected due to media portrayal of nurses as sexy, available, and experienced.

Before implementing any nursing interventions, the nurse should first ensure that the behavior is inappropriate and not an attempt to communicate a physical need. Clients may expose themselves if they are febrile, pull at the penis if a catheter is uncomfortable or irritating, or reach for the nurse if unable to communicate verbally. Nursing strategies to deal with inappropriate sexual behavior are listed in Box 40–4.

Evaluating

The goals established during the planning phase are evaluated according to specific desired outcomes also established during that phase. If any outcomes have not been achieved, the nurse should explore the reasons with questions such as the following:

- Were risk factors correctly identified?
- Did the client convey all significant fears and concerns about sexuality?
- Was the client more comfortable following discussions about sexual matters?
- Did the client understand the nurse's teaching?
- Was the health teaching compatible with the client's culture and religious values?
- Was the client ready to deal with sexuality problems?

BOX 40–4 Nursing Strategies for Inappropriate Sexual Behavior

- Communicate that the behavior is not acceptable by saying, for example, "I really do not like the things you are saying," or "I see you are not dressed. I will be back in 10 minutes and will help you with breakfast when you get your clothes on."
- Tell the client how the behavior makes you feel: "When you act like that toward me, I am very uncomfortable. It embarrasses me and makes it hard for me to give you the nursing care you need."
- Identify the behavior you expect: "Please call me by my name, not 'honey'" or "I expect you to keep yourself covered when I am in the room. If you are feeling hot or something is uncomfortable, let me know, and I will try to make you more comfortable."
- Set firm limits: Take the client's hand and move it away, use direct eye contact, and say, "Don't do that!"
- Try to refocus clients from the inappropriate behavior to their real concerns and fears; offer to discuss sexuality concerns: "All morning you have been making very personal sexual comments about yourself. Sometimes people talk like that when they are concerned about the sexual part of their life and how their illness will affect them. Are there things that you have questions about or would like to talk about?"
- Report the incident to the nurse in charge and, if appropriate, the primary care provider. Discuss the incident, your feelings, and possible interventions.
- Clarify the consequences of continued inappropriate behavior (avoidance, withdrawal of services, no chance to help resolve underlying concerns of client).

Critical Thinking Checkpoint

Mr. Curry is a 50-year-old African American male with diabetes who suffered a heart attack 3 weeks ago. He is doing well and is in a cardiac rehabilitation program. His diabetes is controlled with diet, and his only medications consist of a daily aspirin and an antihypertensive medication. During a routine checkup, you inquire how he is feeling and whether he is doing well on his medications. Reluctantly, he admits that he is having some sexual problems. You encourage further discussion of the matter by displaying interest and explaining that it is okay for him to share his concerns with you. Mr. Curry states that he

is having some difficulty achieving erections, but is more concerned that he will have another heart attack if he engages in sexual activities.

1. Speculate about Mr. Curry's reluctance to discuss his sexual concerns.
2. What factors influence nurses' abilities to discuss sexual concerns with their clients?
3. What is the relationship between health and sexual function?
4. How can you best intervene to help Mr. Curry?

See Critical Thinking Possibilities on student resource website.

Chapter 40 Review

CHAPTER HIGHLIGHTS

- Sexuality is important in developing self-identity, interpersonal relationships, intimacy, and love.
- There is a tremendous range of variation in how people express their sexuality including sexual orientation, gender identity, and erotic preferences.
- Factors that affect sexuality include family, culture, religion, personal expectations and ethics, disease processes, medications, and relationship problems.
- Sexual problems include desire disorders, arousal disorders, orgasmic disorders, sexual pain disorders, and problems with satisfaction.
- Assessing risk for or actual sexual problems is part of the initial nursing assessment.
- Nurses assess attitudes toward sexuality, including factors that affect attitudes and behaviors.
- Before assisting clients with sexual problems, nurses must be aware of their own feelings and beliefs so they can objectively prepare approaches for gathering data and creating the nursing care plan. The nurse uses a culturally sensitive, nonjudgmental, non-threatening, and reassuring approach.
- Nursing diagnoses for clients with sexual problems are related to altered body structure or function, lack of knowledge or misinformation about sexual matters, physical or psychological abuse, value conflicts, and loss or lack of a partner. Common NANDA International nursing diagnoses include *Ineffective Sexuality Pattern* and *Sexual Dysfunction*.
- Nursing interventions focus largely on teaching clients about sexual health and function, responsible sexual behavior that includes the prevention of STIs and unwanted pregnancies, and self-examination of the breasts and testicles.
- Counseling clients with altered sexual functions can be facilitated by using the PLISSIT model: permission giving (P), limited information (LI), specific suggestions (SS), and intensive therapy (IT). Intensive therapy requires intervention by clinical nurse specialists or sex therapists.

TEST YOUR KNOWLEDGE

1. Clients may be unlikely to introduce the topic of sex with health care providers for which reason?
 1. They assume that health care providers know little about sexual functioning.
 2. Most clients have few questions or problems.
 3. Female clients prefer to discuss problems with female health care providers.
 4. They are too embarrassed to introduce the topic of sex.
2. A nurse receives information that a client is transgender. Appropriate care is based on the knowledge that which of the following is most representative of this client?
 1. Gonadal gender, internal organs, and external genitals are contradictory.
 2. Sexual anatomy contradicts gender identity.
 3. Sexual attraction is to individuals of both genders.
 4. Gender identity is altered by acute psychosis.
3. In conducting client teaching, the nurse bases content on knowing that which of the following is true regarding masturbation?
 1. People who masturbate are psychologically disturbed.
 2. Teenage masturbation interferes with academic achievement.
 3. Most people do not masturbate past the teenage years.
 4. Masturbation is a way people learn about their sexual response.
4. A male client is beginning an antidepressant medication. Which of the following should be included in the teaching?
 1. "Your partner will be pleased because your sexual functioning is going to improve."
 2. "You may find that your desire for sex will decrease while on this medication."
 3. "Retrograde ejaculation is a common problem when taking antidepressants."
 4. "Your skin will probably become supersensitive to touch, so you may need to change your activity during sex."
5. A client who had a hysterectomy 3 days ago, says to the nurse, "I no longer feel like a real woman." What is the best response?
 1. "Don't worry about that. The feeling will probably go away."
 2. "You should talk to your doctor about how you feel."
 3. "I don't blame you. I would feel like half a woman also."
 4. "I hear your concern. Tell me more about your feelings."
6. Because a client reports having dyspareunia, it is most appropriate to ask which question?
 1. "Have you talked with your partner about this discomfort?"
 2. "Have you had these spasms since you became sexually active?"
 3. "Do you have pain before your period begins?"
 4. "Do your breasts swell large enough to need a larger bra?"
7. Including at least some sexual health history questions would be most relevant for clients taking which category of drugs?
 1. Anti-inflammatories (such as aspirin or ibuprofen)
 2. Hypnotics (sleeping pills)
 3. Antihypertensives (blood pressure medications)
 4. Antihistamines (cold medications)
8. A nurse informs a client who is 8 1/2 months pregnant that it is best to abstain from intercourse until after the birth of the baby. This communication is most representative of which component of the PLISSIT model?
 1. Permission giving (P)
 2. Limited information (LI)
 3. Specific suggestions (SS)
 4. Intensive therapy (IT)

9. A 75-year-old male client reports decreased frequency of sexual intercourse although he does not express dissatisfaction or difficulty. He seems a little embarrassed by the discussion but is engaged and asks some questions. An appropriate nursing diagnosis would be which of the following?
1. *Sexual Dysfunction*
 2. *Disturbed Body Image*
 3. *Sedentary Lifestyle*
 4. *Readiness for Enhanced Knowledge*
10. Which of the following outcomes may indicate the need for referral to a more highly skilled therapist?
1. The client verbalizes methods of modifying sexual activity according to physical limitations.
 2. The client requests the phone number of a sex education support group.
 3. Suggestions given by the nurse are ineffective in reaching the desired goals.
 4. The client reports experimenting with new sexual activities.

41 Spirituality

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe the interconnection of spirituality and religion concepts as they relate to health and spiritually sensitive nursing care.
2. Compare and contrast spiritual needs, spiritual distress, and spiritual health.
3. Appreciate spiritual development by describing spiritual developmental issues of childhood and aging in particular.
4. Describe the influence of spiritual and religious beliefs and practices that can have an impact on a client's health care: holy days, sacred texts, prayer and meditation, diet, healing, dress, birth, and death.
5. Describe methods to assess the spiritual and religious preferences, strengths, concerns, or distress of clients and plan appropriate nursing care.
6. Describe nursing care/therapeutics to support religiosity and promote clients' spiritual health.
7. Recognize the importance of providing ethical spiritual care.
8. Describe strategies that can increase a nurse's own spiritual awareness.

spirituality, 954

INTRODUCTION

To provide holistic care, nurses need to care not only for the physical body and mind, but also need to care in ways that are sensitive to the client's spirit (Hutchinson, 2011; O'Brien, 2011). Given the mounting research evidence linking spiritual health with physical and mental health (Koenig, King, & Carson, 2012), it is assumed that nursing care that supports clients' spiritual health will help promote other dimensions of health. Furthermore, clients inevitably approach their health challenges, decisions, suffering, and so forth, with a worldview that reflects what are typically considered spiritual or religious beliefs (Peteet & Balboni, 2013; Taylor, 2011a). Failure to appreciate these influential beliefs is to fail to understand what motivates, informs, and comforts a client. Indeed, spiritual beliefs and practices are frequently found to relieve one's suffering; unfortunately, sometimes discomfiting spiritual beliefs can intensify suffering (Taylor, 2011a). Regardless, such beliefs are present at the bedside, and they require recognition and sometimes support or scrutiny.

Recognizing a client's spirituality is like standing on holy ground (O'Brien, 2011). The nurse cannot approach care for the spirit as if it were a pressure ulcer or even as if it were an emotional problem. Spiritual matters are not intangibles that can be fixed, cured, solved, or manipulated. Rather, the nurse's stance toward spiritually sensitive care must be one that seeks to accompany, support, and nurture (Taylor, 2011b). This chapter explores how the nurse can attend to the client who presents with a need to relieve spiritual distress or to enhance spiritual health. Nurses can offer spiritually sensitive nursing care that supports spiritual health, helps with coping and adjustment, or assists one to face a more peaceful death.

954

SPIRITUALITY AND RELATED CONCEPTS DESCRIBED

Spirituality and *religion* are words that are often used interchangeably by clients and professionals alike, yet the nursing literature typically distinguishes them as separate concepts. That is, **spirituality** is generally thought to refer to the human tendency to seek meaning and purpose in life, inner peace and acceptance, forgiveness and harmony, hope, beauty, and so forth. In contrast, the term **religion** is usually applied to ritualistic practices and organized beliefs. Indeed, there has been a tendency in nursing—as in psychology and other fields—to separate these two concepts. Yet trying to make religion an opposite of spirituality (e.g., institutional versus personal, objective versus subjective, narrow versus broad, cerebral versus emotional, bad versus good) is unfair to both concepts. Spirituality and religion are “inherently intertwined” (Hill et al., 2000).

A shift in thinking about these terms is occurring in nursing and health care scholarship. Koenig, a nurse-turned-physician and leader in the area of spirituality and health, suggests that spirituality should be defined as religiosity for research purposes, but defined more broadly for client care purposes (Reinert & Koenig, 2013). This is because spirituality as a concept overlaps with many other concepts often studied in conjunction with spirituality, and religion is a more distinct concept open to observation. Koenig (Koenig et al., 2012) proposes that spirituality “is distinguished from other things . . . by its connection to the transcendent” (p. 46), which he accepts is within and outside of the self. Thus, spirituality generally involves a belief in a relationship with some higher power, creative force, divine being, or infinite source of energy. For example, a person may believe in God,

Allah, the Great Spirit, or a Higher Power. Koenig also views spirituality as interconnected with religion, as it “extends beyond religion (and begins before it).”

Not only is religion a more usable concept for nursing scholarship, it is also often the interpretation clients give to “spirituality” (La Cour & Gotke, 2012; Molzahn et al., 2012). This may be especially true for clients from cultures where religion is a visible aspect of society (Rahnama, Khoshknab, Maddah, & Ahmadi, 2012). Indeed, spiritual experience is often difficult for laypeople to find words to describe. Clients’ spirituality is often expressed in nonreligious language, in stories, and in ways they may not even recognize.

It is important to remember that some people do not accept that there is an Ultimate Other or a spiritual reality. An **agnostic** is a person who doubts the existence of God or a Supreme Being or believes the existence of God has not been proved. An **atheist** is one without belief in a deity. A nursing study of atheists’ preferences for nursing care found that respondents wanted to be respected for their nonbelief and not have clinicians refer to God or offer prayer (Smith-Stoner, 2007). These respondents did, though, desire to find meaning in life, and to remain connected to close individuals and the natural world at the end of life—desires that nurses typically characterize as reflecting spirituality. Most nurses accept a definition of spirituality that allows the assumption of spirituality to be universal. It is essential to ethical nursing care, however, that diverse views regarding spirituality be acknowledged and respected (Taylor, 2011a).

Spiritual Care or Spiritual Nursing Care?

Pesut and Sawatzky (2006) put forward that **spiritual care** should not be prescriptive (i.e., the following of a set guideline for intervening to resolve a client’s spiritual problem). Instead it should be descriptive of ways nurses can offer spiritual support. Therefore, they suggest that:

Spiritual nursing care is an intuitive, interpersonal, altruistic, and integrative expression that is contingent on the nurse’s awareness of the transcendent dimension of life but that reflects the client’s reality. At its foundational level, spiritual nursing care is an expression of self. . . . Spiritual nursing care begins from a perspective of being with the client in love and dialogue but may emerge into therapeutically oriented interventions that take direction from the client’s religious or spiritual reality. (p. 23)

Although nursing terminology usually uses *spiritual care*, a few nurses use less prescriptive, and probably more appropriate, language such as *spiritually sensitive nursing care* or *spiritual nursing care*. Regardless of terminology, promising findings from recent studies indicate that such care does affect positive client outcomes such as satisfaction with care (Lichter, 2013; Taylor, 2011a).

Spiritual Needs, Spiritual Distress, Spiritual Health, and Religious Coping

If one assumes that everybody has a spiritual dimension, then it may also be assumed that all clients have needs that reflect their spirituality. Such needs are not problems to be processed, but perhaps better understood as inner movements, yearnings, or experiences. An awareness of such needs is often heightened by an illness or other health crisis. Clients may find that their beliefs are challenged by their health situation, or may cling to their beliefs more firmly and appreciatively. For example, a study of 62 clients hospitalized for a

sudden cardiac event found that 58% of the clients experienced some religious struggle (e.g., questioned the power of God [Magyar-Russell et al., 2014]), whereas another study of 178 bone marrow transplant clients revealed only 18% as at risk for such struggle (King, Fitchett, & Berry, 2013). Or, a client may have a need to express joy or gratitude, or continue through the inwardly rewarding (yet often painful) process of spiritual transformation. Nurses need to be sensitive to indications of the client’s spiritual needs and respond appropriately, as discussed later. Examples of spiritual needs are listed in Clinical Manifestations of Spiritual Needs.

Spiritual distress refers to “a disturbance in the belief or value system that provides strength, hope, and meaning to life” (Carpenito-Moyet, 2008, p. 436). NANDA International (Herdman & Kamisturu, 2014) categorizes defining characteristics of spiritual distress by whether they reflect an impaired connection with self, others, art/music/literature/nature, or a power greater than self. Examples of defining characteristics of spiritual distress include:

- Expresses lack of hope, meaning of life, inadequate acceptance of self
- Expresses feeling abandoned or anger toward power greater than self
- Refuse interaction with significant others
- Exhibits sudden changes in spiritual practices
- Requests (or refused) to interact with a spiritual leader
- Has no interest in nature or in reading spiritual literature.

No list could be complete, however, considering the complexity and variability of people and their spiritual dimensions. Indeed, a recent analysis of nursing literature defining spiritual distress concluded that further work validating this nursing diagnosis is needed (Caldeira, Carvalho, & Vierira, 2013).

Spiritual health, or **spiritual wellness** or **well-being**, is often portrayed as the opposite of spiritual distress. Spiritual health is thought to not occur by chance, but by choice. That is, spiritual health results when individuals intentionally seek to strengthen their spiritual muscles, as it were, through various spiritual disciplines (e.g., prayer, meditation, service, fellowship with similar believers, learning from a spiritual mentor, worship, study, fasting) (Foster, 2008).

Spiritual or religious coping, both positive and negative, has received considerable research attention during the past couple of decades. It refers to the spiritual beliefs or ways of thinking that help people cope with their challenges. Numerous studies have shown that positive religious coping helps clients adapt to illness, whereas negative religious coping is associated with maladaptation (Taylor, 2011a). For example, thinking that illness is a punishment and feeling abandoned by God are related to depressed mood in women with breast cancer (Thune-Boyle, Stygall, Keshtgar, Davidson, & Newman, 2013). Such negative religious coping also explains, in part, the link between trauma and post-traumatic stress disorder (Wortmann, Park, & Edmonson, 2011).

SPIRITUAL DEVELOPMENT

Theories about human development include not just theories about physical, cognitive, and moral development, but also spiritual development (Fowler, 1981; Taylor, 2007b). Thus, when assessing or supporting client spirituality, it is necessary to appreciate how spirituality and religiosity evolve with age and life experience (see Lifespan Considerations.) A normal part of this development for teens and young adults involves evaluating the beliefs and religiosity of authority figures to form beliefs and practices that are meaningful for them. It is

CLINICAL MANIFESTATIONS

Spiritual Needs

Spiritual Needs

Need for satisfying meaning to ascribe to illness, to life, to dying, to any loss or serious challenge

Need for purpose, vocation, mission

Need for believable beliefs, sensible worldview

Guilt, need to restore relationship

Shame, imperfection, unworthiness

Need to worship, transcend self

Need for peace, composure

Need to be grateful

Need to express love

Isolation, abandonment, betrayal

Illustrations

“Why would this happen to me? Having cancer is a celestial crapshoot!”
“This is so unfair?” “Why do bad things happen?”

“Now that I can’t work anymore, what good is it for me to keep on living?” “What’s there for me to do now with my old body?”

“I’ve been told God is in control and is loving, but that doesn’t make sense to me anymore.”

“I wonder if I’m being punished for something I did when I was younger.” “I know I have to meet my Maker soon, so I’d better get things right with Him.”

“I never was good enough for . . . , but now look how sick/disabled/scarred I am!”
“I am going to do whatever my family wants me to do.” “I’m just using up society resources. I’m such a burden to my family.”

“I am so tired/sick/befuddled/anxious, I’m beside myself. . . . I wish I could feel God was involved in this situation.” “I never get to go to church because I’m always taking care of my husband.”

“I don’t feel comfortable being alone or in silence.” “I just wish I could make it all turn out the way I want it to.”

“I know I should count my blessings; things could be worse.”

“I keep my problems to myself, because I don’t want to trouble my family any more than necessary.” “You nurses do so much for me; I wish I could do nice things for you.”

“Why don’t they come to visit anymore?” “It just seems like all my prayers bounce back to me without being heard.”

not unusual, however, to find adults who have failed to complete this developmental task. Thus, when serious health challenges occur, the beliefs of childhood that have “not kept up with the times” may fail to be satisfactory for explaining such loss or change.

RELIGIOUS PRACTICES THAT NURSES SHOULD KNOW

Many traditional religious practices and rituals are related to life events such as birth, transition from childhood to adulthood, marriage, illness, and death. Religious rules of conduct, typically influenced concurrently by culture, may also apply to matters of daily life such as dress, food, social interaction, menstruation, childrearing, and sexual relationships. When people get sick, they frequently rely on prayer and other spiritual practices. Decisions about health and end-of-life care are guided by spiritual or religious beliefs. Given this deep connection between spiritual or religious practices and the circumstances in which nurses often provide care, it is fitting for nurses to have some awareness and understanding of these practices (Taylor, 2012).

It is possible for nurses to unethically impose personal spiritual beliefs on clients, whose circumstances inherently leave them vulnerable. Observing guidelines for ethical conduct in spiritual caregiving is essential. The following guidelines for nurses were offered by Winslow and Wehtje-Winslow (2007):

- First seek a basic understanding of clients’ spiritual needs, resources, and preferences (i.e., assess).
- Follow the client’s expressed wishes regarding spiritual care.
- Do not prescribe or urge clients to adopt certain spiritual beliefs or practices, and do not pressure them to relinquish such beliefs or practices.

- Strive to understand personal spirituality and how it influences caregiving.
- Provide spiritual care in a way that is consistent with personal beliefs.

CLINICAL ALERT!

Although some clients are eager for nurses’ overt offers of spiritual care, others may be uncertain or opposed to such offers (Taylor, 2011a). Clients often confuse religiosity with spirituality; this may contribute to their uncertainty about receiving spiritual care from nurses. Observing and using the client’s language for spirituality (e.g., “being at peace” or “faith”) and exhibiting large measures of sensitivity and respect will help nurses to converse therapeutically with clients to provide spiritual care.

Holy Days

Solemn religious observances and feast days throughout the year may be referred to as **holy days** and may include fasting or special foods, reflection, rituals, and prayer. Believers who are seriously ill are often exempted from such requirements. Clients may be used to spending such days with family and attending religious services. Examples of such holy days are Rosh Hashanah and Yom Kippur (Jewish), Good Friday and Christmas (Christian), Buddha’s birthday (Buddhists), Mahashivarathri—a celebration of Lord Shiva (Hindu), and the month-long Ramadan (Islam). Because some religions follow calendars other than the Gregorian calendar, a multifaith calendar can be used to identify the holy days of the various religious groups.

Sacred Texts

The concept of the Sabbath is common to both Christians and Jews, in response to the biblical commandment “Remember the Sabbath day

LIFESPAN CONSIDERATIONS | Spiritual Development

CHILDREN

As with adults, children describe their spiritual health and challenges through the stories they tell and behaviors. And as with adults, they can learn spiritual principles from stories caregivers tell. As you create responses, consider the child's cognitive and faith development stage to determine what language will be age appropriate. Do they think concretely and literally about spiritual concepts like God and heaven? Or do they think mythically and abstractly? Follow the child's cues about how to talk.

- Children's spirituality reflects or interacts with that of their authority figure(s) (e.g., parents). The spiritual beliefs and practices of the authority figure(s) will be trusted and adopted by the child. Thus, many of the cues for how to talk with a child will come from that child's parent or guardian. Generally, it is not until teenage years and young adulthood, when children can reason abstractly, that they begin to independently construct their own spiritual beliefs and practices.

OLDER ADULTS

Many older adults highly value religious coping strategies such as prayer. Evidence shows spiritual well-being to be directly correlated with mental health and less medical illness among older adults (Koenig et al., 2012). It is, therefore, important to address the spiritual issues of older adults. Older clients may be especially concerned about living a purposeful life, maintaining loving relationships to avoid social isolation, and preparing for a good death. Nursing care that attends to such spiritual issues includes the following:

- Supporting meaning-making activities (e.g., conducting a life review or reminiscence therapy; allowing the client to weave together the strands of lived life; encouraging the client to

become dedicated to some social, political, religious, or artistic cause; supporting the client to leave a legacy or do an altruistic deed). Such activities provide older adults with a sense of purpose and assist them in making sense of the life they have lived.

- Allowing open discussions about suffering and dying, encouraging client disclosure by asking open-ended questions, and providing responses that are respectful and compassionate. Do not avoid discomforting topics and questions older clients raise by imposing positivity, giving "pat" answers, and otherwise minimizing or avoiding their spiritual pain.
- As appropriate, supporting older clients to reframe the "losses" of aging as "liberations." For example, older adults possess great wisdom and are in a season of life that promotes spiritual growth.

Older adults with dementia present special circumstances for spiritual caregiving. Nurses can help those with early stages of dementia to focus on the positives—the "haves" rather than the losses. Allowing older clients with dementia to tell their stories permits them to maintain some identity (amidst a disease that threatens the very sense of self) and allows the nurse a window into their world. Older clients with dementia can also worship and express their hope and creativity through various art forms (e.g., movement, painting, music). It is also possible for them to experience the compassion of others when they feel their caring touch or hear their soothing voice. Ennis and Kazer's (2013) literature review revealed research supporting the usefulness of spiritual interventions for older adults with dementia, especially religious rituals and music, as memory for these may be unaffected by dementia.

to keep it holy." Most Christians observe the "Lord's Day" on Sunday, whereas Jews and sabbatarian Christians (e.g., Seventh-Day Adventists) observe Saturday as their Sabbath. Muslims traditionally gather on Friday at noon to worship and learn about their faith. Clients who are devout in their religious practices may want to avoid any special treatments or other intrusions on their day of rest and reflection.

People often gain strength and hope from reading religious writings when they are ill or in crisis. Each religion has sacred and authoritative scriptures that provide guidance for its adherents' beliefs and behaviors. In addition, sacred writings frequently tell instructive stories of the religion's leaders, kings, and heroes. In most religions, these scriptures are thought to be the word of the Supreme Being as written down by prophets or other human representatives. Christians rely on the Old and New Testaments of the Bible; Jews on the Hebrew Bible and rabbinic interpretations; and Muslims on the Koran; Hindus have several holy texts, or Vedas; Sikhs cherish the *Adi Granth*; and Buddhists value the teachings of the *Tripitakas*. Scriptures generally set forth religious law in the form of warnings and rules for living (e.g., the Ten Commandments). This religious law may be interpreted in various ways by subgroups of a religion's adherents and may affect a client's willingness to accept treatment suggestions; for example, blood transfusions are in conflict with the Biblical interpretations of Jehovah's Witnesses.

Sacred Symbols

Sacred symbols include jewelry, medals, amulets, icons, totems, or body ornamentation (e.g., tattoos) that carry religious or spiritual significance. They may be worn to pronounce one's faith, to remind the practitioner of the faith, to provide spiritual protection,

or to be a source of comfort or strength. People may wear religious symbols at all times, and they may wish to wear them when they are undergoing diagnostic studies, medical treatment, or surgery. For example, people who are Roman Catholic may carry a rosary for prayer; a Muslim may carry a mala, or string of prayer beads (Figure 41-1 ■).

People may have religious icons or statues in their home, car, or place of work as a personal reminder of their faith or as part of a personal place of worship or meditation. Hospitalized clients or long-term care residents may wish to have their spiritual icons or statues with them as a source of comfort.

Prayer and Meditation

Prayer involves humans pleading or experiencing the divine (however that is perceived). Some would describe prayer as an inner experience for gaining awareness of self (including Self—or the immanent manifestation of the divine). These differing perspectives likely reflect the theological variations about how the divine relates to humanity. For example, some view the divine as transcendent (e.g., God in Heaven), while others experience the divine as immanent (e.g., the inner light or wisdom within people). A more complex perspective would accept that the divine engages with humanity in both—or many—ways (Taylor, 2012).

There are different types of prayer experience. Poloma and Gallup (1991) categorized prayer experiences as follows:

- Ritual (e.g., Hail Mary, memorized prayers that can be repeated)
- Petitionary (e.g., "God, cure me!" or intercessory prayers when one is requesting something of the divine)

Figure 41–1 ■ Clients may bring objects to the hospital to use in prayer or other religious rituals. Caregivers should respect such objects, because they usually have great significance for clients.
Dan Pan/Getty Images.

- Colloquial (i.e., conversational prayers)
- Meditational (e.g., moments of silence focused on nothing, a meaningful phrase, or a certain aspect of the divine).

Although meditational and colloquial prayer experiences have been found to be associated with spiritual well-being and quality of life in healthy adults, ritual and petitionary prayer experiences may be most comforting and appropriate for those who are ill and unable to concentrate (Taylor, 2012).

Some religions have prescribed prayers that are printed in a prayer book, such as the Anglican/Episcopal *Book of Common Prayer* or the Catholic *Missal*. Some religious prayers are attributed to the source of faith; for example, the Lord's Prayer for Christians is attributed to Jesus, and the first sutra for Muslims is attributed to Mohammed.

Some religions prescribe daily prayers or dictate specific times for prayer and worship: the five daily prayers, or *Salat*, of the Muslims (performed while facing east toward Mecca at dawn, noon, midafternoon, sunset, and evening), the daily *Kaddish* of the Jews, or the seven canonical prayers of the Roman Catholics. People who are ill may want to continue or increase their prayer practices (French & Narayanasamy, 2011). They may need uninterrupted quiet time during which they have their prayer books, rosaries, malas, or other icons available to them.

Meditation is the act of focusing one's thoughts or engaging in self-reflection or contemplation. Some people believe that, through deep meditation, one can influence or control physical and psychological functioning and the course of illness. Benson and Klipper's (2000) classic book describing the cardiovascular benefits of faith identified the basic elements of meditation conducive to good health. These included repeating a meaningful, self-selected, short mantra; putting aside extraneous thoughts or "noise" that interrupt; and slow, deep breathing concurrently with the meditation. The nurse may support spiritual health by teaching clients about meditation, or even protecting a meditating client's environment from noise or intrusion.

Beliefs Affecting Diet

Many religions have prescriptions regarding diet. It is important that health care providers prescribe diet plans with an awareness of the client's dietary and fasting beliefs. There may be rules about which foods and beverages are allowed and which are prohibited. For example, Orthodox Jews are not to eat shellfish or pork, and Muslims are not to drink alcoholic beverages or eat pork. Members of the Church of Jesus Christ of Latter-Day Saints (Mormons) are not to drink caffeinated or alcoholic beverages. Older Catholics may choose not to eat meat on Fridays because this was prescribed in years past. Buddhists and Hindus are often vegetarian, not wanting to take life to support life. Religious law may also dictate how food is prepared; for example, many Jewish people require kosher food, which is food prepared according to Jewish law.

Some solemn religious observances are marked by fasting, which is the abstinence from food or certain foods for a specified period of time. Some religions also restrict beverages during a fast; others allow drinking of water or other sustaining beverages on fast days. Examples of religions that observe fasting include Islam, Judaism, and Eastern Orthodox Christians. During the month of Ramadan, devout Muslims eat no food and avoid beverages during daylight hours; the fast is broken after sunset. Members of Jewish synagogues fast on Yom Kippur, and devout Catholics may fast on Good Friday. Most religions lift the fasting requirements for seriously ill believers for whom fasting may be a detriment to health (e.g., clients with diabetes). Some religions may exempt nursing mothers or menstruating women from fasting requirements (Taylor, 2012).

Beliefs About Illness and Healing

Clients may have religious beliefs that attribute illness to a spiritual disease or sin. Some clients may ascribe disease to the innate presence of sin and evil in this world, whereas others may believe the disease is a punishment for sin in their past. Indeed, how clients view the divine, interpret good and evil, and so forth, inevitably influences their thinking about illness and decision making about treatment. Healing for such clients may appear to be unrelated to current treatment practices. When relevant, the nurse should assess the client's beliefs related to health and, if possible, include aspects of healing that are part of the client's belief system in the planning of care. For example, many religious traditions have rituals of healing such as anointing by a leader of the local religious community.

Beliefs About Dress and Modesty

Many religions have traditions that dictate dress. For example, Orthodox and some Conservative Jewish men believe that it is important

Figure 41–2 ■ Hindu women dressed in saris.
Charlie Westerman/Getty Images.

to have their heads covered at all times and therefore wear yarmulkes. Orthodox Jewish women cover their hair with a wig or scarf as a sign of respect to God. Mormons may wear temple undergarments in compliance with religious dictates. For some, it is imperative that they not shave certain hair (e.g., sideburns for Hasidic Jewish men, any hair for a Khalsa [dedicated] Sikh).

Some religions require that women dress in a conservative manner, which may include wearing sleeves and modestly cut tops, and skirts that cover the knees. Many Islamic cultures may require that the body (torso, arms, and legs) be covered, as well as the head (i.e., burkha or hijab). Hindu women accustomed to wearing saris prefer to cover all of the body except arms and feet (Figure 41–2 ■). Hospital gowns may make women wishing to comply with religious dress codes feel uneasy and uncomfortable. Clients may be especially disconcerted when undergoing diagnostic tests or treatments, such as mammography, that require body parts to be bared or shaved. Nurses need to facilitate respectful solutions at such times (Taylor, 2012).

Beliefs Related to Birth

For all religions the birth of a child is an important event giving cause for celebration. Many religions have specific ritual ceremonies that consecrate the new child to God. For example, while a baby is being born, its Muslim mother may recite a prayer. As soon as it is born, its father or someone else will recite a call to prayer into the infant's ears. Likewise, Hindus will perform a number of religious rituals when a baby is born. Most Christian parents will have their babies christened or baptized at some point; however, for some, if their infant is dying, they may want a baptism as soon as possible. In such dire circumstances, Christian parents of seriously ill infants may want baptism performed at birth by a religious nurse or primary care provider if a chaplain or clergy person is not present. In the Jewish and Islamic

traditions, male circumcision is obligatory, whereas Hindus never practice circumcision. When nurses are aware of the religious needs of families and their infants, they can support families in fulfilling their religious obligations (Taylor, 2012).

Beliefs Related to Death

Spiritual and religious beliefs play a significant role in the believer's approach to death just as they do in other major life events. Many believe that the person who dies transcends this life for a better place or state of being. Research findings suggest these religious beliefs may influence end-of-life care choices, such as whether to seek hospice care or have an advanced care plan (Garrido, Idler, Leventhal, & Carr, 2013; Taylor, 2011a).

Some religions have special rituals surrounding dying and death that must be observed by the faithful. Observance of these rituals provides comfort to the dying person and their loved ones. Some rituals are carried out while the person is still alive, and can include special prayers, singing or chants, and reading of sacred scriptures. Roman Catholic priests perform the Sacrament of the Sick (previously referred to as the Last Rites) when clients are very ill or near death; Orthodox Christians have a similar ritual. Muslims who are dying want their body or head turned toward Mecca, whereas Hindus may want to face south. In the Muslim, Hindu, and Jewish traditions, a ritual bath and body preparation for burial may be done by a family member or by a ritual burial society (Taylor, 2012).

Many religious traditions also advocate for rituals during specified periods of mourning after the death. Jews and Muslims have a tradition of burial within 24 hours following death. Hindus cremate the body within 24 hours. Then the bereaved family observes a period of isolation given their defilement from living with the deceased. Jews "sit Shiva" (gather to pay respects) for several days in the home of the deceased. Buddhists perform prayers and rituals to aid the deceased to a better next life (Taylor, 2012).

During a terminal illness the client and/or family should be asked about end-of-life observances that could impact health care. The nurse can support the family of the deceased by providing an environment conducive to the performance of their traditional death rituals.

CLINICAL ALERT!

Sharing Beliefs

Before sharing personal beliefs or practices, a nurse must consider questions such as the following:

- For what purpose am I sharing my beliefs or practices? By doing so, am I meeting my needs or my client's?
- Is my spiritual care reflecting a spiritual assessment?
- Am I preying on a vulnerable client?
- Am I offering my beliefs or practices in a manner that allows my client to refuse comfortably?
- Does my spiritual care hurt or contribute to a therapeutic relationship with the client?

SPIRITUAL HEALTH AND THE NURSING PROCESS

The nursing process, which includes assessing, diagnosing, planning, implementing, and evaluating, has often been applied to spiritual care. Although this can be a helpful approach, it is now thought to misguide spiritually sensitive nursing care (Pesut & Sawatzky, 2006).

For this introductory discussion of spiritual care, content will be presented following this systematic nursing process. Recognize, however, that spiritual care is not about measuring a spiritual titer, planning to fix spiritual pain, prescribing spiritual therapy, spiritual problem solving, or manipulating, controlling, or managing spiritual outcomes or health.

●○○ NURSING MANAGEMENT

Although nurses can play a pivotal role in supporting clients' spirituality, it is important to remember that the nurse is a spiritual care generalist. Spiritual care experts include chaplains, clergy, and other spiritual mentors with whom clients may identify. Likewise, although many clients view nurses as important sources of spiritual support, clients often view their family and friends as their primary spiritual caregivers (Daaleman, 2012; Taylor, 2012).

Although there is scanty evidence directly measuring the outcomes of nurse (or even chaplain) provided spiritual care, some research findings suggest that spiritual care in a health care institution is associated with positive outcomes (Taylor, 2011a). There is evidence that clients in a hospital or in a nursing home who have received spiritual care tend to believe they have also received overall good care at that institution (Astrow, Wexler, Teixeira, He, & Sulmasy, 2007; Daaleman, 2012).

Whereas some research evidence shows that clients often consider their family and friends as their primary sources of spiritual support, there is also evidence that many clients (especially those at the end of life and those who are religious) do want spiritual support (Balboni et al., 2013; Mackenzie, Sanson-Fisher, Carey, & D'Este, 2013). One of the few studies that looked closely at spiritual care from oncology client, nurse, and physician viewpoints concluded that all these stakeholders saw spiritual care as a valuable part of end-of-life care (Balboni et al., 2013). Although only 13% of the 75 clients surveyed in this study reported that they had actually received spiritual care from a nurse, most of the 75 clients agreed that it was appropriate for a clinician to inquire about their spiritual/religious beliefs regarding health, and even to initiate an offer of prayer.

Assessing

The Joint Commission mandates that each client admitted to one of its accredited institutions must be assessed for spiritual beliefs and practices. Data about a client's spiritual beliefs and practices can be obtained from the client's general history (religious preferences or orientation); through a nursing history; and by clinical observations

of the client's behavior, verbalizations, mood, and so on. A few warnings about spiritual assessment are as follows:

- It is assumed that spirituality can be assessed, and that nurses are appropriate clinicians for conducting an initial or relatively superficial level of assessment. Both of these assumptions, however, may be debated (Pesut & Sawatzky, 2006).
- A nurse-conducted spiritual assessment should limit itself to client spirituality as it relates to health (Hodge, 2013; Taylor, 2012). That is, it is not the privilege of clinicians to investigate a client's spirituality unless it has a purpose related to providing health care.
- Nurses should never assume that a client follows all of the practices of the client's stated religion. Similarly, it is important to remember that the degree of religious commitment and orthodoxy (i.e., how strictly one integrates traditional religious prescriptions into daily life) is highly variable within religious traditions. How one Baptist, for example, interprets and lives his religion will be different from his Baptist neighbor.

A two-tiered approach to spiritual assessment is helpful (see Assessment Interview). Initially, the nurse must assess if the client accepts a spiritual reality (Hodge, 2013; Taylor, 2010). If yes, then the client can be asked general questions to elicit information about (a) what beliefs and practices are important to the present health care situation, and (b) what, if anything, the client would like from the health care team to support spiritual health. Then, those who manifest some type of unhealthy spiritual need or are at risk for spiritual distress can be assessed more thoroughly. Even this assessment can be streamlined to hone in on the particular spiritual concern present.

Although the nurse will continually be assessing, the initial spiritual assessment may best be taken at the end of the assessment process, or following the psychosocial assessment, after the nurse has developed a relationship with the client and/or support person. A nurse who has demonstrated sensitivity and personal warmth, creating some rapport, will likely be more successful during a spiritual assessment.

The questions provided in the accompanying Assessment Interview may be suitable. Remembering an acronym such as FICA can also help the nurse to ask appropriate questions:

- F = Faith or beliefs—for example, "What spiritual beliefs are most important to you?"
- I = Implications or influence—for example, "How is your faith affecting the way you cope now?"
- C = Community—for example, "Is there a group of like-minded believers with which you regularly meet?"
- A = Address—for example, "How would you like your health care team to support you spiritually?" (Puchalski & Ferrell, 2010).

ASSESSMENT INTERVIEW Sample Questions

ESSENTIAL CONTENT

- Is spirituality or religion important to you? (Or, how spiritual or religious do you think of yourself as being?)
- What spiritual or religious beliefs and practices are especially important for your health care team to know about?
- In what ways can I/we (nurses, health care team) support your spirit?

OPTIONAL FOLLOW-UP (USE AS APPROPRIATE)

- How will being sick interfere with your religious practices?

- What spiritual or religious beliefs influence you the most as you make health care decisions?
- How is your faith helpful to you? Is it sustaining you the way you would like it to while you are sick? In what ways is it important to you right now?
- Would you like a visit from your spiritual counselor or the hospital chaplain?
- What are your hopes and your sources of strength right now? What comforts you during hard times?

Cues to spiritual and religious preferences, strengths, concerns, or distress may be revealed by one or more of the following (Taylor, 2010):

1. **Environment.** Does the client have a Bible, Torah, Koran, other prayer book, devotional literature, religious medals, a rosary, cross, Star of David, or religious get-well cards in the room? Does a church send altar flowers or Sunday bulletins?
2. **Behavior.** Does the client appear to pray before meals or at other times or read religious literature? Does the client have nightmares and sleep disturbances or express anger at religious representatives or at a deity?
3. **Verbalization.** Does the client mention God or a higher power, prayer, faith, the church, synagogue, temple, a spiritual or religious leader, or religious topics? Does the client ask about a visit from the clergy? Does the client express any of the following: fear of death, concern with the meaning of life, inner conflict about religious beliefs, concern about a relationship with the deity, questions about the meaning of existence or the meaning of suffering, or about the moral or ethical implications of therapy?
4. **Affect and attitude.** Does the client appear lonely, depressed, angry, anxious, agitated, apathetic, or preoccupied?
5. **Interpersonal relationships.** Who visits? How does the client respond to visitors? Does a minister come? How does the client relate to other clients and nursing personnel?

Diagnosing

Nurses, as spiritual care generalists, must be extremely cautious when judging a client's spiritual health and applying a diagnosis that could be inappropriate. In diagnosing spiritual health, the nurse may find that spiritual problems provide the diagnostic label, or that spiritual distress is the etiology of the problem.

Spiritual Issues as the Diagnostic Label

NANDA International (Herdman & Kamitsuru, 2014) recognizes three diagnoses related to spirituality:

- **Spiritual Distress** is “a state of suffering related to the impaired ability to experience meaning in life through connections with self, others, the world, or a superior being” (p. 372). Spiritual distress can be related to situational crises (e.g., illness, unexpected life event) or “sociocultural deprivation” (e.g., inability to attend religious services).
- **Readiness for Enhanced Spiritual Well-Being** recognizes that spiritual well-being is a “pattern of experiencing and integrating meaning and purpose in life through connectedness with self, others, art, music, literature, nature, and/or a power greater than oneself, which can be strengthened” (p. 361). This wellness diagnosis describing spiritual health acknowledges that some people respond to adversity with an increased sensitivity to spirituality or spiritual maturation.
- **Risk for Spiritual Distress** is defined by NANDA as being “vulnerable to an impaired ability to experience and integrate meaning and purpose in life through connectedness with self, literature, nature, and/or a power greater than oneself, which may compromise health” (p. 374). This diagnosis may be appropriate for

a client who presently shows no indication of this disruption of spirit yet may if a nurse fails to intervene.

Religious Issues as the Diagnostic Label

NANDA International (Herdman & Kamitsuru, 2014) accepts three nursing diagnoses that reflect client religious issues:

- **Impaired Religiosity** “Impaired ability to exercise reliance on beliefs and/or participate in rituals of a particular faith tradition” (p. 369).
- **Risk for Impaired Religiosity** “Vulnerable to an impaired ability to exercise reliance on religious beliefs and/or participate in rituals of a particular faith tradition, which may compromise health” (p. 371).
- **Readiness for Enhanced Religiosity** related to illness and hospitalization “A pattern of reliance on religious beliefs and/or participation in rituals of a particular faith tradition, which can be strengthened” (p. 370).

Spiritual or Religious Distress as the Etiology

Spiritual distress may affect other areas of functioning and indicate other diagnoses. In these instances, spiritual distress becomes the etiology. Examples include the following:

- **Fear** related to apprehension about soul's future after death and unpreparedness for death
- **Chronic Low or Situational Low Self-Esteem** related to failure to live within the precepts of one's faith
- **Insomnia** related to spiritual distress
- **Ineffective Coping** related to feelings of abandonment by God and loss of religious faith
- **Decisional Conflict** related to conflict between treatment plan and religious beliefs.

Many other nursing diagnoses could also have spiritual distress or well-being as either a contributor or concurrent condition. Some of the more likely spirituality-related diagnoses include *Resilience*, *Chronic Sorrow*, *Powerlessness*, *Stress*, *Ineffective Coping*, *Risk for Loneliness*, *Readiness for Enhanced Hope*, and *Moral Distress*.

Planning

In the planning phase, the nurse identifies therapeutics to support or promote spiritual health in the context of illness.

Planning in relation to spiritual needs may involve one or more of the following:

- Helping clients to practice their religious rituals
- Supporting clients to recognize and incorporate spiritual beliefs in health care decision making
- Encouraging clients to recognize positive meanings for health challenges
- Promoting a sense of hope and peace
- Providing spiritual resources when requested.

It is important to remember that the goal of spiritual care is not to control clients' spiritual angst for them, tell them how to become transformed by their situation, or impose your goals for them. The plan,

rather, is to gently and sensitively support, facilitate, and accompany in ways that will aid health or a good death.

Implementing

Spiritual nursing care includes actions as diverse as recognizing and validating the inner resources of an individual, such as coping methods, humor, motivation, self-determination, positive attitude, and optimism. It can also include assisting the client to leave a legacy by storytelling and/or recording life stories for family and friends, and encouraging creative expression through art, music, and writing. This keeps the imagination alive and serves to regenerate the body, mind, and spirit. Fostering ways for clients to keep in touch with nature and maintain a sense of wonder are also forms of spiritual care. Recognizing the seasons, the emergence of flowers in spring, the phases of the moon, the migrations of birds, and the unchanging stars provides examples of orderliness in the universe, even in the midst of chaos and loss.

Numerous nursing therapeutics are available to support and promote client spiritual health. Although diverse, some of the most common nursing therapeutics most desired by clients include (a) providing presence, (b) conversing about spirituality, (c) supporting religious practices, (d) assisting clients with prayer, and (e) referring clients for spiritual counseling (Balboni et al., 2013). Clients want spiritual care therapeutics that do not involve much intimacy, are traditional, and are not overtly religious.

Providing Presence

Presencing is a term describing the art of being present, or just being with a client during an “existential moment” (Iseminger, Levitt, & Kirk, 2009). Fredriksson (1999) noted that presencing is a “gift of self” given by the nurse who maintains an attitude of attentiveness toward the client. Thus, nurses who listen attentively to clients yet fail to give of self (i.e., inwardly “make room”) diminish their effectiveness.

Osterman and Schwartz-Barcott (1996) identified four levels or ways of being present for clients:

- Presence (when a nurse is physically present but not focused on the client)
- Partial presence (when a nurse is physically present and attending to some task on the client’s behalf but not relating to the client on any but the most superficial level)
- Full presence (when a nurse is mentally, emotionally, and physically present; intentionally focusing on the client)
- Transcendent presence (when a nurse is physically, mentally, emotionally, and spiritually present for a client; involves a transpersonal and transforming experience).

Presencing is often the best and sometimes the only intervention to support a client who suffers under circumstances that medical interventions cannot address. When a client is helpless, powerless, and vulnerable, a nurse’s presencing can be most beneficial. Rather than worrying about saying or doing “the right thing,” nurses should focus on being fully present (Taylor, 2007b). In this way, nurses can promote healing, diminish client anxiety, create a sense of safety, and improve both client and their own satisfaction with the interaction (Iseminger et al., 2009).

Conversing About Spirituality

Sometimes clients do not want to talk about deep inner pain, spiritual or emotional. They may instead find comfort and help from the nurse who genuinely shows interest in their life, family, and hobbies. However, sometimes clients do want to have spiritual discussions with their nurse.

Taylor (2007b) proposed the goal of verbal spiritual care as being “to provide responses to clients which allow the clients to become intellectually, emotionally, and physically aware of their spirituality so that they can experience life more fully” (p. 7). Yet often when clients raise difficult spiritual concerns, clinicians avoid the topic by imposing a positive spin, minimizing the psychospiritual pain, injecting humor, or giving a pat answer. Instead of avoiding these painful and difficult conversations, nurses can provide a healing response by incorporating principles of empathic communication (Taylor, 2007b). For example, the nurse can respond to clients’ comments about spirituality with a restatement of what is most central in their comments, an open question to prompt their further reflection, or a statement that tentatively names their feeling. Dimensions of a verbal response that promotes spiritual healing are identified in Table 41–1.

Sometimes clients ask nurses about their spiritual or religious beliefs or practices, which may provoke some nurse anxiety. However, it is likely the client wishes to get better acquainted with the nurse to determine if the nurse is safe to disclose to, or because she or he wants to equalize the relationship. Occasionally, the client is collecting data, that is, she or he wants to learn a new comforting or meaningful spiritual perspective. The Practice Guidelines feature titled *Can a Nurse Self-Disclose Personal Spiritual Beliefs?* describes how a nurse can be cautious before sharing personal spiritual or religious beliefs with a client so as not to unethically impose these perspectives.

Supporting Religious Practices

During the assessment of the client, the nurse will have obtained specific information about the client’s religious preference and practices. Nurses need to consider specific religious practices that will affect nursing care, such as the client’s beliefs about birth, death, dress, diet, prayer, sacred symbols, sacred writings, and holy days as discussed

TABLE 41–1 Dimensions of a Spiritually Healing Response

Healing	Not Healing
Client centered (e.g., “It seems you’re feeling like no one cares.”)	Nurse centered (e.g., “But I care about you!”)
Neutral (e.g., “Tell me more about your thinking regarding . . .”)	Judgmental (e.g., “Why do you think that?”)
Immediate contributors to spiritual pain (e.g., “Perhaps underneath all the ‘why’ questions you’re asking, you feel abandoned.”)	Distant, tangential, or abstract contributors to spiritual pain (e.g., “You were wondering what caused your cancer.”)
Accurately names feelings, engages emotion (e.g., “I’m sensing that your belief makes you calm now.”)	Inaccurately or never names feelings, engages thinking (e.g., “What do you believe about . . . ?”)

From “Spiritual Pain,” by E. J. Taylor, 2007a, *Advance for Nurses*, 9(21), pp. 15–16.

PRACTICE GUIDELINES

Can a Nurse Self-Disclose Personal Spiritual Beliefs?

When self-disclosing personal spiritual perspectives, the health care professional can maintain a therapeutic relationship with the client by remembering the following:

- *Do not disclose to gratify your needs. Ask yourself, “Whose needs are being met when I share my beliefs?”* If you are disclosing your beliefs because you think they will benefit the client, yet the client has no desire to know your beliefs, then you are meeting your needs. Asking a client if you can share your beliefs may be inappropriate, given that clients often perceive they are “at your mercy” and may feel uncomfortable declining your offer. For example, asking “Do you mind if I ask a personal question?” often obliges the vulnerable client to say yes, even though they wish to say no. Instead, carefully observe for when a client indicates a desire for your perspective.
- *When clients ask you about your spirituality, you may find it helpful to first assess why they are asking.* For example, “Your question about ‘why?’ is a tough one. What brings you to ask it now?” or “I love talking about my beliefs, but what in particular is it that you’d like to know?” Or, “Before I answer, could we explore what this means to you?” *The why behind their question should guide your response.*
- *Any time you disclose your personal beliefs, follow up the self-disclosure with an open question or reflection of feelings.* Always return the ball to the client’s court. For example, “As you can see, I’m not sure of this myself, but can you tell me what would be comforting to you?” or “I wonder what is going on inside you now?”
- *Use self-disclosure infrequently and keep the disclosures short.* A request about what you believe is not a request for a religious discussion.
- *When responding to a client’s query about your spiritual beliefs, try to incorporate the client’s language when framing your response.* In this way, you may avoid using loaded words that could create tension. For example, if a client asks you about how they can “make things right,” you can couch your response using this language, rather than talk about “repentance” and “being saved” if that is your normal language.
- *Keep your answer honest, authentic.* Sometimes this means simply saying, “I don’t know.”
- *If you are asked a question with which you are uncomfortable or unable to answer, you can still use the moment for healing purposes.* Healing can still occur when you use the microskills introduced above to increase self-awareness. For example, “You know, I have to admit, I’m uncomfortable with your question. I may be uncomfortable with it because I don’t like the answers I’ve heard others give for it. Perhaps asking the question makes you feel uncomfortable, too.” [pause for response] Or, “I’ve been wondering that myself for a long time. Sometimes I wonder if it is . . . , but I don’t know. What ideas have you considered?”
- *Make a referral to a spiritual care specialist.* Assuming the client would like to further explore the spiritual questions that are brought to the surface by health challenges, initiate a referral through the chaplain or spiritual caregiver if the client assents.

From *What Do I Say? Talking with Patients About Spirituality*, by E. J. Taylor, 2007. Philadelphia, PA: Templeton Press.

earlier in this chapter. See Practice Guidelines for ways the nurse can help clients to continue their usual spiritual practices. Box 41–1 provides health-related information about specific religions.

Assisting Clients with Prayer

Prayer allows people to connect with each other and/or with the divine. To pray for another is also a way for loving people to express

care. While most clients may say that prayer makes them feel better, it is also possible that prayer could raise to awareness a spiritual struggle or a disappointment and questions about “unanswered prayers” (Taylor, 2012).

Does prayer heal clients? A recent Cochrane review of the evidence from several randomized experiments that investigated the efficacy of intercessory prayer (that is, having a person

PRACTICE GUIDELINES

Supporting Religious Practices

- Create a trusting relationship with the client so that any religious concerns or practices can be openly discussed and addressed.
- If unsure of client religious needs, ask how nurses can assist in having these needs met. Avoid relying on personal assumptions when caring for clients.
- Do not discuss personal spiritual beliefs with a client unless the client requests it. Be sure to assess whether such self-disclosure contributes to a therapeutic nurse–client relationship.
- Inform clients and family caregivers about spiritual support available at your institution (e.g., chapel or meditation room, chaplain services).
- Allow time and privacy for, and provide comfort measures prior to, private worship, prayer, meditation, reading, or other spiritual activities.
- Respect and ensure safety of the client’s religious articles (e.g., icons, amulets, clothing, jewelry).
- If desired by client, facilitate clergy or spiritual care specialist visitation. Collaborate with chaplain (if available).
- Prepare client’s environment for spiritual rituals or clergy visitations as needed (e.g., have chair near bedside for clergy, create private space).
- Make arrangements with dietitian so that dietary needs can be met. If institution cannot accommodate client’s needs, ask family to bring food. (Most religions have some recommendations about diet, such as espousing vegetarianism, rejecting alcohol.)
- Acquaint yourself with the religions, spiritual practices, and cultures of the area in which you are working.
- Remember there can be a difference between facilitating/supporting a client’s religious practice and participating in it yourself.
- Ask another nurse to assist you if a particular religious practice makes you uncomfortable.
- All spiritual therapeutics must be done within agency guidelines.

BOX 41-1 Health-Related Information About Specific Religions: A Sampler

Amish, Mennonite—Likely will not have insurance coverage; rely on religious community for support.

Anglicans, Episcopalians, Roman Catholics—Appreciate receiving Eucharist (Holy Communion), a ritual of ingesting bread and wine (or grape juice) led by clergy or lay leaders to commemorate death of Jesus. Forehead may be marked by priest with ashes on Ash Wednesday (40 days before Easter); no need to wash off. Lenten season (Ash Wednesday to Easter) may involve some degree of abstinence from food.

Buddhist—May be vegetarian. Facilitate meditation (may desire incense, visual focal point, use breathing or chanting, etc.).

Christian Scientist—Typically oppose Western medical interventions, relying instead on lay and professional Christian Science practitioners.

Hindu—Most eat no beef; many are vegetarian. Cleanliness highly valued. Many food preferences (e.g., foods fresh or cooked in oil).

Jehovah's Witnesses—Abstain from most blood products; need to discuss alternative treatments such as blood conservation strategies, autologous techniques, hematopoietic agents, non-blood volume expanders, and so on; contact local Jehovah's Witness hospital liaison committee.

Jews—Some observe kosher diet to varying degrees (e.g., avoid pork and shellfish, do not mix dairy and meat). Sabbath observance varies (e.g., Orthodox Jews avoid traveling in vehicles, writing, turning on electric appliances and lights, etc.).

Latter-Day Saints (LDS or Mormons)—Avoid alcohol, caffeine, smoking. May prefer to wear temple undergarments. Arrange for blessing with local elders, if requested.

Muslim—Respect modesty, avoid nakedness. Provide same-gender nurse if possible. Support prayers five times daily (may need to assist with ritual washing and positioning beforehand). Allow for family and imam (religious leader) to follow Islamic guidelines for burial when a Muslim client dies. Eat no pork, drink no alcohol. Children, pregnant, older adults, and sick exempt from daytime fast during month of Ramadan.

Roman Catholics—Sacrament of the Sick (previously known as Last Rites) appropriate for the ill. Be aware that some may think rite or offer of prayer means they are dying.

Seventh-Day Adventists—Avoid unnecessary treatments on Saturday (Sabbath). Sabbath begins Friday sundown, ends Saturday sundown. Adventists prefer restful, spirit-nurturing, family activities on Sabbaths. Likely to be vegetarian and abstain from caffeinated beverages. Do not smoke or drink alcohol.

unknown to a client pray for the client's physical healing) concluded that the findings equivocally suggest no clear positive or negative effect of intercessory prayer on health outcomes (Roberts, Ahmed, Hall, & Davison, 2009). A more helpful perspective regarding prayer is offered by Bishop (2003) who observed:

Prayer is a human response to existential moments, to “why” questions. Prayer is not an intervention, a technology to control the universe. It is not merely a psychological response. It is not merely a faith response. It is not a way that unenlightened people delude themselves. It is a human response to serious human questions—questions that every human has likely asked, or will likely ask when faced with serious illness. . . . If it does not work as defined by science, it still works by fulfilling its role in helping a client to seek meaning in the face of existential crises and again no scientific explanation is possible. (p. 1407)

Clients may choose to participate in private prayer or want group prayer with family, friends, or clergy (Figure 41-3 ■). In

such situations the nurse's responsibility is to ensure a quiet environment and privacy. Nursing care may need to be adjusted to accommodate periods for prayer. When it is assessed to be ethical and desired, the nurse who shares a belief in prayer may find praying with a client to be an inwardly powerful experience. Of course, a believing nurse can always pray privately for clients as many health care professionals do. Sometimes this “action” is all one can take in the presence of an otherwise powerless situation. See Practice Guidelines *Praying with Clients* for suggestions on how to pray with clients.

Referring Clients to Spiritual Care Experts

There are times when spiritual care is best referred to other members of the health care team. Referrals can be made for hospitalized clients and their families through the hospital chaplain's office if one is available. Nurses in home and community health settings can identify spiritual resources by checking directories of community service agencies, telephone directories, or religious directories that describe available spiritual counselors and the services provided through the religious community. Many religious counselors will provide assistance to members of their faith who are not members of their specific religious community. For example, a priest may attend a client in the hospital or at home even though the person is not a member of the priest's parish. Be sure to obtain a client's approval before initiating a referral. The client often will have a preferred spiritual care provider to contact.

Referrals may be necessary when the nurse makes a diagnosis of spiritual distress. In this situation the nurse and religious counselor can work together to meet the client's needs. One situation the nurse may encounter is client refusal of necessary medical intervention because of religious tenets. In this case the nurse encourages the client, primary care provider, and spiritual adviser to discuss the conflict and consider alternative methods of therapy. The nurse's major role is to provide information the client needs to make an informed decision and to support the client's decision.

Figure 41-3 ■ Family of a client praying together while holding hands. Asiaselects/Getty Images.

PRACTICE GUIDELINES

Praying with Clients

Sometimes a client may ask a nurse to pray. This request likely reflects the client's inner anxiety, isolation, confusion, or distress, and the yearning for comfort, peace, or understanding. When a client requests prayer, it is ethical to respond with a prayer that is mutually comfortable (Winslow & Wehtje-Winslow, 2007). However, if the client has not asked for prayer, the nurse must weigh whether an offer to pray with the client is appropriate (Taylor, 2012). Following are tips on praying with clients:

- To know if an offer of prayer is ethical, assess and follow client cues. A question that chaplains often use is: Would a prayer be helpful? Keep in mind the questions: Am I praying on a vulnerable client when I offer to pray with them? Am I abusing my powerful position as a nurse to impose what I think comforts?
- Assess for how and what the client would like you to pray. For example: Is there anything in particular for which you'd like me to pray? Is there a certain way of praying that you prefer? Most Americans who pray use a colloquial style of prayer that involves spontaneously expressing gratitude and/or needs to God. Listening to clients talk about their spirituality or religiosity will often inform you as to how to shape the prayer (e.g., to Whom the prayer is addressed).
- Be mindful of one difference between magic and prayer. Magic invokes a greater power for personal gain. Prayer allows the greater power to do the greater good ("Thy will be done").
- Nurses who are unaccustomed to praying aloud or in public may find it helpful to have a formal prayer or a scriptural passage readily available.
- Praying with a client may not involve verbalization. You may feel it will be more comfortable or appropriate if you remain quiet and fully present, praying silently.
- Because prayer can evoke deep feelings, the nurse may want to spend time with the client following a prayer to enable the client to express these feelings. Praying with a client may be a springboard for further discussion.
- Do not use prayer as a substitute for time; do not use prayer to stop a client from talking.
- Facilitate the clients' prayer practices. Schedule time for them when they will be undisturbed, palliate distressing symptoms that interfere with praying, help with articles that accompany prayers (e.g., rosaries, prayer garments, books of prayers), and so on.
- Remember that illness can interfere with some clients' ability to pray. Health challenges can also challenge one's beliefs about prayer and the power of the divine. Thus, to generically encourage a client to pray could potentially add to this sort of existing spiritual distress. A referral to a spiritual care expert who can support the client to reconstruct meaningful beliefs and learn helpful ways to think and practice prayer would be important for such a client.

Evidence-Based Practice Does Reading the Bible Help Clients to Self-Manage Their Stressful Life Events?

EVIDENCE-BASED PRACTICE

A qualitative study by Hamilton, Moore, Johnson, and Koenig (2013) of 54 older African Americans in the southeastern United States described how these individuals used Bible passages to cope with the loss of a loved one or a personal illness. Study methods included a one-time interview during which participants were asked open-ended questions about how they used the Bible to cope with negative moods. This recorded data was then transcribed and the content analyzed. The most common type of Bible passage informants relied on were those that depict God as a protector. Other types of Bible passages that helped included those that describe God as beneficent or as a healer, those that reminded the informant to praise and thank God, and those that placed the present

life in the bigger context with an afterlife void of suffering. "Relying on God's Word" was the sole strategy for many of these informants who were mostly retired, mostly Baptist, and mostly women living in the U.S. "Bible Belt."

IMPLICATIONS

Nurses can support older African Americans who are religious by determining what their favorite Bible passages are. The nurse can promote comfort by reading the passages when the client is unable to or forgetful. Likewise, a nurse can document the information and share it with other caregivers so those caregivers can provide this comfort when the client can no longer self-manage.

Evaluating

Just as there is a question regarding the appropriateness of using the prescriptive nursing process to frame spiritual care, caution is needed when discussing the evaluation of spiritual care. Does spiritually sensitive nursing care lead to observable and measurable client outcomes? If it does not, then is it unsuccessful or unimportant? And what outcomes indicating movement toward improved spiritual health are appropriate for nurses to consider? Indeed, Taylor (2007b) suggested that clinicians' spiritually healing responses often move a client *incrementally* toward spiritual healthiness. Nurses with theistic religious beliefs might add that a client's movement toward spiritual health is evidence of God's grace, and ultimately something that is not within the purview of any clinician or person. Given that many health care institutions require that spiritual care be documented in a nursing care plan, an example of how this is done is on pages 966–967.

SPIRITUAL SELF-AWARENESS FOR THE NURSE

Nurses cannot hear, never mind respond to, a client's spiritual need unless they hear and respond to their own need (Taylor, 2007b; Wright & Neuberger, 2012). Indeed, the notion that effective healers are "wounded healers" has long existed. A nurse's spiritual needs, pains, or woundedness can affect how he or she cares for clients. Nurses who are unaware of, afraid of, or misunderstand their spiritual needs will be very limited in their ability to accurately identify and explore a client's spiritual needs. When clients realize the nurse does not understand them they become quiet, change the topic, give superficial responses to queries, or in other ways indicate disinterest in continuing to talk about their spirituality.

Instead, the nurse can use his or her woundedness and spiritual self-awareness as a bridge or tool for healing communication. A

healing response requires recognizing a client’s innermost feelings. Awareness of one’s own deeper feelings—one’s own spiritual themes and inevitable woundedness—is requisite to being able to hear another’s. Thus, a nurse’s life story with its joys and hurts becomes a source of information for interpreting the client’s story.

Healers do not need to have shared the same *experiences* as have clients, but to be compassionate they do need to recognize how they have shared similar *emotions* (Taylor, 2007b). For example, a nurse may not be able to share with a client the extreme experience of losing a limb, but can likely identify times in life when he or she felt loss, anger, or bewilderment about why tragedy happens. Recognizing and addressing the fears that are inevitable responses to caring for clients (e.g., our own fear of dying or being hurt, our fear of hurting others, or of being overwhelmed by the pain of others) is an essential requisite to spiritual care.

Beckman, Boxley-Harges, Bruick-Sorge, and Salmon (2007) offered the following strategies for nurses who wish to increase their spiritual awareness so that it can impact client care positively:

- **Write a self-epitaph.** Sum up in a couple of lines what is significant about your life or how you would like to be remembered.

- **Explore personal end-of-life issues.** Imagine having a terminal diagnosis. What feelings would you have? What would be your priorities for the time and energy you had left?
- **Create a personal loss history.** Answer questions such as these: What was your first experience of death? What was the most recent or difficult death in your life? How did you cope? What is your coping style at times like this? How did you feel your grief?
- **List significant values.** Write down what possessions, individuals, activities, roles, personal attributes, and so forth, you prize most.
- **Conduct a spiritual self-assessment.** Consider what gives you strength and hope. What makes you joyful or despairing? How do you explain or relate to suffering? What is your sense of purpose or mission in life? What nurtures your spirit?

You may want to test out client spiritual assessment questions on yourself! Another aspect of a spiritual self-assessment is to reflect on what has influenced your spirituality most. How does the religion of your family affect you? How would you describe your spiritual “journey”? And importantly, how does your spirituality influence your vocation—your choosing to be a nurse?

Critical Thinking Checkpoint

Terry is a 32-year-old male who received several pints of blood following an automobile crash 10 years ago. Five years ago he was diagnosed with acquired immunodeficiency syndrome (AIDS) and is now in the hospital with pneumonia and severe diarrhea. He is very ill and very discouraged. While you are caring for Terry, he comments, “I might as well die right now because I’m not going to get well. My folks were Methodist, but I guess I’m being punished because I’m not very religious.”

1. Terry stated that he was “not very religious.” Does that mean that he is not spiritual? Explain.

2. What data suggest that Terry may be experiencing spiritual distress?
3. How might illness affect one’s spiritual beliefs? Religious beliefs?
4. How might a spiritual assessment be of benefit to both you and Terry?
5. What questions might be helpful to ask to further understand Terry?
6. What might you say to show Terry empathy?

See Critical Thinking Possibilities on student resource website.

NURSING CARE PLAN Spiritual Distress		
Assessment Data	Nursing Diagnosis	Desired Outcomes*
<p>Nursing Assessment Mrs. Chris Lee is a 51-year-old hospitalized homemaker who is recovering from a right radical mastectomy. Her primary care provider told her yesterday that due to metastases of the cancer, her prognosis is poor. This morning her nurse finds her tearful, stating she slept poorly and has no appetite. She asks the nurse, “Why has God done this to me?” Throughout the course of the ensuing conversation, the nurse hears Mrs. Lee ponder aloud, “Perhaps it’s because I have sinned in my life. I’ve not gone to church or spoken to a minister in several years. . . . Is there a chapel in the hospital where I could go and pray? . . . I’m terribly afraid of dying and what awaits me.”</p>	<p><i>Spiritual Distress</i> related to feelings of guilt and alienation from God as evidenced by questioning why “God has done this”; inquiries about praying in a chapel; insomnia; no appetite</p>	<p>Spiritual Health [2001] as evidenced by</p> <ul style="list-style-type: none"> • Interacts with spiritual leader of her religion. • Uses a type of spiritual experience that provides her comfort. • Connects with others to share thoughts, feelings, and beliefs.
<p>Physical Examination</p> <p>Height: 165.1 cm (5’5”) Weight: 54.0 kg (119 lb) Temperature: 36.6°C (98°F) Pulse: 88 beats/min Respirations: 22/min Blood Pressure: 146/86 mmHg</p> <p>Large surgical dressing right chest wall and axillary region, dry and intact. Slight edema right hand and arm.</p>	<p>Diagnostic Data</p> <p>RBC: 3.5 × 10⁶/mL Hgb: 10.5 g/L Hct: 35%</p>	

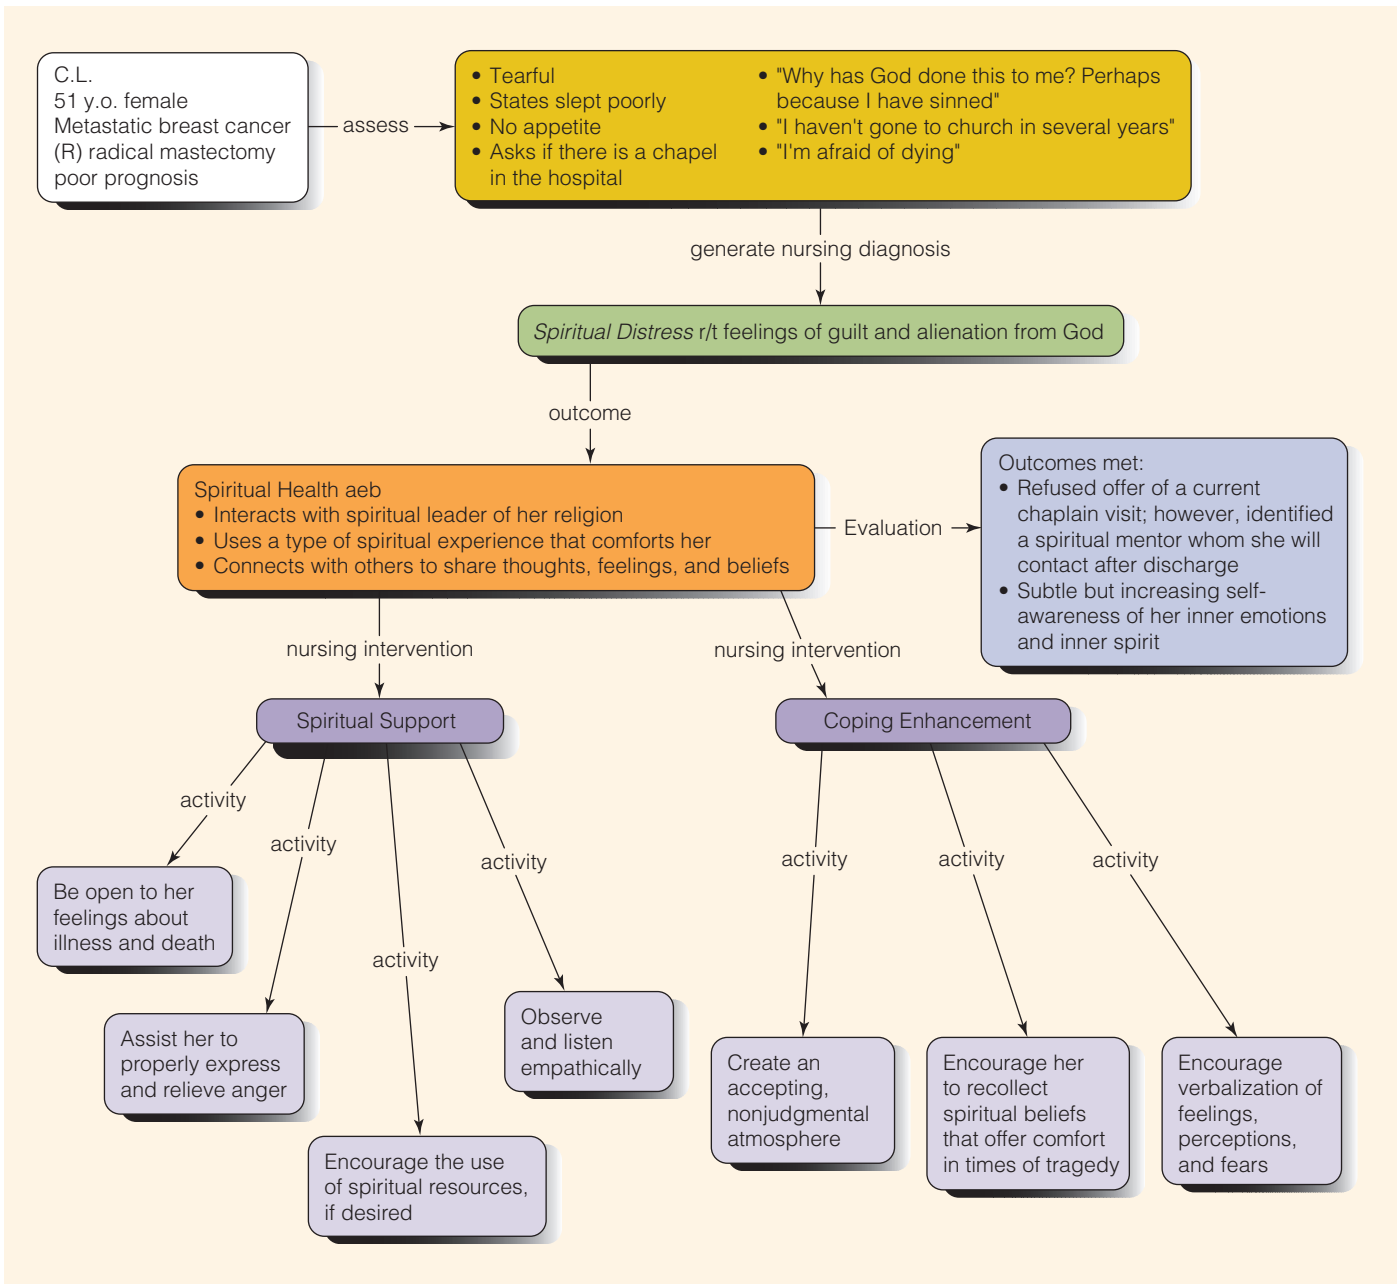

NURSING CARE PLAN Spiritual Distress—continued

Nursing Interventions*/Selected Activities	Rationale
<p>Spiritual Support [5420]</p> <p>Be open to Mrs. Lee's feelings about illness and death. Listen empathically.</p> <p>Assist her to properly express and relieve anger in appropriate ways.</p> <p>Encourage the use of spiritual resources, if desired.</p>	<p><i>Encourages expression of inner fears and concerns and teaches the client the value of confronting issues. Emotions often provide a window through which to peer at the inner workings of the human spirit.</i></p> <p><i>Anger can be a source of energy and its release a source of freedom when expressed in a constructive manner.</i></p> <p><i>Spiritual needs may sometimes be overlooked or ignored. Recognizing and respecting the individual's spiritual needs is an important advocacy role for nurses.</i></p>
<p>Coping Enhancement [5230]</p> <p>Create an accepting, nonjudgmental atmosphere.</p> <p>Encourage verbalization of feelings, perceptions, and fears. Allow time for grieving.</p> <p>Encourage her to recollect spiritual beliefs that offer comfort in times of tragedy.</p> <p>Several other nursing interventions may be appropriate for Mrs. Lee, such as:</p> <p>presence [5340], journaling [4740], hope inspiration [5310], meditation facilitation [5960], forgiveness facilitation [5280], guided imagery [6000], family support [7140], cultural brokerage (if, for example, her religious beliefs appeared to conflict with the health care system's) [7330], bibliotherapy [4680], art therapy [4330], active listening [4920], emotional support [5270], or consultation [7910].</p>	<p><i>Establishes rapport and the therapeutic relationship, which promotes communication and open expression.</i></p> <p><i>Being with the person who is suffering gives meaning to his or her experience.</i></p> <p><i>Spiritual beliefs often provide a framework for explaining tragedy and making sense of suffering.</i></p>
<p>Evaluation</p> <p>Although Mrs. Lee states she still is not satisfied with her hypotheses about why tragedy has struck, she has continued to verbally express her emotions of fear and anger related to a perception of abandonment by God. She has identified a spiritual mentor with whom she plans to discuss her theological questions after discharge. She refused an offer of a chaplain visit. Conversations that used empathy and active listening while Mrs. Lee talked about her spiritual crisis demonstrated her subtle yet increased self-awareness regarding inner emotions and movements of the inner spirit. In these ways, the outcomes were achieved.</p>	

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, indicators, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

CONCEPT MAP

Spiritual Distress

Chapter 41 Review

CHAPTER HIGHLIGHTS

- Clients have a right to receive care that respects their individual spiritual and religious values.
- The spiritual needs of clients and support people often come into focus at a time of illness. Spiritual beliefs can help people make sense of illness and cope with what lies ahead.
- Spiritual distress refers to a disturbance in or a challenge to a person's beliefs that provides strength, hope, and meaning to life. Possible factors in spiritual distress include physiological problems, treatment-related concerns, and situational concerns. Spiritual distress may be reflected in a number of behaviors, including depression, anxiety, verbalizations of unworthiness, and fear of death.
- Nurses must follow ethical guidelines for providing spiritual care, and not impose personal beliefs or practices on clients.
- Nurses can support clients' religious practices if they understand needs related to holy days, sacred texts, sacred symbols, prayer and meditation, dietary practices, dress requirements or prohibitions, healing, birth rituals, and death rituals.
- Spiritual assessment can follow a three-tiered approach. Initially, the nurse must determine if the client accepts a spiritual reality. For those who do, the next tier of questions should collect information not only about spiritual beliefs and practices affecting health, but also about how the client desires spiritual care from the health care team. Only those who manifest a spiritual need require a focused, in-depth assessment. Such an assessment may best be done by a chaplain or spiritual care expert.
- Nursing interventions that promote spiritual health include offering one's presence, conversing about spirituality, supporting the client's religious practices, empathic communication, assisting clients with prayer, and referring the client to a spiritual care expert.
- Nurses need to be aware of their own spiritual beliefs in order to be comfortable assisting others. When disclosing personal spiritual beliefs to a client, the nurse must first determine that the self-disclosure benefits the client rather than meeting the nurse's own personal needs.
- It is important for nurses to increase their own spiritual awareness in order to understand and respond to a client's spiritual needs.

TEST YOUR KNOWLEDGE

1. When planning care for an older client residing in your skilled nursing facility who is searching to make life meaningful, which nursing action would be most beneficial?
 1. Assess for depression.
 2. Diagnose and document that the client has "spiritual distress."
 3. Keep the client busy with social activities.
 4. Explore with the client desired legacy.
2. A client's wife asks the nurse to pray for her. What would be the best initial response for a nurse who believes in prayer?
 1. "May I call the chaplain to come and pray with you?"
 2. "I know your faith is important to you. It is to me, too. Let's pray."
 3. "I'm happy to do that. For what would you like me to pray?"
 4. "Isn't it wonderful that we have a God with whom we can share our concerns?"
3. A client is experiencing severe pain that cannot be controlled by analgesics. An appropriate intervention is full presencing, which involves which of the following?
 1. Physical presence
 2. Physical presence with mental awareness of the client
 3. Physical, mental, and emotional presence
 4. Physical, mental, emotional, and spiritual presence
4. A client reports, "Cancer was the best thing that happened to me! It is making me appreciate life so much more." This statement fits best with which NANDA diagnosis?
 1. *Spiritual Distress*
 2. *Risk for Spiritual Distress*
 3. *Readiness for Enhanced Spiritual Well-Being*
 4. *Cognitive Denial*
5. A dying client states, "Part of what makes dying hard is that I don't know for sure where I'm going. Nurse, what do you believe happens in the hereafter?" Which ethical guideline should guide your response?
 1. Never share personal spiritual beliefs.
 2. Share all spiritual beliefs, favoring none.
 3. Share only your beliefs.
 4. First assess for what prompts the client's question.
6. Research evidence that supports providing spiritual care to older adults suggests that
 1. Older adults are not very religious, but are very spiritual.
 2. Older adults who are more religious have more illness.
 3. Spiritual health and mental health are correlated.
 4. Increased spiritual well-being is found among older adults with depression.
7. A client in the emergency department needs a transfusion of red blood cells. The client tells the nurse that, as a Jehovah's Witness, blood transfusions are not permitted. Which statement would most likely lead to a resolution for this conflict?
 1. You must accept the transfusion or else leave.
 2. Don't worry, you can ask for pardon after taking the blood.
 3. May I please call a representative of your religion so that I can understand your position better?
 4. I understand your position; I'll be here with you as you die.
8. An 88-year-old woman has just been admitted to a skilled nursing facility. She tells the nurse that she has been a Sunday school teacher and volunteers for many of her church's projects. Which of the following NANDA diagnoses is most appropriate?
 1. *Risk for Spiritual Distress*
 2. *Risk for Impaired Religiosity*
 3. *Readiness for Enhanced Spiritual Well-Being*
 4. *Impaired Religiosity*

9. Which of the following thoughts made by a nurse illustrate a “wounded healer”?
1. “I didn’t need that much analgesic when I had abdominal surgery.”
 2. “No pain, no gain!”
 3. “If clients would choose a more positive attitude, they’d feel better.”
 4. “I felt scared when I had surgery; maybe this client feels similarly.”
10. The mother of a pediatric client states, “I can’t understand why God would allow this to happen to my innocent child!” Which NANDA diagnosis is most accurate?
1. *Spiritual Distress* related to search for meaning of child’s illness
 2. *Impaired Religiosity* related to anger at God
 3. *Ineffective Coping* related to anger
 4. *Risk for Spiritual Distress* related to threatened sense of hope

42 Stress and Coping

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Differentiate the concepts of stress as a stimulus, as a response, and as a transaction.
2. Describe the three stages of Selye's general adaptation syndrome.
3. Identify physiological, psychological, and cognitive indicators of stress.
4. Differentiate four levels of anxiety.
5. Identify behaviors related to specific ego defense mechanisms.
6. Discuss types of coping and coping strategies.
7. Identify essential aspects of assessing a client's stress and coping patterns.
8. Identify nursing diagnoses related to stress.
9. Describe interventions to help clients minimize and manage stress.

transactional stress theory, 974

INTRODUCTION

Stress is a universal phenomenon. All people experience it. Parents refer to the stress of raising children, working people talk of the stress of their jobs, and students at all levels talk of the stress of school. Stress can result from both positive and negative experiences. A bride preparing for her wedding, a graduate preparing to start a new job, and a husband concerned about caring for his wife and family following a diagnosis of cancer all experience stress reactions.

The concept of stress is important because it provides a way of understanding the person as a being who responds in totality (mind, body, and spirit) to a variety of changes that take place in daily life.

CONCEPT OF STRESS

Stress is a condition in which an individual experiences changes in the normal balanced state. A **stressor** is any event or stimulus that causes an individual to experience stress. When a person faces stressors, responses are referred to as *coping strategies*, *coping responses*, or *coping mechanisms*.

Sources of Stress

There are many sources of stress. They can be broadly classified as internal or external stressors, or developmental or situational stressors. *Internal stressors* originate within a person, for example, infection or feelings of depression. *External stressors* originate outside the individual, for example, a move to another city, a death in the family, or pressure from peers. *Developmental stressors* occur at predictable times throughout an individual's life (Table 42-1). *Situational stressors* are

unpredictable and may occur at any time during life. Situational stress may be positive or negative. Examples of situational stress include:

- Death of a family member
- Marriage or divorce
- Birth of a child
- New job
- Illness.

The degree to which any of these events has positive or negative effects depends to some extent on an individual's developmental stage. For example, the death of a parent may be more stressful for a 12-year-old than for a 40-year-old.

Effects of Stress

Stress can have physical, emotional, intellectual, social, and spiritual consequences. Usually the effects are mixed, because stress affects the whole person. Physically, stress can threaten a person's physiological homeostasis. Emotionally, stress can produce negative or nonconstructive feelings about the self. Intellectually, stress can influence a person's perceptual and problem-solving abilities. Socially, stress can alter a person's relationships with others. Spiritually, stress can challenge one's beliefs and values. Many health conditions have been linked to stress (Figure 42-1 ■).

MODELS OF STRESS

Models of stress assist nurses to predict stressors in a particular situation and to understand the individual's responses. Nurses can use these models to assist clients in strengthening healthy coping

TABLE 42-1 Selected Stressors Associated with Developmental Stages

Developmental Stage	Stressors
Child	Beginning school Establishing peer relationships Peer competition
Adolescent	Changing physique Relationships involving sexual attraction Exploring independence Choosing a career
Young adult	Marriage Leaving home Managing a home Getting started in an occupation Continuing one's education Children
Middle adult	Physical changes of aging Maintaining social status and standard of living Helping teenage children to become independent Aging parents
Older adult	Decreasing physical abilities and health Changes in residence Retirement and reduced income Death of spouse and friends

responses and in adjusting unhealthy, unproductive responses. Three main models of stress are stimulus based, response based, and transaction based.

Stimulus-Based Models

In **stimulus-based stress models**, stress is defined as a stimulus, a life event, or a set of circumstances that arouses physiological and/or psychological reactions that may increase the individual's vulnerability to illness. In their classic work, Holmes and Rahe (1967) assigned a numerical value to 43 life changes or events. The most recent version of the full scale includes 77 items (Miller & Rahe, 1997); a shortened version (54 items, full stress and coping inventory completed in 15 minutes) has been created even more recently (Rahe & Tolles, 2002). The scale of stressful life events is used to document a person's relatively recent experiences, such as divorce, pregnancy, and retirement. In this view, both positive and negative events are stressful.

Similar scales have since been developed, but all scales should be used with caution because the degree of stress an event presents is highly individual. A divorce may be highly traumatic to one person and cause relatively little anxiety to another. In addition, many scales have not been tested for sensitivity to age, socioeconomic status, or culture.

Response-Based Models

Stress may also be considered as a response. This definition was developed and described by Selye (1956, 1976) as "the nonspecific response of the body to any kind of demand made upon it" (1976, p. 1).

Selye's stress response is characterized by a chain or pattern of physiological events called the **general adaptation syndrome (GAS)** or *stress syndrome*. To differentiate the cause of stress from the response to stress, Selye (1976) used the term *stressor* to denote any factor that produces stress and disturbs the body's equilibrium. Stress can be observed only by the changes it produces in the body. This response of the body, the stress syndrome or GAS, occurs with the release of certain adaptive hormones and subsequent changes in the structure and chemical composition of the body. Parts of the body affected by stress are the gastrointestinal tract, the adrenal glands, and the lymphatic structures. With prolonged stress, deep ulcers appear in the lining of the stomach, the adrenal glands enlarge considerably, and the lymphatic structures, such as the thymus, spleen, and lymph nodes, atrophy (shrink).

Besides adapting globally, the body can also react locally; that is, one organ or a part of the body reacts alone. This is referred to as the **local adaptation syndrome (LAS)**. One example of the LAS is inflammation. Selye (1976) proposed that both the GAS and the LAS have three stages: alarm reaction, resistance, and exhaustion (Figure 42-2 ■).

ALARM REACTION

The initial reaction of the body is the **alarm reaction**, which alerts the body's defenses. Selye (1976) divided this stage into two parts: the shock phase and the countershock phase.

During the **shock phase** (Figure 42-2B), the stressor may be perceived consciously or unconsciously by the person. Stressors stimulate the sympathetic nervous system, which stimulates the hypothalamus. The hypothalamus releases corticotropin-releasing hormone, which stimulates the anterior pituitary gland to release adrenocorticotropic hormone. During times of stress, the adrenal medulla secretes epinephrine and norepinephrine in response to sympathetic stimulation. Significant body responses to epinephrine include the following:

1. Increased myocardial contractility, which increases cardiac output and blood flow to active muscles
2. Bronchial dilation, which allows increased oxygen intake
3. Increased blood clotting
4. Increased cellular metabolism
5. Increased fat mobilization to provide energy and to synthesize other compounds needed by the body.

The principal effect of norepinephrine is decreased blood to the kidneys and increased secretion of renin. Renin is an enzyme that hydrolyzes one of the blood proteins to produce angiotensin. Angiotensin increases the blood pressure by constricting arterioles. All of these adrenal hormonal effects permits the person to perform far more strenuous physical activity than would otherwise be possible. The person is then ready for "fight or flight." This primary response is short-lived, lasting from 1 minute to 24 hours.

The second part of the alarm reaction is called the **countershock phase**. During this time, the changes produced in the body during the shock phase are reversed. A person is best mobilized to react during the shock phase of the alarm reaction.

STAGE OF RESISTANCE

The second stage in the GAS and LAS syndromes, the **stage of resistance**, is when the body's adaptation takes place. In other

Figure 42-1 ■ Some disorders that can be caused or aggravated by stress.

words, the body attempts to cope with the stressor and to limit the stressor to the smallest area of the body that can deal with it.

STAGE OF EXHAUSTION

During the third stage, the **stage of exhaustion**, the adaptation that the body made during the second stage cannot be maintained. This means that the ways used to cope with the stressor have been exhausted. If adaptation has not overcome the stressor, the stress effects may spread to the entire body. At the end of this stage, the body may either rest and return to normal, or death may be the ultimate consequence. The end of this stage depends largely on the adaptive energy resources of the individual, the severity of the stressor, and the external adaptive resources provided, such as oxygen.

Transaction-Based Models

Transactional theories of stress are based on the work of Lazarus (1966), who stated that the stimulus theory and the response theory do not consider individual differences. Neither theory explains which factors lead some people and not others to respond effectively nor interprets why some people adapt for longer periods than others.

Although Lazarus (2006) recognizes that certain environmental demands and pressures produce stress in substantial numbers of people, he emphasizes that people and groups differ in their

sensitivity and vulnerability to certain types of events, as well as in their interpretations and reactions. In terms of illness, one person may respond with denial, another with anxiety, and still another with depression. To explain variations among individuals under comparable conditions, the Lazarus model considers cognitive processes that intervene between the encounter and the reaction, and the factors that affect the nature of this process. In contrast to Selye, who focuses on physiological responses, Lazarus includes mental and psychological components or responses as part of his concept of stress.

Lazarus's **transactional stress theory** encompasses a set of cognitive, affective, and adaptive (coping) responses that arise out of person–environment transactions. The person and the environment are inseparable; each affects and is affected by the other. Stress “refers to any event in which environmental demands, internal demands, or both tax or exceed the adaptive resources of an individual, social system, or tissue system” (Monat & Lazarus, 1991, p. 3). The individual responds to perceived environmental changes with adaptive or coping responses.

INDICATORS OF STRESS

Indicators of an individual's stress may be physiological, psychological, or cognitive.

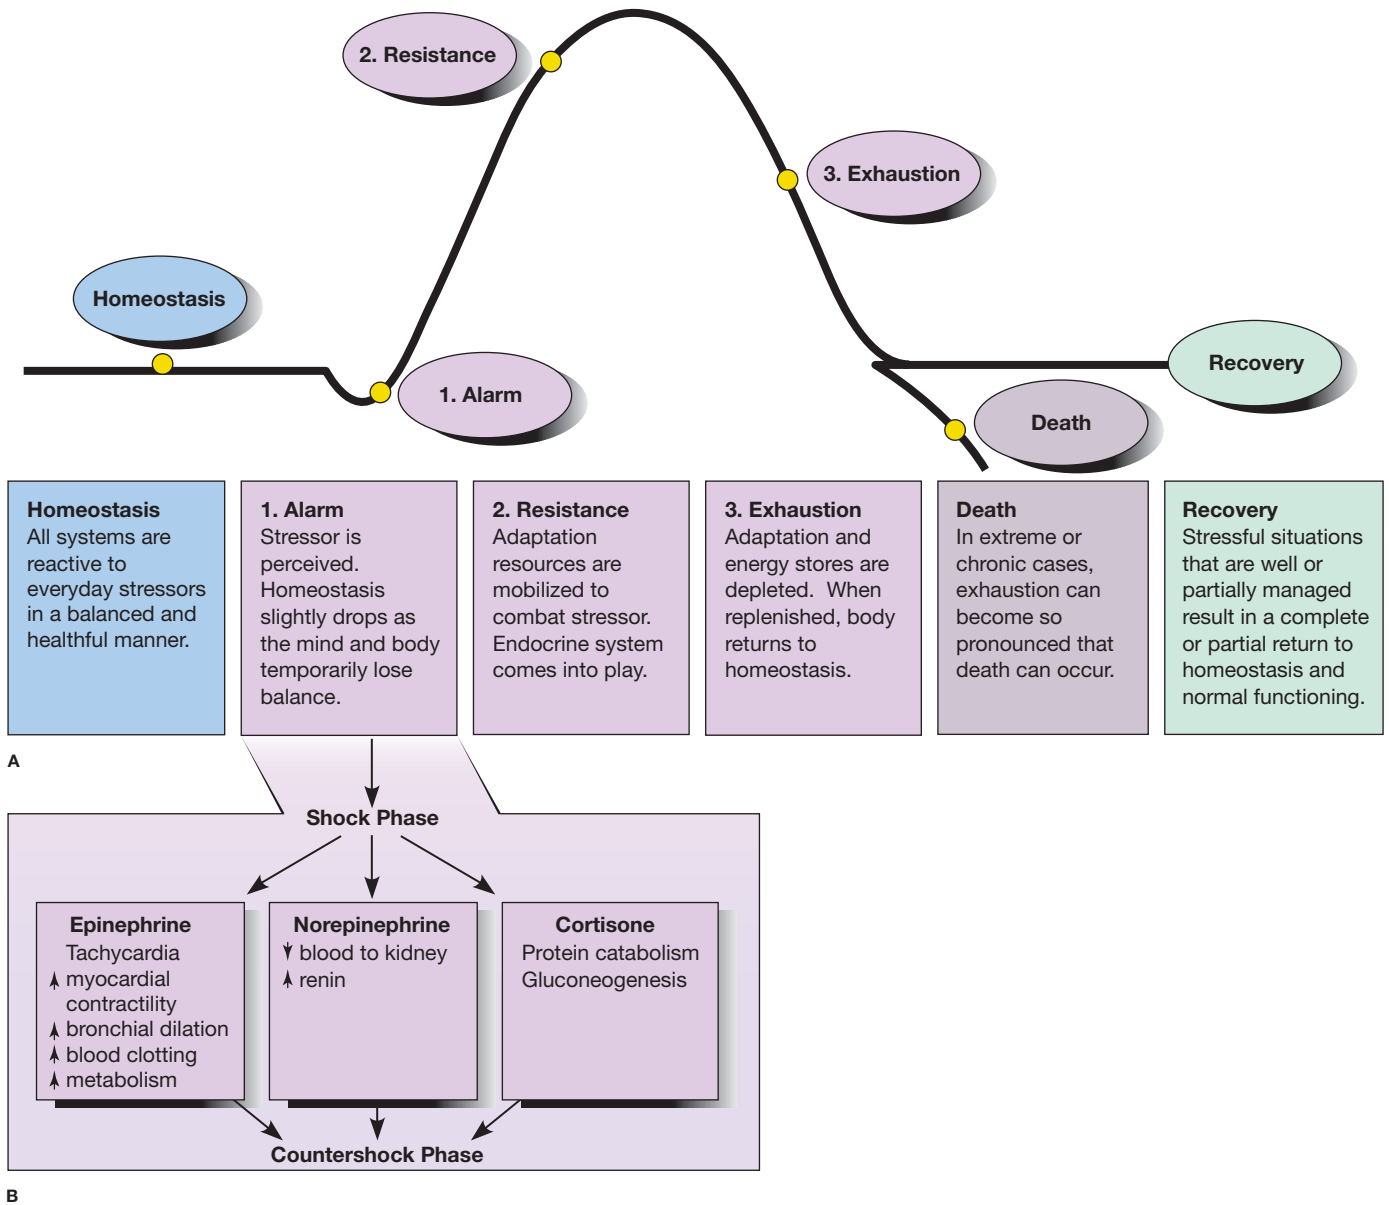

Figure 42-2 ■ The three stages of adaptation to stress: The alarm reaction, the stage of resistance, and the stage of exhaustion. Part A is from *Wellness: Concepts and Application*, 8th ed. (p. 310), by D. J. Anspaugh, M. Hamrick, and F. D. Rosato, 2011, New York, NY: McGraw-Hill. Reprinted with permission.

Physiological Indicators

Responses to stress vary depending on the individual's perception of events. The physiological signs and symptoms of stress result from activation of the sympathetic and neuroendocrine systems of the body. Clinical Manifestations lists physiological indicators of stress.

Psychological Indicators

Psychological manifestations of stress include anxiety, fear, anger, depression, and unconscious ego defense mechanisms. Some coping patterns are helpful; others are a hindrance, depending on the situation and the length of time they are used or experienced.

ANXIETY AND FEAR

A common reaction to stress is **anxiety**, a state of mental uneasiness, apprehension, dread, or foreboding or a feeling of helplessness related to an impending or anticipated unidentified threat to self or significant relationships. Anxiety can be experienced at the conscious,

subconscious, or unconscious level. A systematic review of international research studies indicates that anxiety disorders are very common (approximately 1 in every 14 individuals), although there are some cultural differences (Baxter, Scott, Vos, & Whiteford, 2013).

Anxiety may be manifested on four levels:

1. *Mild anxiety* produces a slight arousal that enhances perception, learning, and productive abilities. Most healthy people experience mild anxiety, perhaps as a feeling of mild restlessness that prompts a person to seek information and ask questions.
2. *Moderate anxiety* increases the arousal to a point where the person expresses feelings of tension, nervousness, or concern. Perceptual abilities are narrowed. Attention is focused more on a particular aspect of a situation than on peripheral activities.
3. *Severe anxiety* consumes most of the person's energies and requires intervention. Perception is further decreased. The person, unable to focus on what is really happening, focuses on only one detail of the situation generating the anxiety.

CLINICAL MANIFESTATIONS

Stress

- Pupils dilate to increase visual perception when serious threats to the body arise.
- Sweat production (diaphoresis) increases to control elevated body heat due to increased metabolism.
- Heart rate and cardiac output increase to transport nutrients and by-products of metabolism more efficiently.
- Skin is pallid because of constriction of peripheral blood vessels, an effect of norepinephrine.
- Sodium and water retention increase due to release of mineralocorticoids, which increases blood volume.
- Rate and depth of respirations increase because of dilation of the bronchioles, promoting hyperventilation.
- Urinary output decreases.
- Mouth may be dry.
- Peristalsis of the intestines decreases, resulting in possible constipation and flatus.
- For serious threats, mental alertness improves.
- Muscle tension increases to prepare for rapid motor activity or defense.
- Blood sugar increases because of release of glucocorticoids and gluconeogenesis.

4. *Panic* is an overpowering, frightening level of anxiety causing the person to lose control. It is less frequently experienced than other levels of anxiety. The perception of a panicked person can be affected to the degree that the person distorts events.

Table 42–2 lists indicators of these levels.

SELF-CARE ALERT

Mild or moderate anxiety motivates goal-directed behavior. In this sense, anxiety is an effective coping strategy. For example, mild anxiety motivates students to study. Excessive anxiety, however, often has destructive effects.

Fear is an emotion or feeling of apprehension aroused by impending or seeming danger, pain, or another perceived threat. The fear may be in response to something that has already occurred, in response to an immediate or current threat, or in response to something the person believes will happen. The nursing student may be fearful in anticipation of the first experience in a client care setting. The student may fear that the client will not want to be cared for by the student or that the student might inadvertently harm the client. The object of fear may or may not be based in reality.

Anxiety and fear differ in four ways:

- The source of anxiety may not be identifiable; the source of fear is identifiable.
- Anxiety is related to the future, that is, to an anticipated event. Fear is related to the past, present, and future.
- Anxiety is vague, whereas fear is definite.
- Anxiety results from psychological or emotional conflict; fear results from a specific physical or psychological entity.

ANGER

Anger is an emotional state consisting of a subjective feeling of animosity or strong displeasure. A verbal expression of anger can be a signal to others of one’s internal psychological discomfort and a call for assistance to deal with perceived stress. In contrast, hostility is usually marked by overt antagonism and harmful or destructive behavior; aggression is an unprovoked attack or a hostile, injurious, or destructive action or outlook; and violence is the exertion of physical force to injure or abuse. Verbally expressed anger differs from hostility, aggression, and violence, but it can lead to destructiveness and violence if the anger persists unabated.

A clearly expressed verbal communication of anger, when the angry person tells the other person about the anger and carefully identifies the source, is constructive. This clarity of communication

TABLE 42–2 Indicators of Levels of Anxiety

Category	Level of Anxiety			
	Mild	Moderate	Severe	Panic
Verbalization changes	Increased questioning	Voice tremors and pitch changes	Communication difficult to understand	Communication may not be understandable
Motor activity changes	Mild restlessness	Tremors, facial twitches, and shakiness	Increased motor activity, inability to relax	Increased motor activity, agitation
	Sleeplessness	Increased muscle tension	Fearful facial expression	Unpredictable responses
Perception and attention changes	Feelings of increased arousal and alertness	Narrowed focus of attention	Inability to focus or concentrate	Trembling, poor motor coordination
		Able to focus but selectively inattentive	Easily distracted	Perception distorted or exaggerated
	Uses learning to adapt	Learning slightly impaired	Learning severely impaired	Unable to learn or function
Respiratory and circulatory changes	None	Slightly increased respiratory and heart rates	Tachycardia, hyperventilation	Dyspnea, palpitations, choking, chest pain, or pressure
Other changes	None	Mild gastric symptoms (e.g., “butterflies in the stomach”)	Headache, dizziness, nausea	Feeling of impending doom Paresthesia, sweating

Source: Based on *Contemporary Psychiatric–Mental Health Nursing*, 3rd ed., by C. R. Kneisl and E. Trigoboff, 2013, Upper Saddle River, NJ: Pearson Education.

gets the anger out into the open so the other person can deal with it and help to alleviate it. The angry person “gets it off the chest” and prevents an emotional buildup.

DEPRESSION

Depression is a common reaction to events that seem overwhelming or negative. **Depression**, an extreme feeling of sadness, despair, dejection, lack of worth, or emptiness, affects millions of Americans a year. The signs and symptoms of depression and the severity of the problem vary with the client and the significance of the precipitating event. Emotional symptoms can include feelings of tiredness, sadness, emptiness, or numbness. Behavioral signs of depression include irritability, inability to concentrate, difficulty making decisions, loss of sexual desire, crying, sleep disturbance, and social withdrawal. Physical signs of depression may include loss of appetite, weight loss, constipation, headache, and dizziness. Many people experience short periods of depression in response to overwhelming stressful events, such as the death of a loved one or loss of a job; prolonged depression, however, is a cause for concern and may require treatment.

EGO DEFENSE MECHANISMS

Ego defense mechanisms are unconscious psychological adaptive mechanisms or, according to Anna Freud (1967), mental mechanisms that develop as the personality attempts to defend itself, establish compromises among conflicting impulses, and calm inner tensions. Defense mechanisms are the unconscious mind working to protect the person from anxiety. They can be precursors to conscious cognitive coping mechanisms that will ultimately solve the problem. Like some verbal and motor responses, defense mechanisms release tension. Table 42–3 describes these mechanisms and lists examples of their adaptive and maladaptive use.

Cognitive Indicators

Cognitive indicators of stress are thinking responses that include problem solving, structuring, self-control or self-discipline, suppression, and fantasy. *Problem solving* involves thinking through the threatening situation, using specific steps to arrive at a solution. The person assesses the situation or problem, analyzes or defines it, chooses alternatives, carries out the selected alternative, and evaluates whether the solution succeeded.

TABLE 42–3 Defense Mechanisms

Name	Definition	Example
Denial	Blocking out painful or anxiety-inducing events or feelings	A manager tells an employee he may have to fire him. On the way home, the employee shops for a new car.
Displacement	Discharging pent-up feelings on people less dangerous than those who initially aroused the emotion	A student who has received a low grade on a term paper blows up at his girlfriend when she asks about his grade.
Dissociation	Handling emotional conflicts, or internal or external stressors, by a temporary alteration of consciousness or identity	A woman has amnesia for the events surrounding a fatal automobile accident in which she was the speeding driver.
Fantasy	Symbolic satisfaction of wishes through nonrational thought	A student struggling through graduate school thinks about a prestigious, high-paying job she wants.
Identification	Unconscious assumption of similarity between oneself and another	After hospitalization for minor surgery, a girl decides to become a nurse.
Intellectualization	Separating an emotion from an idea or thought because the emotional reaction is too painful to be acknowledged	A man learns from his doctor that he has cancer. He studies the physiology and treatment of cancer without experiencing any emotion.
Introjection	Acceptance of another's values and opinions as one's own	A woman who prefers a simple lifestyle assumes the materialistic, prestige-oriented values of her husband.
Projection	Attributing one's own unacceptable feelings and thoughts to others	A man who is quite critical of others thinks that people are joking about his appearance.
Rationalization	Falsification of experience through the construction of logical or socially approved explanations of behavior	A man cheats on his income tax return and tells himself it's alright because everyone does it.
Reaction formation	Unacceptable feelings disguised by repression of the real feeling and by reinforcement of the opposite feeling	A woman who dislikes her mother-in-law is always very nice to her.
Regression	Reverting to an earlier stage of development	A man exposes his genitalia to women he sees in public places.
Repression	Unconsciously keeping unacceptable feelings out of awareness	A man is jealous of a good friend's success but is unaware of his feelings.
Suppression	Consciously keeping unacceptable feelings and thoughts out of awareness	A student taking an examination is upset about an argument with her boyfriend, but deliberately puts it out of her mind so she can finish the test.
Undoing	Attempting to take back an unconscious thought or behavior that is unacceptable or hurtful	A young woman realizes that she has just insulted her boyfriend and spends the rest of the evening complimenting him on his looks and his athletic ability.

From "Stress, Anxiety, and Coping," by C. R. Kneisl. In C. R. Kneisl & E. Trigoboff, *Contemporary Psychiatric–Mental Health Nursing*, 3rd ed. (p. 153), 2013, Upper Saddle River, NJ: Pearson. Reprinted with permission.

Structuring is the arrangement or manipulation of a situation so threatening events do not occur. For example, a nurse can structure or control an interview with a client by asking only direct, closed questions so the client will not wander into areas that may be stressful. Structuring can be productive in certain situations. A person who schedules a dental examination semiannually to prevent severe dental disease is using productive structuring.

Self-control (discipline) is assuming a manner and facial expression that convey a sense of being in control or in charge. When self-control prevents panic and harmful or nonproductive actions in a threatening situation, it is a helpful response that conveys strength. Self-control carried to an extreme, however, can delay problem solving and prevent a person from receiving the support of others, who may perceive the person as handling the situation well, as cold, or as unconcerned.

Suppression is consciously and willfully putting a thought or feeling out of mind: “I won’t deal with that today. I’ll do it tomorrow.” This response relieves stress temporarily but does not solve the problem. A man who keeps ignoring a toothache, pushing it out of his mind because he fears the pain of having a filling, will not obtain relief of his symptoms.

Fantasy or daydreaming is likened to make-believe. Unfulfilled wishes and desires are imagined as fulfilled, or a threatening experience is reworked or replayed so it ends differently from reality. Experiences can be relived, everyday problems solved, and plans for the future made. The outcome of current problems may also be fantasized. For example, a client awaiting the results of a breast biopsy may fantasize the surgeon as saying, “You do not have cancer.” Fantasy responses can be helpful if they lead to problem solving. For example, the client awaiting breast biopsy results might say to herself, “Even if the doctor says, ‘You have cancer,’ as long as he also says it can be treated, I can accept that.” Fantasies can be destructive and nonproductive if a person uses them to excess and retreats from reality.

COPING

Coping may be described as dealing with change—successfully or unsuccessfully. A **coping strategy (coping mechanism)** is a natural or learned way of responding to a changing environment or specific problem or situation. According to Folkman and Lazarus (1991), coping is “the cognitive and behavioral effort to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person” (p. 210).

Two types of coping strategies have been described: problem focused and emotion focused. *Problem-focused coping* refers to efforts to improve a situation by making changes or taking action. *Emotion-focused coping* includes thoughts and actions that relieve emotional distress. Emotion-focused coping does not improve the situation, but the person often feels better. Both types of strategies usually occur together (Lazarus, 2006).

Coping strategies are also viewed as long term or short term. *Long-term coping strategies* can be constructive and practical. In certain situations, talking with others and trying to find out more about the situation are long-term strategies. Other long-term strategies include a change in lifestyle patterns such as eating a healthy diet, exercising regularly, balancing leisure time with working, or using problem solving in decision making instead of anger or other nonconstructive responses.

Short-term coping strategies can reduce stress to a tolerable limit temporarily but are ineffective ways to permanently deal with reality. They may even have a destructive or detrimental effect on the person.

Examples of short-term strategies are using alcoholic beverages or drugs, daydreaming and fantasizing, relying on the belief that everything will work out, and giving in to others to avoid anger.

Coping strategies vary among individuals and are often related to the individual’s perception of the stressful event. Three approaches to coping with stress are to alter the stressor, adapt to the stressor, or avoid the stressor. A person’s coping strategies often change with a re-appraisal of a situation. There is never only one way to cope. Some people choose avoidance; others confront a situation to cope. Still others seek information or rely on religious beliefs.

Coping can be adaptive or maladaptive. *Adaptive coping* helps the person to deal effectively with stressful events and minimizes distress associated with them. *Maladaptive coping* can cause unnecessary distress for the person and others associated with the person or stressful event. In nursing literature, effective and ineffective coping are often differentiated. *Effective coping* results in adaptation; *ineffective coping* results in maladaptation.

Although the coping behavior may not always seem appropriate, the nurse needs to remember that coping is always purposeful. The effectiveness of an individual’s coping is influenced by several factors, including:

- The number, duration, and intensity of the stressors
- Past experiences of the individual
- Support systems available to the individual
- Personal qualities of the person.

If the duration of the stressors is extended beyond the coping powers of the individual, that person becomes exhausted and may develop increased susceptibility to health problems. Reaction to long-term stress is seen in family members who undertake the care of a person in the home for a long period. This stress is called **caregiver burden** and produces responses such as chronic fatigue, sleeping difficulties, and high blood pressure. In the case of caregiver burden, the caregiver also becomes the nurse’s client and a care plan to intervene should be created (Wells & Cagle, 2011). Prolonged stress can also result in mental illness. As coping strategies or defense mechanisms become ineffective, the individual may have interpersonal problems, work difficulties, and a significant decrease in the ability to meet basic human needs (Table 42–4).

TABLE 42–4 Examples of the Negative Effects of Stress on Basic Human Needs

Needs	Effects
Physiological	Altered elimination pattern Change in appetite Altered sleep pattern
Safety and security	Expresses nervousness and feelings of being threatened Focuses on stressors, inattention to safety measures
Love and belonging	Isolated and withdrawn Becomes overly dependent Blames others for own problems
Self-esteem	Fails to socialize with others Becomes a workaholic Draws attention to self
Self-actualization	Preoccupied with own problems Shows lack of control Unable to accept reality

●○○ NURSING MANAGEMENT

Assessing

Nursing assessment of a client's stress and coping patterns includes (a) nursing history and (b) physical examination of the client for indicators of stress (e.g., nail biting, nervousness, weight changes) or stress-related health problems (e.g., hypertension, dyspnea). When obtaining the nursing history, the nurse poses questions about client-perceived stressors or stressful incidents, manifestations of stress, and past and present coping strategies. During the physical examination, the nurse observes for verbal, motor, cognitive, or other physical manifestations of stress. Remember, however, that clinical signs and symptoms may not occur when cognitive coping is effective.

In addition, the nurse should be aware of expected developmental transitions (predictable tasks that must be accomplished if the person is to grow psychologically as well as physically; see Chapters 20 to 23 ∞). Individuals go through different developmental stages from infancy to old age when certain tasks are expected to be completed or resolved. When these tasks are carried over and not resolved, stress increases as they become older. For example, if an infant does not learn to trust those around him during infancy, this mistrust may accompany him through life, influencing his relationships and possibly being the root of dysfunction, stress, and ineffective coping. This knowledge helps the nurse identify additional stressors and the

client's response to them (see Table 42–1). Questions to elicit data about the client's stress and coping patterns are shown in the accompanying Assessment Interview.

Diagnosing

NANDA International (Herdman & Kamitsuru, 2014) diagnostic labels related to stress, adaptation, and coping include (in alphabetical order):

- **Anxiety:** Vague, uneasy feeling of discomfort or dread accompanied by an autonomic response (the source often nonspecific or unknown to the individual); a feeling of apprehension caused by the anticipation of danger. It is an alerting signal that warns of impending danger and enables the individual to take measures to deal with a threat.
- **Caregiver Role Strain:** Difficulty in performing the family caregiver role.
- **Compromised Family Coping:** A usually supportive primary person (family member or close friend) provides insufficient, ineffective, or compromised support, comfort, assistance, or encouragement that may be needed by the client to manage or master adaptive tasks related to his or her health challenge.
- **Defensive Coping:** Repeated projection of falsely positive self-evaluation based on a self-protective pattern that defends against underlying perceived threats to positive self-regard.

ASSESSMENT INTERVIEW Stress and Coping Patterns

- On a scale of 1 to 10, where 1 is “very minor” and 10 is “extreme,” how would you rate the stress you are experiencing in the following areas?
 - Home
 - Work or school
 - Finance
 - Recent illness or loss of loved one
 - Your health
 - Family responsibilities
 - Relationships with friends
 - Relationship with parents or children
 - Relationship with partner
 - Recent hospitalization
 - Other (specify)
- How long have you been dealing with these stressors?
- How do you usually handle stressful situations? If the client does not adequately describe, prompt with the following:
 - Cry
 - Get angry
 - Talk to someone (Who?)
 - Withdraw from the situation
 - Control others or situation
 - Go for a walk or perform physical exercise
 - Try to arrive at a solution
 - Pray
 - Laugh, joke, or use some other expression of humor
 - Meditate or use some other relaxation technique such as yoga or guided imagery
- How well does your usual coping strategy work?

Evidence-Based Practice What Coping Strategies Are Used by Nurses Working in Dialysis Units?

EVIDENCE-BASED PRACTICE

Care of clients who have end-stage renal disease and require hemodialysis can be highly stressful because the clients are extremely ill, the treatment can be complicated, and emergencies frequently occur during treatments. The purpose of this pilot study by Ashker, Penprase, and Salman (2012) was to identify and describe work-related emotional stressors that affect the well-being of nurses working in hemodialysis units and to identify their coping techniques. Nineteen participants from six hemodialysis centers completed the Ways of Coping Questionnaire, a 66-item survey. Findings revealed that participants' most frequently used ways of coping were problem solving (action directed toward altering the actual stressful situation), followed by self-control, positive thinking, and seeking social support when dealing with work-related stressors. Often, more than one of these methods was used in

combination. These findings are consistent with the theoretical perspectives of Lazarus and Folkman.

IMPLICATIONS

Although this was a pilot study with a small number of participants, the results do not indicate significant differences in the coping strategies of dialysis nurses as compared to other populations of nurses that have been studied in larger numbers. The most common coping strategies used by these nurses are ones that support a positive resolution of stress (whereas strategies such as confrontation, distancing, and escape/avoidance would have been maladaptive). Nurses should consider both the degree of stress they are likely to experience in different care settings and their own ability to manage stress when selecting their work environment.

- **Disabled Family Coping:** Behavior of significant individual (family member or other primary person) that disables his or her capacities and the client's capacities to effectively address tasks essential to either person's adaptation to the health challenge.
- **Ineffective Coping:** Inability to form a valid appraisal of the stressors, inadequate choices of practiced responses, and/or inability to use resources.
- **Ineffective Denial:** Conscious or unconscious attempt to disavow the knowledge or meaning of an event to reduce anxiety/fear, but leading to the detriment of health.
- **Post-Trauma Syndrome:** Sustained maladaptive response to a traumatic, overwhelming event.
- **Relocation Stress Syndrome:** Physiological and/or psychosocial disturbance following transfer from one environment to another.

Planning

The nurse develops plans in collaboration with the client and significant support people when possible, according to the client's state of health (e.g., ability to return to work), level of anxiety, support resources, coping mechanisms, and sociocultural and religious affiliation. The nurse with little experience intervening with clients undergoing stress may wish to consult with a more experienced nurse to develop effective plans. The nurse and client set goals to change the existing client responses to the stressor or stressors.

The overall client goals for individuals experiencing stress-related responses are to:

- Decrease or resolve anxiety.
- Increase ability to manage or cope with stressful events or circumstances.
- Improve role performance.

A sample nursing care plan and a concept map with NIC interventions and selected activities are shown on pages 984–985.

Planning for Home Care

Clients hospitalized and experiencing stress may require ongoing nursing support or referral to community agencies that can provide support to meet client needs and enhance client coping. Determining how much and what type of planning and home care follow-up is needed is based in great part on the nurse's knowledge of how the client and family have coped with previous stressors and the nature

of the present stressor. Home Care Assessment describes data to be gathered for home care or follow-up assessment.

Implementing

Although stress is part of daily life, it is also highly individual; a situation that to one person is a major stressor may not affect another. Some methods to help reduce stress will be effective for one person; other methods will be appropriate for a different person. A nurse who is sensitive to clients' needs and reactions can choose those methods of intervention that will be most effective for each individual.

Encouraging Health Promotion Strategies

Several health promotion strategies are often appropriate as interventions for clients with stress-related nursing diagnoses. Among these are physical exercise, optimal nutrition, adequate rest and sleep, and time management.

Exercise

Regular exercise promotes both physical and emotional health. Physiological benefits include improved muscle tone, increased cardiopulmonary function, and weight control. Psychological benefits include relief of tension, a feeling of well-being, and relaxation. Federal guidelines recommend 150 minutes of moderate-intensity weekly exercise for adults (U.S. Department of Health and Human Services, 2008).

Nutrition

Optimal nutrition is essential for health and in increasing the body's resistance to stress. To minimize the negative effects of stress (e.g., irritability, hyperactivity, anxiety), people need to avoid excesses of caffeine, salt, sugar, and fat, and deficiencies in vitamins and minerals. Guidelines for a well-balanced, healthy diet are detailed in Chapter 47 .

CLINICAL ALERT!

Many individuals have "comfort foods"—foods they like to eat that make them feel better emotionally. These should be allowed whenever they are not contraindicated by the person's health condition.

Sleep

Sleep restores the body's energy levels and is an essential aspect of stress management. To ensure adequate sleep, clients may need help

Home Care Assessment Stress and Coping

PATIENT-CENTERED CARE

CLIENT

- **Knowledge:** client's understanding of the nature of the stressors
- **Current coping strategies:** effectiveness of current coping strategies and willingness to learn new stress management techniques
- **Self-care abilities:** physical, emotional, social, and financial ability to minimize associated stressors
- **Role expectations:** client's perception of the need to return to prior roles and possible stressors associated with these roles

FAMILY

- **Knowledge:** family members' and significant others' understanding of the nature of the client's stressors and their own relationship with client stressors

- **Family coping strategies:** effectiveness of family members' and significant others' coping strategies and willingness to learn new stress management techniques
- **Role expectations:** family members' and significant others' perception of the need for the client to return to family and work roles
- **Availability and skills of support people:** family members' and significant others' sensitivity to the client's emotional and physical needs and ability to provide a supportive environment

COMMUNITY

- **Resources:** availability of and familiarity with possible sources of assistance for stress management such as massage therapists, religious or spiritual centers, physical care providers, support groups, and so on

to attain comfort (such as pain management) and to learn techniques that promote peace of mind and relaxation. (See the *Using Relaxation Techniques* section below.)

Time Management

People who manage their time effectively usually experience less stress because they feel more in control of their circumstances. Clients who feel overwhelmed often need help to prioritize tasks and to consider whether modifications can be made to decrease role demands. Working parents, for example, may need to consider delegating tasks to family members or hiring part-time help. Controlling the demands of others is also an important aspect of effective time management because requests made by others cannot always be met. Clients may need to learn to develop an awareness of which requests they can meet without undue stress, which ones can be negotiated, and which ones need to be declined. Feelings of control can be enhanced when clients schedule a daily or weekly period of time to deal with specific tasks. Time management must address both what is important to the client and what can realistically be achieved. For example, clients need to consider whether a clean house and time spent with the children can both be accomplished satisfactorily and, if not, which is more important. Clients feeling overwhelmed need to reexamine the “should do,” “ought to do,” and “must do” situations in their lives and develop realistic self-expectations.

Minimizing Anxiety

Nurses carry out measures to minimize clients’ anxiety and stress. For example, nurses encourage clients to take deep breaths before an injection, explain procedures before they are implemented including sensations likely to be experienced during the procedure, administer a massage to help the client relax, and offer support to clients and families during times of illness. The nurse recognizes that quick action may be necessary to avoid the contagious nature of anxiety. That is, the anxious feeling of one person makes others around him or her also anxious. This can include family members, other clients nearby, or health care providers. General guidelines for helping clients who are stressed and feeling anxious are outlined in Box 42–1.

Mediating Anger

Often nurses find clients’ anger difficult to handle. Caring for the client who is angry is difficult for two reasons:

- Clients seldom state, “I feel angry or frustrated,” or indicate the reason for their anger. Instead, they may refuse treatment, become verbally abusive or demanding, threaten violence, or become overly critical. Their complaints rarely reflect the cause of their anger.
- Anger from clients can elicit fear and anger in the nurse, who may respond in a manner that intensifies the client’s anger, even to the point of violence. Nurses respond in a way that reduces their own stress rather than the client’s stress.

Delaune (2013) recommends the following strategies for dealing with clients’ anger:

- Remember that there is a difference between anger (a subjective feeling) and aggression (a harmful behavior).
- Approach each client with a calm, reassuring manner. This will help the client feel less threatened and more secure.

BOX 42–1 Minimizing Stress and Anxiety

- Listen attentively; try to understand the client’s perspective on the situation.
- Provide an atmosphere of warmth and trust; convey a sense of caring and empathy.
- Determine if it is appropriate to encourage clients’ participation in the plan of care; give them choices about some aspects of care but do not overwhelm them with choices.
- Stay with clients as needed to promote safety and feelings of security and to reduce fear.
- Control the environment to minimize additional stressors such as reducing noise, limiting the number of individuals in the room, and providing care by the same nurse as much as possible.
- Implement suicide precautions if indicated.
- Communicate in short, clear sentences.
- Help clients to:
 - a. Determine situations that precipitate anxiety and identify signs of anxiety.
 - b. Verbalize feelings, perceptions, and fears as appropriate. Some cultures discourage the expression of feelings.
 - c. Identify personal strengths.
 - d. Recognize usual coping patterns and differentiate positive from negative coping mechanisms.
 - e. Identify new strategies for managing stress (e.g., exercise, massage, progressive relaxation).
 - f. Identify available support systems.
- Teach clients about:
 - a. The importance of adequate exercise, a balanced diet, and rest and sleep to energize the body and enhance coping abilities.
 - b. Support groups available such as Alcoholics Anonymous, Weight Watchers or Overeaters Anonymous, and parenting and child abuse support groups.
 - c. Educational programs available such as time management, assertiveness training, and meditation groups.
- Involve clients in their own care as much as possible. This will increase their sense of control, which helps decrease anger.
- When a client’s aggression is escalating, you must protect the safety of that client, other clients, yourself, and other staff.
- Call for help immediately if your interventions have not de-escalated the client’s aggressive behavior.

SAFETY ALERT!

SAFETY

A nurse who is concerned for his or her own safety while working with an angry client should withdraw from the situation or obtain support from another individual.

Using Relaxation Techniques

Several relaxation techniques can be used to quiet the mind, release tension, and counteract the fight-or-flight responses of GAS discussed earlier in this chapter. Nurses can teach these techniques to clients. Nurses should also encourage clients to use these techniques when they encounter stressful health situations. Examples of these situations are (a) during childbirth, (b) postoperatively to cope with pain, and (c) before and during a painful procedure. Many agencies now have relaxation tapes available that the client can borrow or purchase. Some clients make their own recordings. Specific

relaxation techniques are discussed in Chapter 19 ∞ and include the following:

- Breathing exercises
- Massage
- Progressive relaxation
- Imagery
- Biofeedback
- Yoga
- Meditation
- Therapeutic touch
- Music therapy
- Humor and laughter.

Crisis Intervention

A *crisis* is an acute, time-limited state of disequilibrium resulting from situational, developmental, or societal sources of stress. A person in crisis is temporarily unable to cope with or adapt to the stressor by using previous methods of problem solving. People in crisis generally have a distorted perception of the event and do not have adequate situational support or coping mechanisms. Common characteristics of crises are shown in Box 42–2.

Crisis intervention is a short-term helping process of assisting clients to (a) work through a crisis to its resolution and (b) restore their precrisis level of functioning. It is a process that includes not only the client in crisis but also various members of the client's support network. Crisis intervention is not the specialty of any one professional group. People who intervene in crises come from the fields of nursing, medicine, psychology, social work, and theology. Police officers, teachers, school guidance counselors, and rescue workers, among others, are often on the spot in moments of crisis.

Because a state of disequilibrium is so uncomfortable, a crisis is self-limiting. However, a person experiencing a crisis alone is more vulnerable to unsuccessful negotiation than is a person working through a crisis with help. Working with another person increases the likelihood that the person in crisis will resolve it in a positive way. Often a state of crisis offers the individual or family potential for growth and change.

BOX 42–2 Common Characteristics of Crises

- All crises are experienced as sudden. The person is usually not aware of a warning signal, even if others could “see it coming.” The individual or family members may feel that they had little or no preparation for the event or trauma.
- The crisis is often experienced as life threatening, whether this perception is realistic or not.
- Communication with significant others is often decreased or cut off.
- There may be perceived or real displacement from familiar surroundings or loved ones.

All crises have an aspect of loss, whether actual or perceived. The losses can include an object, a person, a hope, a dream, or any significant factor for that individual.

The traditional steps of the nursing process correspond closely to the steps of crisis intervention. In assessment, the nurse or helper must focus on the person and the problem, collecting data about the client, the client's coping style, the precipitating event, the situational supports, the client's perception of the crisis, and the client's ability to handle the problem. This information is the basis for later decisions about how and when to intervene and whom to call. An individual's perception of the event and personal response will determine the nursing diagnoses. The most common nursing diagnoses for people in crisis are similar to those cited earlier in this chapter. In addition, diagnoses such as *Risk for Self-Directed Violence*, *Risk for Other-Directed Violence*, *Rape-Trauma Syndrome*, and *Hopelessness* may be appropriate.

Effective planning for crisis intervention must be based on careful assessment and developed in active collaboration with the person in crisis and the significant people in that person's life.

Implementation involves crisis counseling and home crisis visits. Crisis counseling focuses on solving immediate problems and it involves individuals, groups, or families. Crisis intervention centers rely heavily on telephone counseling by volunteers who have professional consultation available to them. Also known as hotlines and often available around the clock, they allow callers to remain anonymous. The volunteers usually work within a protocol that indicates what information they need from the client to assess the crisis. Their goal is to plan steps to provide immediate relief and then long-term follow-up if necessary.

Crisis home visits are made when telephone counseling does not suffice or when the crisis workers need to obtain additional information by direct observation or to reach a client who is unobtainable by telephone. Home visits are appropriate when crisis workers need to initiate contact rather than waiting for clients to come to them; for example, when a telephone caller is assessed to be highly suicidal or when a concerned neighbor, primary care provider, or clergy member informs the agency of clients in potential crisis.

Stress Management for Nurses

Nurses, like clients, are susceptible to experiencing anxiety and stress. Nursing practice involves many stressors related to both clients and the work environment—understaffing, increasing severity of client illnesses, adjusting to various work shifts, being expected to assume responsibilities for which one is not prepared, inadequate support from supervisors and peers, visiting homes that are depressing, caring for dying clients, and so on. Although most nurses cope effectively with the physical and emotional demands of nursing, in some situations nurses become overwhelmed and develop **burnout**, a complex syndrome of behaviors that can be likened to the exhaustion stage of the general adaptation syndrome. The nurse with burnout manifests physical and emotional depletion, a negative attitude and self-concept, and feelings of helplessness and hopelessness.

Nurses can prevent burnout by using the techniques to manage stress discussed for clients. Nurses must first recognize their stress and become attuned to such responses as feelings of being overwhelmed, fatigue, angry outbursts, physical illness, and increases in drinking alcohol, smoking, or substance abuse. Once attuned to

DRUG CAPSULE

Selective Serotonin Reuptake Inhibitor (SSRI) sertraline HCl (Zoloft)**CLIENT TAKING ANTIANXIETY MEDICATION**

Sertraline is approved to treat depression, social anxiety disorder, post-traumatic stress disorder (PTSD), panic disorder, obsessive-compulsive disorder (OCD), and premenstrual dysphoric disorder (PMDD) in adults over age 18. It is also approved for OCD in children and adolescents ages 6 to 17 years. It prevents serotonin from being reabsorbed by the sending nerve cells so that more serotonin is available for acceptance by the receiving nerve cells.

NURSING RESPONSIBILITIES

- Sertraline may be given with or without meals but with sufficient water. It is taken once per day.
- Sertraline is available as oral concentrate or tablets. The concentrate must be diluted after measurement.
- This medication should not be taken if the client is already taking a monoamine oxidase inhibitor (MAOI) or pimozone. Use with caution in clients taking anticoagulant medications. Always check the list of client medications for possible interactions.
- Adverse effects may include dry mouth, insomnia, sexual side effects, diarrhea, nausea, and sleepiness.
- There is a warning from the U.S. Food and Drug Administration (FDA) on all materials related to antidepressants due to an increased risk of suicidal thoughts and behavior from 2% to 4% in people under age 18. This risk must be balanced with the medical need. Those starting medication should be watched

closely for suicidal thoughts, worsening of depression, or unusual changes in behavior.

- This is an expensive medication. It can cost more than \$2.50 per day. Explore insurance and other forms of the client's ability to manage this cost.

CLIENT AND FAMILY TEACHING

- This medication is not habit forming and does not cause weight gain (as do some medications prescribed for similar purposes).
- Do not stop taking this medication without consulting the primary care provider. Some symptoms might improve within 1 to 2 weeks, but it could take up to 8 weeks, depending on the person. Treatment may last 6 months to 1 year.
- Sertraline comes in different dose strengths, and the primary care provider may need to adjust the dosage to find the correct amount.
- Avoid alcohol while taking sertraline.
- Take at the same time every day.
- Store at room temperature.
- Use caution when driving, operating machinery, or performing other hazardous activities because sertraline may cause dizziness or drowsiness.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

stress and personal reactions, it is necessary to identify which situations produce the most pronounced reactions so steps may be taken to reduce the stress. Suggestions include:

- Plan a daily relaxation program with meaningful quiet time to reduce tension (e.g., read, listen to music, soak in a tub, or meditate).
- Establish a regular exercise program to direct energy outward.
- Study assertiveness techniques to overcome feelings of powerlessness in relationships with others. Learn to say no.
- Learn to accept failures—your own and others—and make it a constructive learning experience. Recognize that most people do the best they can. Learn to ask for help, to show your feelings with colleagues, and to support your colleagues in times of need.
- Accept what cannot be changed. There are certain limitations in every situation. Get involved in constructive change efforts if organizational policies and procedures cause stress.
- Develop collegial support groups to deal with feelings and anxieties generated in the work setting.
- Participate in professional organizations to address workplace issues.
- Seek counseling if indicated to help clarify and cope with concerns.

Evaluating

Using the desired outcomes developed during the planning stage as a guide, the nurse collects data needed to determine whether client goals and outcomes have been achieved. Examples of client goals and related outcomes are shown in the accompanying Nursing Care Plan.

If outcomes are not achieved, the nurse, client, and support people, if appropriate, need to explore the reasons before modifying the care plan. Questions such as the following need to be considered:

- How does the client perceive the problem?
- Is there an underlying problem not identified?
- Have new stressors occurred that interfere with successful coping?
- Were existing coping strategies sufficient to meet intended outcomes?
- How does the client perceive the effectiveness of new coping strategies?
- Did the client implement new coping strategies properly?
- Did the client access and use available resources?
- Have family members and significant others provided effective support?

LIFESPAN CONSIDERATIONS Stress and Coping

INFANTS AND CHILDREN

- Children’s perceptions of and responses to stress depend on their developmental stage. Infants sense stressors in their environment and respond in a diffuse way, often crying and clinging. Toddlers and preschool-age children may be frightened and react by withdrawing or losing control. School-age children and adolescents are more capable of thinking about incidents that cause stress (e.g., a catastrophic accident) and talking about it with adults.
- Temperament influences how children respond to stress. An outgoing, low-sensitivity child is less likely than a timid, intense child to be upset by a family move to a different state.
- Anxiety disorders are common psychiatric disorders in children but are frequently unrecognized (Mohr & Schneider, 2013).
- As children grow, they can develop more coping skills to manage stressful situations. Nurses have an important role in teaching parents to recognize stress in their children and to help their children cope.

MIDDLE-AGED ADULTS

- Middle-aged adults are often called the “sandwich generation.” They care for children and grandchildren and often caring for aging parents at the same time. When these activities become time and energy consuming, there is often not enough time

left for attention to self. Nurses need to be aware of this and assist in suggesting resources and effective planning to ease the strain.

OLDER ADULTS

- Older adults experience many losses and changes in their lives. They may be incremental and, over time, become stressful and possibly overwhelming. Changes in health, decreased functional ability and independence, need for relocation, loss of family and friends, and becoming a caregiver for a spouse or friend are a few of the stresses often experienced by older adults. Many have survived significant challenges in their earlier lives and have learned effective coping skills. Nurses can help them plan, evaluate their strategies, and learn new strategies, if needed. Informal and formal social supports are very important in learning to successfully live with these changes and stress.
- Some effective coping methods for older adults are exercise, learning different relaxation techniques, participation in activities, adequate nutrition and rest, and engaging in expressive creative activities, such as art, music, and journaling. Referral to community resources and supports should be done when appropriate. It is most important to see older adults as unique individuals, with unique past experiences and specific needs as they age.

NURSING CARE PLAN Ineffective Coping

Assessment Data

Nursing Assessment

Ruby Smithson is a 55-year-old mother of four children who is hospitalized with breast cancer. She is scheduled for a modified radical mastectomy. Ruby was relatively healthy until she found a lump in her right breast 1 week ago. She and her husband are extremely anxious about the surgery. Ruby confides to the admitting nurse that “I can’t stand the idea of having one of my breasts cut off; I don’t know how I’m going to be able to even look at myself.” Mr. Smithson informs the nurse that Ruby has been abusing alcohol since her diagnosis and neglecting her responsibilities as a mother. She is tearful and doesn’t see how she will be able to continue her work as a dress designer.

Physical Examination

Height: 164 cm (5’5”)
 Weight: 58 kg (128 lb)
 Temperature: 37°C (98.6°F)
 Pulse rate: 88 beats/min
 Respirations: 16/min
 Blood pressure: 142/88 mmHg

Diagnostic Data

Chest x-ray negative, CBC, and urinalysis within normal limits

Nursing Diagnosis

Ineffective Coping related to personal vulnerability secondary to mastectomy (as evidenced by verbalization of inability to cope, substance abuse, inability to meet role expectations)

Desired Outcomes*

- Coping [1302], as evidenced by often demonstrating ability to
- Identify effective and ineffective coping patterns.
 - Verbalize sense of control.
 - Report decrease in negative feelings.
 - Modify lifestyle as needed.
- Social Support [1504], as evidenced by substantially adequate
- Willingness to call on others for help.
 - Emotional assistance provided by others.

Nursing Interventions*/Selected Activities

Rationale

Coping Enhancement [5230]

- Provide an atmosphere of acceptance.
- Provide factual information concerning the diagnosis, treatment, and prognosis.
- Appraise Ruby’s adjustment to changes in body image.

Establishing rapport is essential to a therapeutic relationship and supports the client in self-reflection. Recognizing problems and sharing feelings is best brought about in an atmosphere of warmth and trust.

Factual information serves as a foundation for Ruby to explore feelings and alternative coping strategies. Stressed clients often misunderstand facts and require frequent clarification so that appropriate conclusions can be drawn. Having valid information helps relieve stress.

Alteration in body image may be a major issue for Ruby and should be explored to facilitate therapeutic intervention. Coping strategies often change with a reappraisal of the situation.

NURSING CARE PLAN Ineffective Coping—continued

Nursing Interventions*/Selected Activities	Rationale
Arrange situations that encourage her autonomy. Give her as many opportunities as possible to make decisions/choices for herself.	Enhances a sense of control, personal achievement, and self-esteem.
Explore with her previous methods of dealing with life problems.	Present and past coping status assists both Ruby and her husband in capitalizing on successful methods, identifying ineffective strategies, and developing new skills more appropriate to the present situation. Also determines risk for inflicting self-harm.
Encourage verbalization of feelings, perceptions, and fears.	Open, nonthreatening discussions facilitate the identification of causative and contributing factors.
Encourage Ruby to identify her own strengths and abilities.	Assists Ruby to develop appropriate strategies for coping based on personal strengths and previous experiences. Improves self-concept and sense of ability to manage stress.
Encourage Ruby to realistically describe changes in her role.	Individuals experiencing stress may have unrealistic perceptions or reality distortions. Helping Ruby clearly describe her role would be beneficial in developing realistic goals for role achievement.
Foster constructive outlets for anger and hostility.	Assists the individual in channeling potentially harmful emotions and physical energy into constructive behavior.
Support System Enhancement [5440]	
Observe the degree of family support.	Assessing family interaction serves as a basis for identifying Ruby's support systems or lack thereof.
Determine barriers to using support systems.	Although adequate support systems may be available, Ruby may not be using them or may be using them ineffectively.
Involve husband, family, and friends in the care and planning.	Supporting Ruby in acknowledging changes in her appearance conveys acceptance and provides a foundation for her to begin to adjust.
Discuss with concerned others how they can help.	Family and friends are often willing but unsure how to help. Identifying specific strategies such as praise and encouragement during rehabilitation and healing will promote acceptance of change.
Refer Ruby to a community-based breast cancer support group.	Community support is beneficial in helping to meet unresolved needs, decreasing feelings of social isolation, and facilitating a positive self-image.

Evaluation

The coping outcome was not met. Following surgery, Ruby was withdrawn. During bathing, she would not assist and turned her head away when the dressing was removed. She refused to learn how to manage the wound drain or to discuss her feelings or plans for the future. Because clients having a mastectomy are often only hospitalized for a few days, it may be that she requires more time to reach the desired outcome. Continue to offer information and demonstrate availability for when she is ready to verbalize feelings. Social support outcome partly met. Ruby allows her husband to provide direct care and emotional support for her. A social worker was consulted and discharge was delayed for 24 hours. Ruby has agreed that the social worker can contact a breast cancer support group and ask the group to call her.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, indicators, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

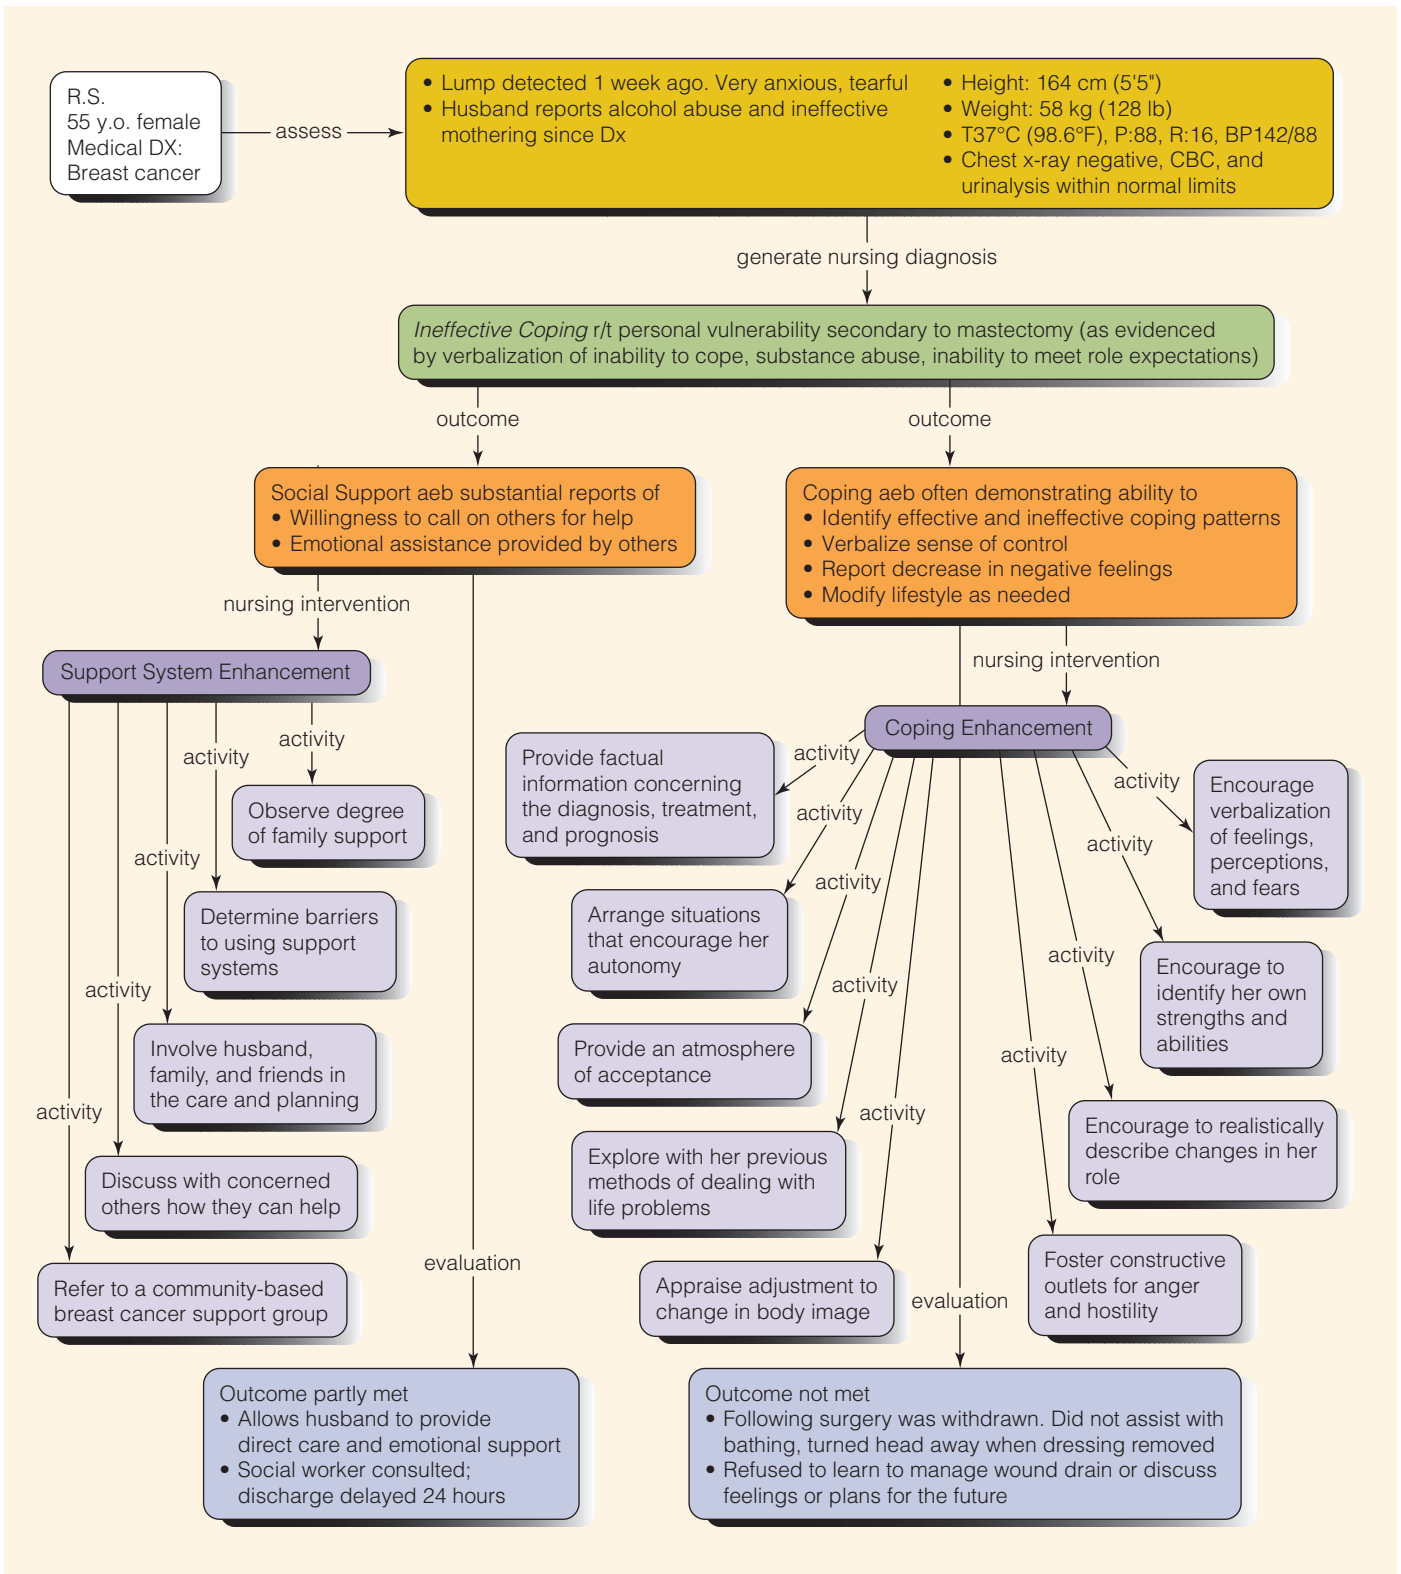

Applying Critical Thinking

1. If Ruby had been able to choose a lumpectomy rather than a mastectomy (less visible, smaller, potentially less "meaningful" tissue removal), would the nursing diagnosis and expected outcomes remain the same? Why or why not?
2. Does Ruby's situation reflect more of a stimulus-based model or a response-based model? Why?
3. While working with Ruby, she becomes very angry and says to you, "You don't understand. You've never had to go through this." How would you respond?
4. Based on the evaluation above, do you believe that Ruby is in crisis? What factors led to your decision? How does your view change the modifications stated in her care plan?
5. Give one example of how Ruby might use the defense mechanisms described earlier in Table 42–3. Explain whether this is adaptive or maladaptive.

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Ineffective Coping

Chapter 42 Review

CHAPTER HIGHLIGHTS

- Stress is a state of physiological and psychological tension that affects the whole person—physically, emotionally, intellectually, socially, and spiritually.
- Models view stress as a stimulus, as a response, or as a transaction.
- General adaptation syndrome (GAS) is a multisystem response to stress and involves three steps: alarm reaction, stage of resistance, and stage of exhaustion.
- Local adaptation syndrome (LAS) is a localized physiological response that also expresses the three stages of GAS. An example of LAS is the inflammatory response.
- There are physiological, psychological, and cognitive indicators of stress. Physiological indicators result from increased activity of the sympathetic and neuroendocrine systems.
- Common psychological indicators are anxiety, fear, anger, and depression. Anxiety, the most common response, has four levels: mild, moderate, severe, and panic. Ego defense mechanisms such as denial, rationalization, compensation, and sublimation protect individuals from anxiety.
- Cognitive indicators or thinking responses to stress include problem solving, structuring, self-control or self-discipline, suppression, and fantasy.
- Coping strategies to deal with stress vary significantly among individuals. Strategies may be problem focused or emotion focused, long term or short term, and effective or ineffective.
- The effectiveness of individual coping depends on the number, duration, and intensity of the stressors; past experience; support systems available; and the personal qualities of the person.
- Prolonged stress and ineffective coping interfere with the meeting of basic needs and can affect physical and mental health.
- Nursing assessment of a client experiencing stress involves a nursing history to identify perceptions of and duration of stressors and coping strategies and also a physical examination for physical indicators of stress.
- Nursing interventions for clients who are stressed are aimed at encouraging health promotion strategies (exercise, healthy diet, adequate rest, and time management), minimizing anxiety, mediating anger, teaching about specific relaxation techniques, and implementing crisis interventions as needed.
- Because nursing practice involves many stressors related to both clients and the work environment, nurses are susceptible to anxiety and burnout. Like clients, they need to implement stress reduction measures.

TEST YOUR KNOWLEDGE

1. After the death of several long-term clients, which action indicates the nurse is demonstrating ineffective coping?
 1. The nurse talks at length to her partner about the deaths.
 2. The nurse keeps busy with other actions and doesn't think about the deaths for several days.
 3. The nurse offers to work extra shifts for several weeks.
 4. Several nurses schedule a group session with the agency clergy to discuss the deaths.
2. The nurse helps a 50-year-old client with diabetes who is to begin giving insulin injections identify previously successful coping strategies that may be useful in the current situation. Which stressor is closely related to the new stressor?
 1. Interviewing for a new job
 2. Death of a pet while the person was a teenager
 3. The person's partner filing for a divorce
 4. Starting to wear eyeglasses at age 30
3. Two people have been in a motor vehicle crash and have similar injuries. According to the transaction-based model, their degree of stress from the crash would be
 1. Based on previous experience and personal characteristics.
 2. Extremely similar since they had the same stimulus.
 3. The identical physiological alarm reaction.
 4. Different depending on their external resources and support levels.
4. A client informed of a cancer diagnosis assures the nurse he is fine. Which of the following is the most indicative physical evidence to the nurse of the client's stress?
 1. Constricted pupils
 2. Dilated peripheral blood vessels (flush)
 3. Hyperventilation
 4. Decreased heart rate
5. Immediately after the parents of a hospitalized child are informed that the child has leukemia, the father responds by continuing his usual work schedule, rarely visiting, and asking when the child can return to school. Of the following, which is the **least** likely to be an appropriate nursing diagnosis at this time?
 1. *Ineffective Denial*
 2. *Caregiver Role Strain*
 3. *Fear*
 4. *Compromised Family Coping*
6. The nurse has recently changed jobs to work with young adults and recognizes that sources of stress common to that population include which of the following? Select all that apply.
 1. Marriage
 2. Aging parents
 3. Starting a new job
 4. Leaving the parental home
 5. Decreased physical abilities
 6. Changing body structure

7. A middle-aged male client is experiencing job-related stress associated with the fear of being laid off, resulting in his accepting projects that require a great deal of travel. Which of the following would be the most important health promotion strategy for this client?
 1. Exercise
 2. Sleep
 3. Nutrition
 4. Time management
8. The first time the nurse enters the client's room, the client is on the phone. Immediately, the client slams down the phone, sweeps everything off the overbed table, and demands that the nurse perform several duties "this very minute." Which of the following would be the most appropriate response for the nurse?
 1. Tell the client "I will return" and then leave the room.
 2. Tell the client no care will be given until the screaming ends.
 3. Begin providing needed care calmly and quietly.
 4. Allow the client to complete venting, then respond calmly.
9. A client newly diagnosed with a chronic condition that will significantly change the lifestyle must learn aspects of self-care. The client exhibits severe anxiety: increased blood pressure and pulse, headache, and nervousness. Based on this situation, how would the nurse appropriately plan the teaching?
 1. Recognize that the client's ability to learn is severely impaired and teach only the immediate, critical needs and plan to follow up and reinforce this teaching later.
 2. Recognize that the client's learning will be adaptive and begin immediately to implement the full teaching and learning plan.
 3. Recognize that the client's ability to learn will be slightly impaired and modify the usual teaching strategies to accommodate for this impairment.
 4. Recognize that the client cannot learn at this time, that the level of anxiety must first be reduced, and then teaching can be based on this new level of anxiety.
10. Which of the following defense mechanisms for coping with stress could be effective and constructive? Select all that apply.
 1. Compensation
 2. Displacement
 3. Minimization
 4. Repression
 5. Regression

Any nurse is susceptible to burnout from the stress of the job. Recognizing this, and putting prevention strategies in place early, may decrease the chances of becoming burned out. This article suggests several practical solutions.

43 Loss, Grieving, and Death

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe types and sources of losses.
2. Discuss selected frameworks for identifying stages of grieving.
3. Identify clinical symptoms of grief.
4. Discuss factors affecting a grief response.
5. Identify measures that facilitate the grieving process.
6. List clinical signs of impending and actual death.
7. Describe the process of helping clients die with dignity.
8. Describe the role of the nurse in working with families or caregivers of dying clients.
9. Describe nursing measures for care of the body after death.

INTRODUCTION

Everyone experiences loss, grieving, and death during his or her life. People may suffer the loss of valued relationships through life changes, such as moving from one city to another; separation or divorce; or the death of a parent, spouse, or friend. People may grieve changing life roles as they watch grown children leave home or they retire from their lifelong work. Losing valued material objects through theft or natural disaster can evoke feelings of grief and loss. When people's lives are affected by civil or national strife, they may grieve the loss of valued ideals such as safety, freedom, or democracy.

In the clinical setting, the nurse encounters clients who may experience grief related to declining health, loss of a body part, terminal illness, or the impending death of self or a significant other. The nurse may also work with clients in community settings who are grieving losses related to a personal crisis (e.g., divorce, separation, financial loss) or disaster (war, earthquakes, or terrorism). Therefore, it is important for the nurse to understand the significance of loss and develop the ability to assist clients as they work through the grieving process.

Nurses may interact with dying clients and their families or caregivers in a variety of settings, from a fetal demise (death of an unborn child), to the adolescent victim of an accident, to the older client who finally succumbs to a chronic illness. Nurses must recognize the influences on the dying process—legal, ethical, spiritual, biologic, psychological—and be prepared to provide sensitive, skilled, and supportive care to all those affected.

LOSS AND GRIEF

Loss is an actual or potential situation in which something that is valued is changed or no longer available. People can experience the loss of body image, a significant other, a sense of well-being, a job, personal possessions, or beliefs. Illness and hospitalization often produce losses.

Death is a loss both for the dying person and for those who survive. Although death is inevitable, it can stimulate people to grow in their understanding of themselves and others. People experiencing loss often search for the meaning of the event, and it is generally accepted that finding meaning is needed in order for healing to occur. However, individuals can be well adjusted without searching for meaning, and even those who find meaning may not see it as an end point but rather as an ongoing process.

Types and Sources of Loss

There are two general types of loss, actual and perceived. An **actual loss** can be recognized by others. A **perceived loss** is experienced by one person but cannot be verified by others. Psychological losses are often perceived losses because they are not directly verifiable. For example, a woman who leaves her employment to care for her children at home may perceive a loss of independence and freedom. Both losses can be anticipatory. An **anticipatory loss** is experienced before the loss actually occurs. For example, a woman whose husband is dying may experience actual loss in anticipation of his death.

Loss can be viewed as situational or developmental. Losing one's job, the death of a child, and losing functional ability because of acute illness or injury are situational losses. Losses that occur in normal development—such as the departure of grown children from the home, retirement from a career, and the death of aged parents—are developmental losses that can, to some extent, be anticipated and prepared for.

There are many sources of loss: (a) loss of an aspect of oneself—a body part, a physiological function, or a psychological attribute; (b) loss of an object external to oneself; (c) separation from an accustomed environment; and (d) loss of a loved or valued person.

ASPECT OF SELF

Losing an aspect of self changes a person's body image, even though the loss may not be obvious. A face scarred from a burn is generally

obvious; loss of part of the stomach or loss of the ability to feel emotion may not be as obvious. The degree to which these losses affect a person largely depends on the integrity of the person's body image.

During old age, changes occur in physical and mental capabilities. Again the self-image is vulnerable. Old age is the stage when people may experience many losses: of employment, of usual activities, of independence, of health, of friends, and of family.

EXTERNAL OBJECTS

Loss of external objects includes (a) loss of inanimate objects that have importance to the person, such as losing money or the burning down of a family's house; and (b) loss of animate (live) objects such as pets that provide love and companionship.

FAMILIAR ENVIRONMENT

Separation from an environment and people who provide security can cause a sense of loss. The 6-year-old is likely to feel loss when first leaving the home environment to attend school. The university student who moves away from home for the first time also experiences a sense of loss.

LOVED ONES

Losing a loved one or valued person through illness, divorce, separation, or death can be very disturbing. In some illnesses (such as Alzheimer's dementia), a person may undergo personality changes that make friends and family feel they have lost that person. The death of a loved one is a permanent and complete loss.

Grief, Bereavement, and Mourning

Grief is the total response to the emotional experience related to loss. Grief is manifested in thoughts, feelings, and behaviors associated with overwhelming distress or sorrow. **Bereavement** is the subjective response experienced by the surviving loved ones. **Mourning** is the behavioral process through which grief is eventually resolved or altered; it is often influenced by culture, spiritual beliefs, and custom. Grief and mourning are experienced not only by the person who faces the death of a loved one but also by the person who suffers other kinds of losses. Grieving permits the individual to cope with the loss gradually and to accept it as part of reality. Grief is a social process; it is best shared and carried out with the assistance of others.

Working through one's grief is important because bereavement may have potentially devastating effects on health. Among the symptoms that can accompany grief are anxiety, depression, weight loss, difficulties in swallowing, vomiting, fatigue, headaches, dizziness, fainting, blurred vision, skin rashes, excessive sweating, menstrual disturbances, palpitations, chest pain, and dyspnea. The grieving and the bereaved may experience alterations in libido, concentration, and patterns of eating, sleeping, activity, and communication.

Although bereavement can threaten health, a positive resolution of the grieving process can enrich the individual with new insights, values, challenges, openness, and sensitivity. For some, the pain of loss, though diminished, recurs for the rest of their lives.

TYPES OF GRIEF RESPONSES

A normal grief reaction may be abbreviated or anticipatory. Abbreviated grief is brief but genuinely felt. This can occur when the lost object is not significantly important to the grieving person or may have been replaced immediately by another, equally esteemed object.

Anticipatory grief is experienced in advance of the event such as

the wife who grieves before her ailing husband dies. A young person may grieve before an operation that will leave a scar. Because many of the normal symptoms of grief will have already been expressed in anticipation, the reaction when the loss actually occurs is sometimes quite abbreviated.

Disenfranchised grief occurs when a person is unable to acknowledge the loss to other people. Situations in which this may occur often relate to a socially unacceptable loss that cannot be spoken about, such as suicide, abortion, or giving a child up for adoption. Other examples include losses of relationships that are socially unsanctioned and may not be known to other people (such as homosexuality or extramarital relationships).

Unhealthy grief—that is, pathologic or **complicated grief**—exists when the strategies to cope with the loss are maladaptive and out of proportion or inconsistent with cultural, religious, or age-appropriate norms. The disorder, referred to by physicians as persistent complex bereavement disorder, may be said to exist if the preoccupation lasts for more than 6 months and leads to reduced ability to function formally (Simon, 2013). Many factors can contribute to complicated grief, including a prior traumatic loss, family or cultural barriers to the emotional expression of grief, sudden death, strained relationships between the survivor and the deceased, and lack of adequate support for the survivor.

Complicated grief may take several forms. *Unresolved* or *chronic grief* is extended in length and severity. The same signs are expressed as with normal grief, but the bereaved may also have difficulty expressing the grief, may deny the loss, or may grieve beyond the expected time. With *inhibited grief*, many of the normal symptoms of grief are suppressed and other effects, including somatic, are experienced instead. *Delayed grief* occurs when feelings are purposely or subconsciously suppressed until a much later time. A survivor who appears to be using dangerous activities as a method to lessen the pain of grieving may experience *exaggerated grief*.

Complicated grief after a death may be inferred from the following data or observations:

- The client fails to grieve; for example, a husband does not cry at, or absents himself from, his wife's funeral.
- The client avoids visiting the grave and refuses to participate in memorial services, even though these practices are a part of the client's culture.
- The client becomes recurrently symptomatic on the anniversary of a loss or during holidays.
- The client develops persistent guilt and lowered self-esteem.
- Even after a prolonged period, the client continues to search for the lost person. Some may consider suicide to affect reunion.
- A relatively minor event triggers symptoms of grief.
- Even after a period of time, the client cannot discuss the deceased with composure; for example, the client's voice cracks and quivers, and eyes become teary.
- After the normal period of grief, the client experiences physical symptoms similar to those of the person who died.
- The client's relationships with friends and relatives worsen following the death.

Many factors contribute to unresolved grief after a death:

- Ambivalence (intense feelings, both positive and negative) toward the lost person

- A perceived need to be brave and in control; fear of losing control in front of others
- Endurance of multiple losses, such as losing an entire family, which the bereaved finds too overwhelming to contemplate
- Extremely high emotional value invested in the dead person; failure to grieve in this instance helps the bereaved avoid the reality of the loss
- Uncertainty about the loss—for example, when a loved one is “missing in action”
- Lack of support systems.

Stages of Grieving

Many authors have described stages or phases of grieving, perhaps the most well known of them being Kübler-Ross (1969), who described five stages: denial, anger, bargaining, depression, and acceptance (Table 43–1). Engel (1964) identified six stages of grieving: shock and disbelief, developing awareness, restitution, resolving the loss, idealization, and outcome (Table 43–2). Sanders (1998) described five phases of bereavement: shock, awareness of loss, conservation/withdrawal, healing, and renewal (Table 43–3).

TABLE 43–1 Client Responses and Nursing Implications in Kübler-Ross's Stages of Grieving

Stage	Behavioral Responses	Nursing Implications
Denial	Refuses to believe that loss is happening. Is unready to deal with practical problems, such as prosthesis after the loss of a leg. May assume artificial cheerfulness to prolong denial.	Verbally support client but do not reinforce denial. Examine your own behavior to ensure that you do not share in client's denial.
Anger	Client or family may direct anger at nurse or staff about matters that normally would not bother them.	Help client understand that anger is a normal response to feelings of loss and powerlessness. Avoid withdrawal or retaliation; do not take anger personally. Deal with needs underlying any angry reaction. Provide structure and continuity to promote feelings of security. Allow clients as much control as possible over their lives.
Bargaining	Seeks to bargain to avoid loss (e.g., “let me just live until and then I will be ready to die”).	Listen attentively, and encourage client to talk to relieve guilt and irrational fear. If appropriate, offer spiritual support.
Depression	Grieves over what has happened and what cannot be. May talk freely (e.g., reviewing past losses such as money or job), or may withdraw.	Allow client to express sadness. Communicate nonverbally by sitting quietly without expecting conversation. Convey caring by touch.
Acceptance	Comes to terms with loss. May have decreased interest in surroundings and support people. May wish to begin making plans (e.g., will, prosthesis, altered living arrangements).	Help family and friends understand client's decreased need to socialize. Encourage client to participate as much as possible in the treatment program.

TABLE 43–2 Engel's Stages of Grieving

Stage	Behavioral Responses
Shock and disbelief	Refuses to accept loss. Has stunned feelings. Accepts the situation intellectually, but denies it emotionally.
Developing awareness	Reality of loss begins to penetrate consciousness. Anger may be directed at agency, nurses, or others.
Restitution	Conducts rituals of mourning (e.g., funeral).
Resolving the loss	Attempts to deal with painful void. Still unable to accept new love object to replace lost person or object. May accept more dependent relationship with support person. Thinks over and talks about memories of the lost object.
Idealization	Produces image of lost object that is almost devoid of undesirable features. Represses all negative and hostile feelings toward lost object. May feel guilty and remorseful about past inconsiderate or unkind acts to lost person. Unconsciously internalizes admired qualities of lost object. Reminders of lost object evoke fewer feelings of sadness. Reinvests feelings in others.
Outcome	Behavior influenced by several factors: importance of lost object as source of support, degree of dependence on relationship, degree of ambivalence toward lost object, number and nature of other relationships, and number and nature of previous grief experiences (which tend to be cumulative).

From “Grief and Grieving,” by G. L. Engel, 1964, *American Journal of Nursing*, 64(9), pp. 93–98. Adapted with permission.

TABLE 43–3 Sander’s Phases of Bereavement

Phase	Description	Behavioral Responses
Shock	Survivors are left with feelings of confusion, unreality, and disbelief that the loss has occurred. They are often unable to process normal thought sequences. Phase may last from a few minutes to many days.	Disbelief Confusion Restlessness Feelings of unreality Regression and helplessness State of alarm Physical symptoms: dryness of mouth and throat, sighing, weeping, loss of muscular control, uncontrolled trembling, sleep disturbance, loss of appetite Psychological symptoms: egocentric phenomenon, preoccupation with thoughts of the deceased, psychological distancing
Awareness of loss	Friends and family resume normal activities. The bereaved experience the full significance of their loss.	Separation anxiety Conflicts Acting out emotional expectations Prolonged stress Physical symptoms: yearning, anger, guilt, frustration, shame, crying, sleep disturbance, fear of death Psychological symptoms: oversensitivity, disbelief and denial, dreaming, sense of presence of the deceased
Conservation/withdrawal	During this phase, survivors feel a need to be alone to conserve and replenish both physical and emotional energy. The social support available to the bereaved has decreased, and they may experience despair and helplessness.	Withdrawal Despair Diminished social support Helplessness Physical symptoms: weakness, fatigue, need for more sleep, a weakened immune system Psychological symptoms: hibernation or holding pattern, obsessional review, grief work, turning point
Healing: the turning point	During this phase, the bereaved move from distress about living without their loved one to learning to live more independently.	Assuming control Identity restructuring Relinquishing roles, such as spouse, child, or parent Physical symptoms: increased energy, sleep restoration, immune system restoration, physical healing Psychological symptoms: forgiving, forgetting, searching for meaning, closing of the circle, hope
Renewal	In this phase, survivors move on to a new self-awareness, an acceptance of responsibility for self, and learning to live without the loved one.	New self-awareness Acceptance of responsibility Process of learning to live without Physical symptoms: functional stability, revitalization, caring for physical needs Assumption of responsibility for self-care needs Psychological symptoms: living for oneself, loneliness, anniversary reactions, reaching out to others, time for the process of bereavement

From Grief: The Mourning After: Dealing with Adult Bereavement, 2E by Catherine M. Sanders. Published by John Wiley & Sons, Inc., © 1999.

Martocchio (1985) described five clusters of grief—shock and disbelief; yearning and protest; anguish, disorganization, and despair; identification in bereavement; and reorganization and restitution—and maintained that there is no single correct way, nor a correct timetable, by which a person progresses through the grief process. Whether a person can integrate the loss and how this is accomplished are related to that person’s individual development and personal makeup. In addition, individuals responding to the very same loss cannot be expected to follow the same pattern or schedule in resolving their grief, even while they support each other.

Manifestations of Grief

The nurse assesses the grieving client or family members following a loss to determine the phase or stage of grieving. Physiologically,

the body responds to a current or anticipated loss with a stress reaction. The nurse can assess the clinical signs of this response (see Chapter 42 ∞).

Manifestations of grief considered normal include verbalization of the loss, crying, sleep disturbance, loss of appetite, and difficulty concentrating. Complicated grieving may be characterized by extended time of denial, depression, severe physiological symptoms, or suicidal thoughts.

Factors Influencing the Loss and Grief Responses

Several factors affect a person’s response to a loss or death. These factors include age, significance of the loss, culture, spiritual beliefs, gender, socioeconomic status, support systems, and the cause of the

loss or death. Nurses can learn general concepts about the influence of these factors on the grieving experience, but the constellation of these factors and their significance will vary from individual to individual.

AGE

Age affects a person's understanding of and reaction to loss. With familiarity, people usually increase their understanding and acceptance of life, loss, and death.

People rarely experience the loss of loved ones at regular intervals. As a result, preparation for these experiences is difficult. Other life losses, such as losing a pet, a friend, youth, or a job, can help people anticipate the more severe loss of death of loved ones by teaching them successful coping strategies.

CHILDHOOD Children differ from adults not only in their understanding of loss and death but also in how they are affected by losing others. Losing a parent or other significant person can threaten the child's ability to develop, and regression sometimes results. Assisting the child with the grief experience includes helping the child regain the normal continuity and pace of emotional development.

Some adults may assume that children do not have the same need as an adult to grieve the loss of others. In situations of crisis and loss, children are sometimes pushed aside or protected from the pain. They can feel afraid, abandoned, and lonely. Careful work with bereaved children is especially necessary because experiencing a loss in childhood can have serious effects later in life (Figure 43-1 ■).

EARLY AND MIDDLE ADULTHOOD As people grow, they come to experience loss as part of normal development. By middle age, for example, the loss of a parent through death seems a more normal occurrence compared to the death of a younger person. Coping with the death of an aged parent has even been viewed as an essential developmental task of the middle-aged adult.

The middle-aged adult can experience losses other than death. For example, losses resulting from impaired health or body function and losses of various role functions can be difficult for the middle-aged adult. How the middle-aged adult responds to such losses is influenced by previous experiences with loss, the person's sense of self-esteem, and the strength and availability of support.

Figure 43-1 ■ Children experience the same emotions of grief as adults.

Juan Silva/Getty Images.

LATE ADULTHOOD Losses experienced by older adults include loss of health, mobility, independence, and work role. Limited income and the need to change one's living accommodations can also lead to feelings of loss and grieving.

For older adults, the loss through death of a longtime mate is profound. Although individuals differ in their ability to deal with such a loss, research suggests that health problems for widows and widowers increase following the death of the spouse (Sorrell, 2012).

Because the majority of deaths occur among older people, and because the number of older people is increasing in North America, nurses will need to be especially alert to the potential problems of older grieving adults. These problems may intensify because the very old grieving person may have children who, themselves, are older and possibly unwell. Some older adults no longer have living peer support people and the nurse may need to fill some of that role.

SIGNIFICANCE OF THE LOSS

The significance of a loss depends on the perceptions of the individual experiencing the loss. One person may experience a great sense of loss over a divorce; another may find it only mildly disrupting. Several factors affect the significance of the loss:

- Importance of the lost person, object, or function
- Degree of change required because of the loss
- The person's beliefs and values.

For older people who have already encountered many losses, an anticipated loss such as their own death may not be viewed as highly negative, and they may be apathetic about it instead of reactive. More than fearing death, some may fear loss of control or becoming a burden.

CULTURE

Culture influences an individual's reaction to loss. How grief is expressed is often determined by the customs of the culture. Unless an extended family structure exists, grief is handled by the nuclear family. The death of a family member in a typical nuclear family leaves a great void because the same few individuals fill most of the roles. In cultures where several generations and extended family members either reside in the same household or are physically close, the impact of a family member's death may be softened because the roles of the deceased are quickly filled by other relatives.

Some individuals believe that grief is a private matter to be endured internally. Therefore, feelings tend to be repressed and may remain unidentified. People socialized to "be strong" and "make the best of the situation" may not express deep feelings or personal concerns when they experience a serious loss.

Some cultural groups value social support and the expression of loss. In some groups, expressions of grief through wailing, crying, physical prostration, and other outward demonstrations are acceptable and encouraged. Other groups may frown on this demonstration as a loss of control, favoring a more quiet and stoic expression of grief. In cultural groups where strong kinship ties are maintained, physical and emotional support and assistance are provided by family members.

SPIRITUAL BELIEFS

Spiritual beliefs and practices greatly influence both a person's reaction to loss and subsequent behavior. Most religious groups have practices related to dying, and these are often important to the client

and support people. To provide support at a time of death, nurses need to understand the client's particular beliefs and practices (see Chapter 41 ∞).

GENDER

The gender roles into which many people are socialized in the United States affect their reactions at times of loss. Males are frequently expected to “be strong” and show very little emotion during grief, whereas it is acceptable for females to show grief by crying. When a wife dies, the husband, who is the chief mourner, may be expected to repress his own emotions and to comfort sons and daughters in their grieving.

Gender roles also affect the significance of body image changes to clients. A man might consider his facial scar to be “macho,” but a woman might consider hers ugly. Thus the woman, but not the man, would see the change as a loss.

SOCIOECONOMIC STATUS

The socioeconomic status of an individual often affects the support system available at the time of a loss. A pension plan or insurance, for example, can offer an individual who is widowed or disabled a choice of ways to deal with a loss; a person who is confronted with both severe loss and economic hardship may not be able to cope with either.

SUPPORT SYSTEM

The people closest to the grieving individual are often the first to recognize and provide needed emotional, physical, and functional assistance. However, because many people are uncomfortable or inexperienced in dealing with losses, the usual support people may instead withdraw from the grieving individual. In addition, support may be available when the loss is first recognized, but as the support people return to their usual activities, the need for ongoing support may be unmet. Sometimes, the grieving individual is unable or unready to accept support when offered.

CAUSE OF LOSS OR DEATH

Individual and societal views on the cause of a loss or death may significantly influence the grief response. Some diseases are considered “clean,” such as cardiovascular disorders, and engender compassion,

whereas others may be viewed as repulsive and less unfortunate. A loss or death beyond the control of those involved may be more acceptable than one that is preventable, such as a drunk driving incident. Injuries or deaths that occur during respected activities, such as “in the line of duty,” are considered honorable, whereas those occurring during illicit activities may be considered the individual's just rewards.

●○○ NURSING MANAGEMENT

Assessing

Nursing assessment of the client experiencing a loss includes three major components: (1) nursing history, (2) assessment of personal coping resources, and (3) physical assessment. During the routine health assessment of every client, the nurse poses questions regarding previous and current losses. The nature of the loss and the significance of such losses to the client must be explored.

If there is a current or recent loss, greater detail is needed in the assessment. Because clients do not always associate physical ailments with emotional responses such as grief, the nurse may need to probe to identify possible loss-related stresses. If the client reports significant losses, examine how the client usually copes with loss and what resources are available to assist the client in coping. Data regarding general health status; other personal stressors; cultural and spiritual traditions, rituals, and beliefs related to loss and grieving; and the person's support network will be needed to determine a plan of care (see the Assessment Interview). In assessing the client's response to a current loss, the nurse may identify complicated grief, which is best treated by a health care professional expert in assisting such clients. If the nursing assessment reveals severe physical or psychological signs and symptoms, the client should be referred to an appropriate care provider.

Diagnosing

NANDA International nursing diagnoses (Herdman & Kamitsuru, 2014) relating specifically to grieving include the following:

- **Grieving:** a normal complex process that includes emotional, physical, spiritual, social, and intellectual responses and behaviors

ASSESSMENT INTERVIEW Loss and Grieving

PREVIOUS LOSS

- Have you ever lost someone or something very important to you?
- Have you or your family ever moved to a new home or location?
- What was it like for you when you first started school? Moved away from home? Got a job? Retired?
- Are you physically able to do all the things you used to do?
- Has anyone important or close to you died?
- Do you think there will be any losses in your life in the near future?

If there has been previous grieving:

- Tell me about [the loss]. What was losing like for you?
- Did you have trouble sleeping? Eating? Concentrating?
- What kinds of things did you do to make yourself feel better when something like that happened?
- Did you observe any spiritual or cultural practices when you had a loss like that?
- Whom did you turn to if you were very upset about [the loss]?
- How long did it take you to feel more like yourself again and go back to your usual activities?

CURRENT LOSS

- What have you been told about [the loss]? Is there anything else you would like to know or don't understand?
- What changes do you think this [illness, surgery, problem] will cause in your life? What do you think it will be like without [the lost object]?
- Have you ever experienced a loss like this before?
- Can you think of anything good that might come out of this?
- What kind of help do you think you will need? Who is going to be helping you with this loss?
- Are there any people or organizations in your community that might be able to help?

If there is current grieving:

- Are you having trouble sleeping? Eating? Concentrating? Breathing?
- Do you have any pain or other new physical problems?
- What are you doing to help you deal with this loss?
- Are you taking any drugs or medications to help you cope with this loss?

Home Care Assessment Grieving

PATIENT-CENTERED CARE

CLIENT

- *Knowledge*: client's understanding of the implications of the loss
- *Self-care abilities*: skill in caring for self, based on any physical abilities that may have been altered by the loss
- *Current coping*: stage in the grieving or bereavement process
- *Current manifestations of the grief response*: adaptive or maladaptive signs and symptoms; cultural or spiritually based behaviors
- *Role expectations*: client's perception of the need to return to work or family roles

FAMILY

- *Knowledge*: various family members' perception of the loss
- *Support people's availability and skills*: sensitivity to the client's emotional and physical needs; ability to provide an accepting environment
- *Role expectations*: family perception of client's need to return to work or family roles

COMMUNITY

- *Resources*: availability and familiarity with possible sources of assistance such as grief support groups, religious or spiritual centers, counseling services, physical care providers

by which individuals, families, and communities incorporate an actual, anticipated, or perceived loss into their daily lives

- **Complicated Grieving/Risk for Complicated Grieving**: a disorder that occurs after the death of a significant other, in which the experience of distress accompanying bereavement fails to follow normative expectations and manifests in functional impairment.

Other nursing diagnoses may include the following:

- *Interrupted Family Processes* if the loss has such impact on the individual and family that usual effective roles and interactions are negatively affected
- *Risk-Prone Health Behavior* if the client has great difficulty placing the loss in appropriate perspective to his or her other life activities
- *Risk for Loneliness* related to the loss of relationships with others.

Planning

The overall goals for clients grieving the loss of body function or a body part are to adjust to the changed ability and to redirect both physical and emotional energy into rehabilitation. The goals for clients grieving the loss of a loved one or thing are to remember them without feeling intense pain and to redirect emotional energy into one's own life and adjust to the actual or impending loss.

Planning for Home Care

Clients who have sustained or anticipate a loss may require ongoing nursing care to assist them in adapting to the loss. Determining how much and what type of home care follow-up is needed is based in great part on the nurse's knowledge of how the client and family have coped with previous losses. To prepare for home care, the nurse reassesses the client's abilities and needs. The Home Care Assessment describes data to gather for home care or follow-up assessment.

Implementing

Besides providing physical comfort, maintaining privacy/dignity, and promoting independence, the skills most relevant to situations of loss and grief are those of effective communication: attentive listening, silence, open and closed questioning, paraphrasing, clarifying and reflecting feelings, and summarizing. Less helpful to clients are responses that give advice and evaluation, those that interpret and analyze, and those that give unwarranted reassurance. Communication with grieving clients must relate to their stage of grief. Whether the client is angry or depressed affects how

the client hears messages and how the nurse interprets the client's statements.

Besides using effective communication skills, the nurse implements a plan to provide client and family teaching and to help the client work through the stages of grief.

Facilitating Grief Work

- Explore and respect the client's and family's ethnic, cultural, religious, and personal values in their expressions of grief.
- Teach the client or family what to expect in the grief process, such as that certain thoughts and feelings are normal (acceptable) and that labile emotions, feelings of sadness, guilt, anger, fear, and loneliness will stabilize or lessen over time. Knowing what to expect may lessen the intensity of some reactions.
- Encourage the client to express and share grief with support people. Sharing feelings reinforces relationships and facilitates the grief process.
- Teach family members to encourage the client's expression of grief, not to push the client to move on or enforce his or her own expectations of appropriate reactions. If the client is a child, encourage family members to be truthful and to allow the child to participate in the grieving activities of others.
- Encourage the client to resume normal activities on a schedule that promotes physical and psychological health. Some clients may try to return to normal activities too quickly. However, a prolonged delay in return may indicate complicated grieving.

Providing Emotional Support

- Use silence and personal presence along with techniques of therapeutic communication. These techniques enhance exploration of feelings and let clients know that the nurse acknowledges their feelings.
- Acknowledge the grief of the client's family and significant others. Family support persons are part of the grieving client's world.
- Offer choices that promote client autonomy. Clients need to have a sense of some control over their own lives at a time when much control may not be possible.
- Provide information regarding how to access community resources: clergy, support groups, and counseling services.
- Suggest additional sources of information and help such as:
 - a. American Association of Retired Persons
 - b. Caring Connections
 - c. Compassionate Friends (for those who have lost a child)
 - d. Grief Recovery Institute.

Examples of nursing actions appropriate for clients in various stages of the grief process are shown in the Concept Map on page 1004.

Evaluating

Evaluating the effectiveness of nursing care of the grieving client is difficult because of the long-term nature of the life transition. Criteria for evaluation must be based on goals set by the client and family.

Client goals and related desired outcomes for a grieving client will depend on the characteristics of the loss and the client. If outcomes are not achieved, the nurse needs to explore why the plan was unsuccessful. Such exploration begins with reassessing the client in case the nursing diagnoses were inappropriate. Examples of questions guiding the exploration include these:

- Do the client's grieving behaviors indicate dysfunctional grieving or another nursing diagnosis?
- Is the expected outcome unrealistic for the given time frame?
- Does the client have additional stressors previously not considered that are affecting grief resolution?
- Have nursing orders been implemented consistently, compassionately, and genuinely?

DYING AND DEATH

The concept of death is developed over time, as the person grows, experiences various losses, and thinks about concrete and abstract concepts. In general, humans move from a childhood belief in death as a temporary state, to adulthood in which death is accepted as very real but also very frightening, to older adulthood in which death may be viewed as more desirable than living with a poor quality of life. Table 43–4 describes some of the specific beliefs common to different age groups. The nurse's knowledge of these developmental stages helps in understanding some of the client's responses to a life-threatening situation.

Responses to Dying and Death

The reaction of any person to another person's impending or real death, or to the potential reality of his or her own death, depends on all the factors regarding loss and the development of the concept of death. In spite of the individual variations in a person's views about the cause of death, spiritual beliefs, availability of support systems, or any other factor, responses tend to cluster in the phases described by theorists (see Tables 43–1 to 43–3).

Both the client who is dying and the family members grieve as they recognize the loss. Defining characteristics for the nursing

TABLE 43–4 Development of the Concept of Death

Age	Beliefs/Attitudes
Infancy–5 years	Does not understand concept of death. Infant's sense of separation forms basis for later understanding of loss and death. Believes death is reversible, a temporary departure, or sleep. Emphasizes immobility and inactivity as attributes of death.
5–9 years	Understands that death is final. Believes own death can be avoided. Associates death with aggression or violence. Believes wishes or unrelated actions can be responsible for death.
9–12 years	Understands death as the inevitable end of life. Begins to understand own mortality, expressed as interest in afterlife or as fear of death.
12–18 years	Fears a lingering death. May fantasize that death can be defied, acting out defiance through reckless behaviors (e.g., dangerous driving, substance abuse). Seldom thinks about death, but views it in religious and philosophic terms. May seem to reach "adult" perception of death but be emotionally unable to accept it. May still hold concepts from previous developmental stages.
18–45 years	Has attitude toward death influenced by religious and cultural beliefs.
45–65 years	Accepts own mortality. Encounters death of parents and some peers. Experiences peaks of death anxiety. Death anxiety diminishes with emotional well-being.
65+ years	Fears prolonged illness. Encounters death of family members and peers. Sees death as having multiple meanings (e.g., freedom from pain, reunion with already deceased family members).

CLINICAL ALERT!

People may use a variety of terms instead of the word *died*. Serious examples include *passed away*, *gone to a better place*, *lost*, or *free from suffering*. Humorous examples include *bought the farm*, *kicked the bucket*, or *croaked*.

diagnosis of *Grieving* include denial, guilt, anger, despair, feelings of worthlessness, crying, and inability to concentrate. They may extend to thoughts of suicide, delusions, and hallucinations. *Fear*, the feeling of disruption related to an identifiable source (in this case someone's death), may also be present. Many of the characteristics seen in a fearful person are similar to those of grieving and include crying, immobility, increased pulse and respirations, dry mouth, anorexia, difficulty sleeping, and nightmares. *Hopelessness* occurs when the person perceives no solutions to a problem—when the death becomes inevitable and the person cannot see how to move beyond the death. The nurse may observe apathy, pessimism, and inability to decide. A person who perceives a solution to the problem but does not believe that it is possible to implement the solution may be said to experience *Powerlessness*. This loss of control may be manifested by anger, violence, acting out, or depression and passive behavior.

SAFETY ALERT!

SAFETY

The rate of suicide increases over age 65 and is highest among White men over age 85 (Feldman, 2011).

Caregivers, both professionals and support persons, also respond to the impending death. The NANDA International diagnosis *Risk for Caregiver Role Strain* may apply to this group. The ongoing responsibilities for providing physical, economic, psychological, and social support to a dying person can create extreme stress for the provider. Often, the time between a terminal diagnosis and when death will occur is unknown and the people supporting the dying person become fatigued and depressed. There may be anger due to loss of time and resources for personal activities or attention to other people. Within a family that usually functions effectively, death of a member may cause *Interrupted Family Processes*. In this situation, the family may be unable to meet the physical, emotional, or spiritual needs of the members and may have difficulty communicating and problem solving.

Professional caregivers, including nurses, may experience role strain due to repeated interactions with dying clients and their families. Although most nurses who work in oncology, hospice, intensive care, emergency, or other areas where client deaths are common have chosen such assignments, there can still be a sense of failure when clients die. Just as there must be support systems for grieving clients, there must also be support systems for grieving health care professionals.

Some people may think of death as the worst occurrence in life and do their best to avoid thinking or talking about death—especially their own. Nurses are not immune to such attitudes. Nurses who are uncomfortable with dying clients tend to impede the clients' attempts to discuss dying and death in these ways:

- Change the subject (e.g., "Let's think of something more cheerful" or "You shouldn't say things like that").
- Offer false reassurance (e.g., "You are doing very well").
- Deny what is happening (e.g., "You don't really mean that" or "You're going to live until you're a hundred").
- Be fatalistic (e.g., "Everyone dies sooner or later" or "What's meant to be, will be").
- Block discussion (e.g., "I don't think things are really that bad") and convey an attitude that stops further discussion of the subject.

- Be aloof and distant or avoid the client.
- "Manage" the client's care and make the client feel increasingly dependent and powerless.

SELF CARE ALERT

Nurses need to take time to analyze their own feelings about death before they can effectively help others with a terminal illness.

Caring for the dying and the bereaved is one of the nurse's most complex and challenging responsibilities, bringing into play all the skills needed for holistic physiological and psychosocial care. To be effective, nurses must confront their own attitudes toward loss, death, and dying, because these attitudes will directly affect their ability to provide care.

Definitions and Signs of Death

The traditional clinical signs of death were cessation of the apical pulse, respirations, and blood pressure, also referred to as **heart-lung death**. However, since the advent of artificial means to maintain respirations and blood circulation, identifying death is more difficult. In 1968, the World Medical Assembly (Gilder, 1968) adopted the following guidelines for physicians as indications of death:

- Total lack of response to external stimuli
- No muscular movement, especially breathing
- No reflexes
- Flat encephalogram (brain waves).

In instances of artificial support, absence of brain waves for at least 24 hours indicates death. Only then can a physician pronounce death, and only after this pronouncement can life-support systems be shut off.

Another definition of death is **cerebral death** or **higher brain death**, which occurs when the higher brain center, the cerebral cortex, is irreversibly destroyed. In this case, there is "a clinical syndrome characterized by the permanent loss of cerebral and brainstem function, manifested by absence of responsiveness to external stimuli, absence of cephalic reflexes, and apnea. An isoelectric electroencephalogram for at least 30 minutes in the absence of hypothermia and poisoning by central nervous system depressants supports the diagnosis" (*Stedman's Medical Dictionary for the Health Professions and Nursing*, 2012). People who support this definition of death believe the cerebral cortex, which holds the capacity for thought, voluntary action, and movement, is the individual.

Death-Related Religious and Cultural Practices

Cultural and religious traditions and practices associated with death, dying, and the grieving process help people cope with these experiences. Nurses are often present through the dying process and at the moment of death. Knowledge of the client's religious and cultural heritage helps nurses provide individualized care to clients and their families, even though they may not participate in the rituals associated with death.

In some cultures, people prefer a peaceful death at home rather than in the hospital. Members of certain ethnic groups may request that health professionals not reveal the prognosis to dying clients.

They believe the person's last days should be free of worry. Other cultures prefer that a family member (preferably a male in some cultures) be told the diagnosis so the client can be tactfully informed by a family member in gradual stages or not be told at all. Nurses also need to determine whom to call, and when, as the impending death draws near.

Beliefs and attitudes about death, its cause, and the soul also vary among cultures. Unnatural deaths, or “bad deaths,” are sometimes distinguished from “good deaths.” In addition, the death of a person who has behaved well in life may be less threatening based on the belief that the person will be reincarnated into a good life or go to heaven.

Beliefs about preparation of the body, autopsy, organ donation, cremation, and prolonging life are closely allied to the person's religion. Autopsy, for example, may be prohibited, opposed, or discouraged by Eastern Orthodox religions, Muslims, Jehovah's Witnesses, and Orthodox Jews. Some groups, such as Hindus, may oppose autopsy based on not wanting non-Hindus to touch the body (Carpenter et al., 2011). Some religions prohibit the removal of body parts or dictate that all body parts be given appropriate burial. Organ donation is prohibited by Jehovah's Witnesses and Muslims, whereas Buddhists in America consider it an act of mercy and encourage it. However, in general the most significant factor in the decision to donate a family member's organs is how religious the consentor is (Ashkenazi & Klein, 2012). Cremation is discouraged, opposed, or prohibited by the Bahá'í, Mormon, Eastern Orthodox, Islamic, and Roman Catholic faiths. Hindus, in contrast, prefer cremation and cast the ashes in a holy river. Prolongation of life is generally encouraged; however, some religions, such as Christian Science, are unlikely to recommend medical means to prolong life, and the Jewish faith generally opposes prolonging life after irreversible brain damage. In hopeless illness, Buddhists may permit euthanasia.

Nurses also need to be knowledgeable about the client's death-related rituals, such as last rites (Figure 43–2 ■), chanting at the bedside, and other practices, such as special procedures for washing, dressing, positioning, shrouding, and attending the dead. Certain cultures retain their native customs in which family members of the same sex wash and prepare the body for burial and cremation. Muslims also customarily turn the body toward Mecca. In several religions, the body cannot be left unattended while awaiting burial and individuals may be hired to sit with the body if family members do not perform this duty. Nurses need to ask family members about their preference and verify who will carry out these activities. Burial clothes and other cultural or religious items are often important symbols for the funeral. Mormons are often dressed in their “temple clothes.” Some Native Americans may be dressed in elaborate apparel and jewelry and wrapped in new blankets with money. The nurse must ensure that any ritual items present in the health care agency are returned to the family or to the funeral home.

●○○ NURSING MANAGEMENT

Assessing

To gather a complete database that allows accurate analysis and identification of appropriate nursing diagnoses for dying clients and their families, the nurse first needs to recognize the states of awareness manifested by the client and family members.

In cases of terminal illness, the state of awareness shared by the dying person and the family affects the nurse's ability to communicate freely with clients and other health care team members and to assist

Figure 43–2 ■ Catholic clients may request last rites or the sacrament of the sick.

Dennis MacDonald/PhotoEdit.

in the grieving process. Three types of awareness that have been described are closed awareness, mutual pretense, and open awareness (Glaser & Strauss, 1965).

In **closed awareness**, the client is not made aware of impending death. The family may choose this because they do not completely understand why the client is ill or they believe the client will recover. The primary care provider may believe it is best not to communicate a diagnosis or prognosis to the client. Nursing personnel may experience an ethical problem in this situation. See Chapter 5 ∞ for further information on ethical dilemmas.

With **mutual pretense**, the client, family, and health care personnel know that the prognosis is terminal but do not talk about it and make an effort not to raise the subject. Sometimes the client refrains from discussing death to protect the family from distress. The client may also sense discomfort on the part of health care personnel and therefore not bring up the subject. Mutual pretense permits the client a degree of privacy and dignity, but it places a heavy burden on the dying person, who then has no one in whom to confide.

With **open awareness**, the client and others know about the impending death and feel comfortable discussing it, even though it is difficult. This awareness provides the client an opportunity to finalize affairs and even participate in planning funeral arrangements.

Not all people are comfortable with open awareness. Some believe that terminal clients acquire knowledge of their condition even if they are not directly informed. Others believe that clients remain unaware of their condition until the end. It is difficult, however, to distinguish what clients know from what they will accept or acknowledge.

Federal law requires health care providers to determine clients' end-of-life care wishes using an advance health care directive

CLINICAL MANIFESTATIONS

Signs of Impending Clinical Death

LOSS OF MUSCLE TONE

- Relaxation of the facial muscles (e.g., the jaw may sag)
- Difficulty speaking
- Difficulty swallowing and gradual loss of the gag reflex
- Decreased activity of the gastrointestinal tract, with subsequent nausea, accumulation of flatus, abdominal distention, and retention of feces, especially if narcotics or tranquilizers are being administered
- Possible urinary and rectal incontinence due to decreased sphincter control
- Diminished body movement

SLOWING OF THE CIRCULATION

- Diminished sensation
- Mottling and cyanosis of the extremities
- Cold skin, first in the feet and later in the hands, ears, and nose (the client, however, may feel warm if there is a fever)
- Slower and weaker pulse
- Decreased blood pressure

CHANGES IN RESPIRATIONS

- Rapid, shallow, irregular, or abnormally slow respirations
- Noisy breathing, referred to as the death rattle, due to collecting of mucus in the throat
- Mouth breathing, dry oral mucous membranes

SENSORY IMPAIRMENT

- Blurred vision
- Impaired senses of taste and smell

(see Chapter 4 ∞). This document describes preferences for future treatment, whether or not the client is currently unwell. For individuals already diagnosed with serious, progressive, or chronic illnesses, almost every U.S. state uses an additional document known as the Physician Orders for Life-Sustaining Treatment (POLST). The POLST is signed by both the client or health care decision maker and the primary care provider, and specifies current preferences for resuscitation; medical interventions such as comfort measures, intravenous medications, and noninvasive airway support; and artificial nutrition. This document remains with the client when transferred to different levels of care.

Nursing care and support for the dying client and family include making an accurate assessment of the physiological signs of approaching death. Besides signs related to the client's specific disease, certain other physical signs indicate impending death. The four main characteristic changes are loss of muscle tone, slowing of the circulation, changes in respirations, and sensory impairment. Clinical Manifestations lists indications of impending clinical death.

Various levels of consciousness may exist just before death. Some clients are alert, whereas others are drowsy, stuporous, or comatose. Hearing is thought to be the last sense lost.

As death approaches, the nurse assists the family and other significant people to prepare. Depending in part on knowledge of the person's state of awareness, the nurse asks questions that help identify ways to provide support during the period before and after death. In particular, the nurse needs to know what the family expects to happen when the person dies so accurate information can be given at the appropriate depth. See the Assessment Interview for sample interview questions. When the family members know what to expect, they may better support the dying person and others who are grieving. In addition, they may make certain decisions about events surrounding the death such as whether they will want to view the body after death.

Diagnosing

A range of nursing diagnoses, addressing both physiological and psychosocial needs, can apply to the dying client, depending on the assessment data. Diagnoses that may be particularly appropriate for the dying client are *Fear*, *Hopelessness*, and *Powerlessness*. In addition, *Risk for Caregiver Role Strain* and *Interrupted Family Processes* are not uncommon diagnoses for caregivers and family members.

Planning

Major goals for dying clients are (a) maintaining physiological and psychological comfort and (b) achieving a dignified and peaceful death, which includes maintaining personal control and accepting declining health status. When planning care with these clients, the Dying Person's Bill of Rights (Box 43-1) can be a useful guide.

BOX 43-1 The Dying Person's Bill of Rights

- I have the right to be treated as a living human being until I die.
- I have the right to maintain a sense of hopefulness however changing its focus may be.
- I have the right to express my feelings and emotions about my approaching death in my own way.
- I have the right to participate in decisions concerning my care.
- I have the right to expect continuing medical and nursing attention even though cure goals must be changed to comfort goals.
- I have the right not to die alone.
- I have the right to be free from pain.
- I have the right to have my questions answered honestly.
- I have the right not to be deceived.
- I have the right to have help from and for my family in accepting my death.
- I have the right to die in peace and with dignity.
- I have the right to retain my individuality and not be judged for my decisions which may be contrary to the beliefs of others.
- I have the right to be cared for by caring, sensitive, knowledgeable people who will attempt to understand my needs and will be able to gain some satisfaction in helping me face my death.

From "The Dying Person's Bill of Rights," by A. J. Barbus, 1975, created at the workshop *The Terminally Ill Patient and the Helping Person*, Lansing, MI: South Western Michigan Inservice Education Council.

ASSESSMENT INTERVIEW The Family of the Dying Client

Ask the spouse, partner, or significant others:

- Have you ever been close to someone who was dying before?
- What have you been told about what may happen when death occurs?
- Do you have questions about what may happen at the time of death?
- How do you think you would like to say goodbye?
- How are you taking care of yourself during these times?
- Whom can you turn to for help at this time?
- Is there anyone you would like us to contact now or when the death occurs?

Planning for Home Care

People facing death may need help accepting that they have to depend on others. Some dying clients require only minimal care; others need continuous attention and services. People need help, well in advance of death, in planning for the period of dependence. They need to consider what will happen and how and where they would like to die.

Although 70% of Californians polled in 2011 stated that they would prefer to die at home, only 32% of the state's deaths occurred there. However, that is significantly higher than the 13% of Californians who died at home in 1989 (California Healthcare Foundation, 2012). A major factor in determining whether a person will die in a health care facility or at home is the availability of willing and able caregivers. If the dying person wishes to be at home, and family or others can provide care to maintain symptom control, the nurse should facilitate a referral to outpatient hospice services. Hospice staff and nurses will then conduct a full assessment of the home and care providers' skills.

Implementing

The major nursing responsibility for clients who are dying is to assist the client to a peaceful death. More specific responsibilities include the following:

- To minimize loneliness, fear, and depression
- To maintain the client's sense of security, self-confidence, dignity, and self-worth
- To help the client accept losses
- To provide physical comfort.

Helping Clients Die with Dignity

Nurses need to ensure that the client is treated with dignity, that is, with honor and respect. Dying clients often feel they have lost control over their lives and over life itself. Helping clients die with dignity involves maintaining their humanity, consistent with their values, beliefs, and culture. By introducing options available to the client and significant others, nurses can restore and support feelings of control. Some choices that clients can make are the location of care (e.g., hospital, home, or hospice facility), times of appointments with health professionals, activity schedule, use of health resources, and times of visits from relatives and friends.

Clients want to manage the events preceding death so they can die peacefully. Nurses can help clients to determine their own physical, psychological, and social priorities. Dying people often strive for self-fulfillment more than for self-preservation, and may need to find

meaning in continuing to live while suffering. Part of the nurse's challenge is to support the client's will and hope.

Although it is natural for people to be uncomfortable discussing death, steps can be taken to make such discussions easier for both the nurse and the client. Strategies include the following:

- Identify your personal feelings about death and how they may influence interactions with clients. Acknowledge personal fears about death, and discuss them with a friend or colleague.
- Focus on the client's needs. The client's fears and beliefs may differ from the nurse's. It is important for the nurse to avoid imposing personal fears and beliefs on the client or family.
- Talk to the client or family members about how the client usually copes with stress. Clients will use their usual coping strategies for dealing with impending death. For example, if they are usually quiet and reflective, they will become more quiet and withdrawn when facing terminal illness.
- Establish a communication relationship that shows concern for and commitment to the client. Communication strategies that let the client know you are available to talk about death include the following:
 - a. Describe what you see, for example, "You seem sad. Would you like to talk about what's happening to you?"
 - b. Clarify your concern, for example, "I'd like to know better how you feel and how I may help you."
 - c. Acknowledge the client's struggle, for example, "It must be difficult to feel so uncomfortable. I would like to help you be more comfortable."
 - d. Provide a caring touch. Holding the client's hand or offering a comforting massage can encourage the client to verbalize feelings.
- Determine what the client knows about the illness and prognosis.
- Respond with honesty and directness to the client's questions about death.
- Make time to be available to the client to provide support, listen, and respond.

Hospice and Palliative Care

The hospice movement was founded by the physician Cecily Saunders in London, England, in 1967. **Hospice** care focuses on support and care of the dying person and family, with the goal of facilitating a peaceful and dignified death. Hospice care is based on holistic concepts, emphasizes care to improve quality of life rather than cure, supports the client and family through the dying process, and supports the family through bereavement. Assessing the needs of

Evidence-Based Practice What Evidence Supports Nursing Actions That Provide Death with Dignity?

EVIDENCE-BASED PRACTICE

Nurses need to have evidence to support the efficacy of their interventions. This is particularly true when nursing actions combine to form a specialty practice such as end-of-life care. In this study, Brown, Johnston, and Östlund (2011) used a qualitative design based on a theoretical model to obtain data from clients, caregivers, and health care providers regarding those activities that supported dignity in dying. The researchers conducted six focus group interviews: two with nurses, one with physicians, one with clients, one with caregivers, and one with clients and caregivers combined. Responses were categorized under the headings of illness-related concerns (level of independence and symptom distress), dignity-conserving repertoire (dignity-conserving perspectives and dignity-conserving practices),

and social dignity inventory (privacy boundaries, social support, care tenor, burden to others, and aftermath concerns).

IMPLICATIONS

This research is an example of work that nurses need to do in order to move to an evidence-based approach to practice. The authors began by basing their inquiry on an existing framework (Chochinov model of dignity), which provides the third corner of the theory-research-practice structure. Although dying and death are obviously extremely personal experiences, this research demonstrates that there are themes of concerns and needs that can be used in developing nursing care planning.

Figure 43-3 ■ Family members may be closely involved in both physical and psychological support of the dying.
Jeff Greenberg/PhotoEdit.

the client's family is just as important as caring for the client who is receiving hospice care (Figure 43-3 ■). The condition of the client usually deteriorates, and attention needs to be focused on the caregivers to ensure that they are receiving support and resources as these changes occur. If the hospice team meets regularly, these needs can be discussed and interventions initiated. Physical needs are usually apparent, but emotional and behavioral signs are often more subtle. A good assessment and ongoing evaluation can help indicate when modifications or changes are needed.

The principles of hospice care can be carried out in a variety of settings, the most common being the home, the hospital, or a nursing home-based unit. Services focus on symptom control and pain management. Commonly, clients are eligible for hospice care or hospice insurance benefits when certified by a physician to be likely to die within 6 months. Hospice care is always provided by a team of both health professionals and nonprofessionals to ensure a full range of care services. The National Hospice and Palliative Care Organization (2013) reports that more than 1.5 million Americans access hospice services each year, representing approximately 45% of all deaths. Contrary to popular belief, only about 37% of hospice clients are diagnosed with cancer. The top four noncancer primary diagnoses for those admitted to hospice are unspecified debility, dementia, heart disease, and lung disease.

More than 18,000 nurses in the United States are nationally certified in hospice and palliative care (National Board for Certification of Hospice and Palliative Nurses, 2012).

Palliative care, as described by the World Health Organization,

is an approach that improves the quality of life of clients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual. Palliative care:

- provides relief from pain and other distressing symptoms;
- affirms life and regards dying as a normal process;
- intends neither to hasten nor postpone death;
- integrates the psychological and spiritual aspects of client care;
- offers a support system to help clients live as actively as possible until death;

- offers a support system to help the family cope during the client's illness and in their own bereavement;
- uses a team approach to address the needs of clients and their families, including bereavement counseling, if indicated;
- will enhance quality of life, and may also positively influence the course of illness;
- is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications. (n.d.)

“The palliative care service facilitates religious, spiritual, and cultural rituals or practices as desired by patient and family, especially at and after the time of death” (National Consensus Project for Quality Palliative Care, 2013, p. 30). This care may differ from hospice because the client is not necessarily believed to be imminently dying. Both hospice and palliative care can include **end-of-life care**, that is, the care provided in the final weeks before death.

Meeting the Physiological Needs of the Dying Client

The physiological needs of people who are dying are related to a slowing of body processes and to homeostatic imbalances. Interventions include providing personal hygiene measures; controlling pain; relieving respiratory difficulties; assisting with movement, nutrition, hydration, and elimination; and providing measures related to sensory changes (see Table 43-5).

Pain control is essential to enable clients to maintain some quality in their life and their daily activities, including eating, moving, and sleeping. Many drugs have been used to control the pain associated with terminal illness: morphine, heroin, methadone, and alcohol. Usually the primary care provider determines the dosage, but the client's opinion should be considered; the client is the one ultimately aware of personal pain tolerance and fluctuations of internal states. Because primary care providers usually prescribe dosage ranges for pain medication, nurses use their own judgment on the amount and frequency of pain medication in providing client relief. Because of decreased blood circulation, if analgesics cannot be administered orally, they are given topically, by intravenous infusion, sublingually, or rectally, rather than subcutaneously or intramuscularly. Clients on narcotic pain medications also require implementation of a protocol to treat opioid-induced constipation. See Chapter 46 ∞ for more on pain management.

Providing Spiritual Support

Spiritual support is of great importance in dealing with death. Although not all clients identify with a specific religious faith or belief, most have a need for meaning in their lives, particularly as they experience a terminal illness.

The nurse has a responsibility to ensure that the client's spiritual needs are attended to, either through direct intervention or by arranging access to individuals who can provide spiritual care. Nurses need to be aware of their own comfort with spiritual issues and be clear about their own ability to interact supportively with the client. Nurses have an ethical and moral responsibility to not impose their own religious or spiritual beliefs on a client but to respond to the client in relation to the client's own background and needs. Communication skills are most important in helping the client articulate needs and in developing a sense of caring and trust.

TABLE 43–5 Physiological Needs of Dying Persons

Problem	Nursing Care
Airway clearance	Fowler's position: conscious clients Throat suctioning: conscious clients Lateral position: unconscious clients Nasal oxygen for hypoxic clients Anticholinergic medications may be indicated to help dry secretions
Air hunger	Open windows or use a fan to circulate air Morphine may be indicated in an acute episode
Bathing/hygiene	Frequent baths and linen changes if diaphoretic Mouth care as needed for dry mouth Liberal use of moisturizing creams and lotions for dry skin Moisture-barrier skin preparations for incontinent clients
Physical mobility	Assist client out of bed periodically, if able Regularly change client's position Support client's position with pillows, blanket rolls, or towels as needed Elevate client's legs when sitting up Implement pressure ulcer prevention program and use pressure-relieving surfaces as indicated
Nutrition	Antiemetics or a small amount of an alcoholic beverage to stimulate appetite Encourage liquid foods as tolerated
Constipation	Dietary fiber as tolerated Stool softeners or laxatives as needed
Urinary elimination	Skin care in response to incontinence of urine or feces Bedpan, urinal, or commode chair within easy reach Call light within reach for assistance onto bedpan or commode Absorbent pads placed under incontinent client; linen changed as often as needed Catheterization, if necessary Keep room as clean and odor free as possible
Sensory/perceptual changes	Check preference for light or dark room Hearing is not diminished; speak clearly and do not whisper Touch is diminished, but client will feel pressure of touch Implement pain management protocol if indicated

Interventions may include facilitating expressions of feeling, prayer, meditation, reading, and discussion with clergy or a spiritual adviser. It is important for nurses to establish an effective interdisciplinary relationship with spiritual support specialists. For a further discussion of spiritual issues, see Chapter 41 .

Supporting the Family

The most important aspects of providing support to the family members of a dying client involve using therapeutic communication to facilitate their expression of feelings. When nothing can reverse the inevitable dying process, the nurse can provide an empathetic and caring presence. The nurse also serves as a teacher, explaining what is happening and what the family can expect. Due to the stress of moving through the grieving process, family members may not absorb what they are told and may need to have information provided repeatedly. The nurse must have a calm and patient demeanor.

CLINICAL ALERT!

Individuals who have experienced the deaths of multiple significant others, such as members of the AIDS community, do not necessarily feel the loss or grieve any more or less than those who have experienced fewer deaths.

Family members should be encouraged to participate in the physical care of the dying person as much as they wish to and are able. The nurse can suggest they assist with bathing, speak or read to

the client, and hold hands. The nurse must not, however, have specific expectations for family members' participation. The dying and the family must be allowed as much privacy as they desire in order to meet their needs for physical and emotional intimacy. Those who feel unable to care for or be with the dying person also require support from the nurse and from other family members. They should be shown an appropriate waiting area if they wish to remain nearby.

Sometimes, it seems as if the client is "holding on," possibly out of concern for the family not being ready for the client to die. It may be therapeutic for both the client and the family for the family to verbally give permission to the client to "let go," to die when he or she is ready. This is a painful process, and the nurse must be prepared to encourage and support the family through saying their last good-byes.

CLINICAL ALERT!

Even when the client appears unresponsive, the nurse must always provide high-quality care. Though the client is dying, and actions may seem futile, the client deserves respect and appropriate interventions. Nurses don't provide *less* care to dying clients, just *different* care.

After the client dies, the family should be encouraged to view the body (with or without a nurse present), because this has been shown to facilitate the grieving process (Williams, Lewis, Burgio, & Goode, 2012). They may wish to clip a lock of hair as a remembrance. Children should be included in the events surrounding the death if they wish to. If the family was not present prior to the death, they

may have questions about events surrounding the final hours that the nurse should answer sensitively and honestly.

Postmortem Care

Rigor mortis is the stiffening of the body that occurs about 2 to 4 hours after death. Rigor mortis starts in the involuntary muscles (heart, bladder, and so on), then progresses to the head, neck, and trunk, and finally reaches the extremities.

Because the deceased person's family often wants to view the body, and because it is important that the deceased appear natural and comfortable, nurses need to place the body in an anatomic position, place dentures in the mouth, and close the eyes and mouth before rigor mortis sets in. Rigor mortis usually leaves the body about 96 hours after death.

Algor mortis is the gradual decrease of the body's temperature after death. When blood circulation terminates and the hypothalamus ceases to function, body temperature falls about 1°C (1.8°F) per hour until it reaches room temperature. Simultaneously, the skin loses its elasticity and can easily be broken when removing dressings and adhesive tape.

After blood circulation has ceased, the red blood cells break down, releasing hemoglobin, which discolors the surrounding tissues. This discoloration, referred to as **livor mortis**, appears in the lowermost or dependent areas of the body.

Tissues after death become soft and eventually liquefied by bacterial fermentation. The hotter the temperature, the more rapid the change. Therefore, bodies are often stored in cool places to delay this process. Embalming prevents the process through injection of chemicals into the body to destroy the bacteria.

Nursing personnel may be responsible for care of a body after death. Postmortem care should be carried out according to the policy of the hospital or agency. Because care of the body may be influenced by religious law, the nurse should check the client's religion and make every attempt to comply. If the deceased's family or friends wish to view the body, make the environment clean and pleasant and to make the body appear natural and comfortable. All equipment, soiled linen, and supplies should be removed from the bedside. Some agencies require that all tubes in the body remain in place; in other agencies, tubes may be cut to within 2.5 cm (1 in.) of the skin and taped in place; in others, all tubes may be removed.

Normally the body is placed in a supine position with the arms either at the sides, palms down, or across the abdomen. One pillow

is placed under the head and shoulders to prevent blood from discoloring the face by settling in it. The eyelids are closed and held in place for a few seconds so they remain closed. Dentures are usually inserted to help give the face a natural appearance. The mouth is then closed.

Soiled areas of the body are washed; however, a complete bath is not necessary, because the body will be washed by the **mortician** (also referred to as an **undertaker**), a person trained in care of the dead. Absorbent pads are placed under the buttocks to take up any feces and urine released because of relaxation of the sphincter muscles. A clean gown is placed on the client, and the hair is arranged. All jewelry is removed, except a wedding band in some instances, which is taped to the finger. The top bed linens are adjusted neatly to cover the client to the shoulders. Soft lighting and chairs are provided for the family.

In the hospital, after the body has been viewed by the family, the deceased's wrist identification tag is left on and additional identification tags are applied. The body is wrapped in a **shroud**, a large piece of plastic or cotton material used to enclose a body after death. Identification is then applied to the outside of the shroud. The body is taken to the morgue if arrangements have not been made to have a mortician pick it up from the client's room. Nurses have a duty to handle the deceased with dignity and to label the corpse appropriately. Mishandling can cause emotional distress to survivors. Mislabeling can create legal problems if the body is inappropriately identified and prepared incorrectly for burial or a funeral.

Evaluating

To evaluate the achievement of client goals, the nurse collects data in accordance with the desired outcomes established in the planning phase. Evaluation activities may include the following:

- Listening to the client's reports of feeling in control of the environment surrounding death, such as control over pain relief, visitation of family and support people, or treatment plans
- Observing the client's relationship with significant others
- Listening to the client's thoughts and feelings related to hopelessness or powerlessness.

Some of the special needs of older adults and their families during death and dying are found in Lifespan Considerations.

LIFESPAN CONSIDERATIONS Responses to Death

CHILDREN

- Children's response to death or loss depends on the messages they get from adults and others around them as well as their understanding of death. When adults are able to cope effectively with a death, they are more likely to be able to support children through the process.
- As children develop, they will "reprocess" their grieving around a loss or death. Preschoolers who have lost a parent, for example, often reconceptualize their understanding of that loss when they reach school age and adolescence and have greater cognitive and emotional skills. The same process occurs with parents who have lost a child to death; as the years pass and the child "would have been in first grade," for example, parents must cope with the added dimensions of the loss.

OLDER ADULTS

Older adults who are dying often have a need to know that their lives had meaning. An excellent way to assure them of this is to make recordings of them telling stories of their lives. This gives the client a sense of value and worth and also lets him or her know that family members and friends will also benefit from it. Doing this with children and grandchildren often eases communication and support during this difficult time.

Caregivers of a dying person need ongoing support and ongoing teaching as the client's condition changes. Some of these needs are teaching:

- Ways to feed the client when swallowing becomes difficult
- Ways to transfer and reposition the client safely
- Ways to communicate if verbalization becomes more difficult
- Nonpharmacologic methods of pain control
- Comfort measures, such as frequent oral care and frequent repositioning
- When and whom to call if the client's condition changes.

Critical Thinking Checkpoint

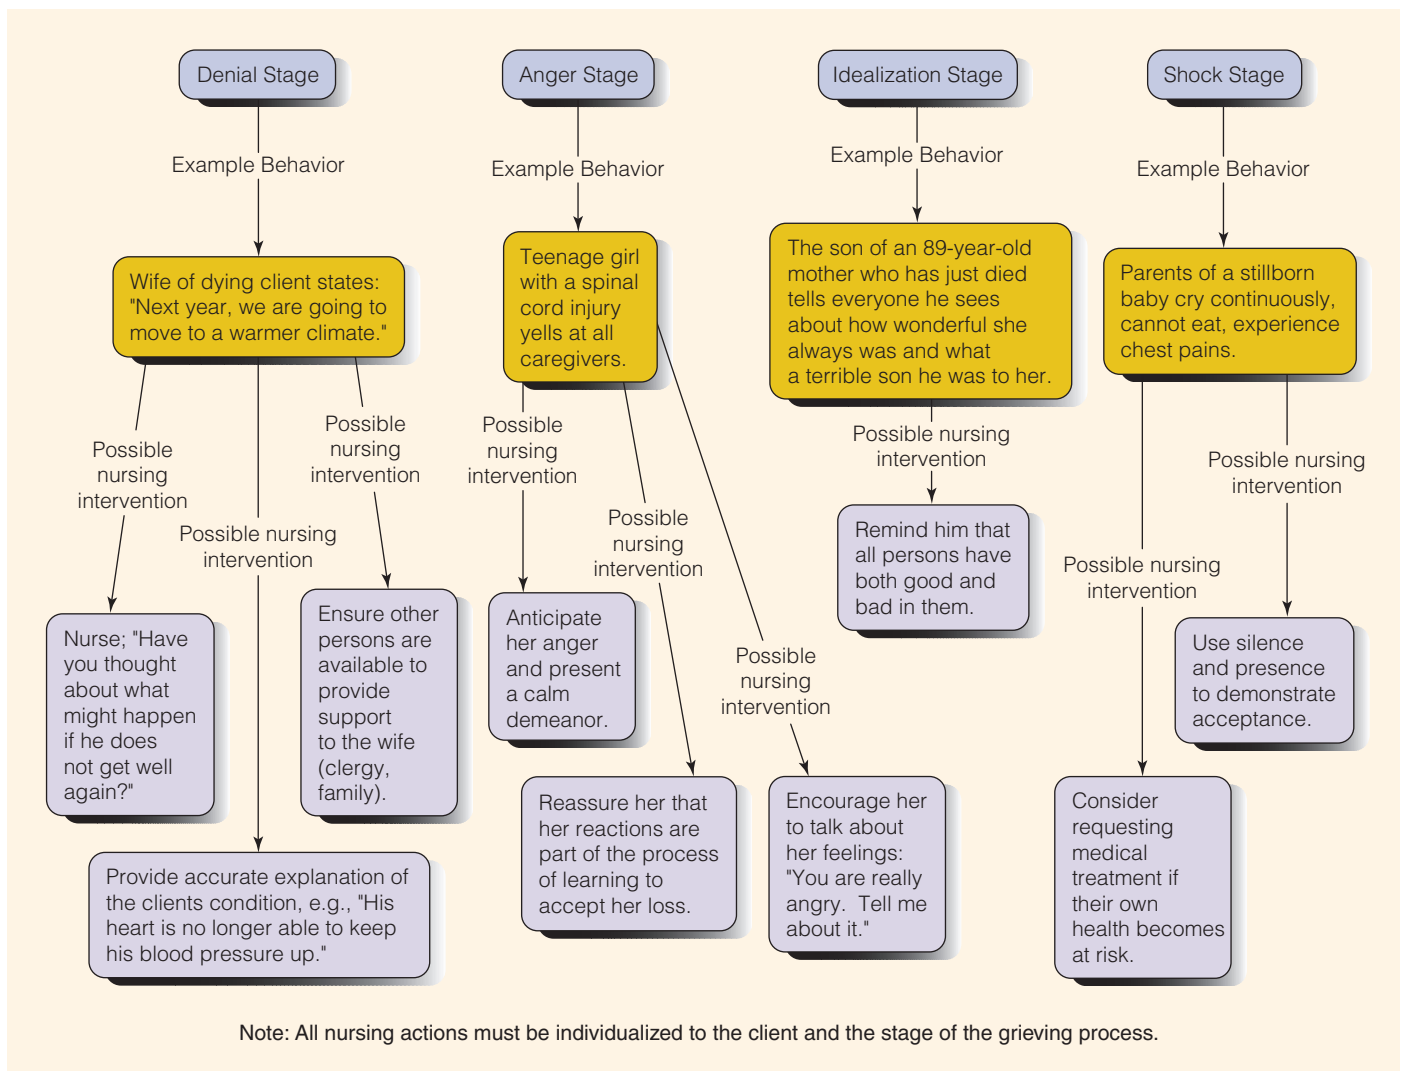

Mrs. Govinda, 75, was admitted to the hospital after repeated episodes of pneumonia. Despite aggressive antibiotic therapy, her condition rapidly deteriorated and she died unexpectedly 1 week after being admitted to the hospital. Mrs. Govinda's oldest son, who lived nearby and frequently cared for his mother, arranged for the funeral and visited with relatives. He misses his mother and cries occasionally but managed to return to work the following week. The youngest son had difficulty attending the funeral, has been unable to sleep or eat, cannot concentrate at work, and cannot believe that his mother is dead. The middle son did not weep at the funeral and had little to say to his brothers or other relatives. He returned home to another state but has remained distant. He is back to work but feels very fatigued and apathetic.

1. From the data provided, describe the phase of bereavement being experienced by each of the three surviving sons.
2. What factors may have affected how each of the sons reacted to the death of their mother?
3. What cues, other than physical signs, might have indicated that Mrs. Govinda was dying, even though her death was unexpected?
4. With the diagnosis of pneumonia, a respiratory infection, what physiological (palliative) needs might she have had?
5. How might your own feelings about death affect the care you provide to the dying client?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

The Grieving Client

Chapter 43 Review

CHAPTER HIGHLIGHTS

- Nurses help clients deal with many losses, including loss of body image, a loved one, a sense of well-being, or a job.
- Loss, especially loss of a loved one or a valued body part, can be viewed as either a situational or a developmental loss and as either an actual or a perceived loss (both of which can be anticipatory).
- Grieving is a normal, subjective emotional response to loss; it is essential for mental and physical health. Grieving allows the bereaved person to cope with loss gradually and to accept it as part of reality.
- Knowledge of different stages or phases of grieving and factors that influence the loss reaction can help the nurse understand the responses and needs of clients.
- How an individual deals with loss is closely related to the individual's age, culture, spiritual beliefs, gender, socioeconomic status, support systems, and the significance and cause of the loss or death.
- Caring for the dying and the bereaved is one of the nurse's most complex and challenging responsibilities.
- Nurses' attitudes about death and dying directly affect their ability to provide care.
- Nurses must consider the entire family as requiring care in situations involving loss, especially death.
- Dying clients require open communication, physical help, and emotional and spiritual support to ensure a peaceful and dignified death. They need to maintain a sense of control in managing the events preceding death.

TEST YOUR KNOWLEDGE

1. Which of the following may be considered normal or "healthy" types of grief? Select all that apply.
 1. Abbreviated grief
 2. Anticipatory grief
 3. Disenfranchised grief
 4. Complicated grief
 5. Unresolved grief
 6. Inhibited grief
2. A client's family tells the nurse that their culture does not permit a dead person to be left alone before burial. Hospital policy states that after 6:00 pm when mortuaries are closed, bodies are to be stored in the hospital morgue refrigerator until the next day. How would the nurse best manage this situation?
 1. Gently explain the policy to the family and then implement it.
 2. Inquire of the nursing supervisor how an exception to the policy could be made.
 3. Call the client's primary care provider for advice.
 4. Move the deceased to an empty room and assign an aide to stay with the body.
3. The shift changed while the nursing staff was waiting for the adult children of a deceased client to arrive. The oncoming nurse has never met the family. Which of the following initial greetings is most appropriate?
 1. "I'm very sorry for your loss."
 2. "I'll take you in to view the body."
 3. "I didn't know your father but I am sure he was a wonderful person."
 4. "How long will you want to stay with your father?"
4. At which age does a child begin to accept that he or she will someday die?
 1. Less than 5 years old
 2. 5–9 years old
 3. 9–12 years old
 4. 12–18 years old
5. An 82-year-old man has been told by his primary care provider that it is no longer safe for him to drive a car. Which statement by the client would indicate beginning positive adaptation to this loss?
 1. "I told the doctor I would stop driving, but I am not going to yet."
 2. "I always knew this day would come, but I hoped it wouldn't be now."
 3. "What does he know? I'm a better driver than he will ever be."
 4. "Well, at least I have friends and family who can take me places."
6. When asked to sign the permission form for surgical removal of a large but noncancerous lesion on her face, the client begins to cry. Which of the following is the most appropriate response?
 1. "Tell me what it means to you to have this surgery."
 2. "You must be very glad to be having this lesion removed."
 3. "I cry when I am happy or relieved sometimes, too."
 4. "Isn't it wonderful that the lesion is not cancer?"
7. A nursing care plan includes the desired outcome of "quality of life" for a client with a chronic degenerative illness who is likely to live for many more years. Which of the following is one example that would indicate the outcome has been met?
 1. The client demonstrates having adequate financial resources to pay for health care for many more years.
 2. The client spends the majority of his or her time in spiritual reflection.
 3. The client has no signs or symptoms of preventive complications of the illness.
 4. The client verbalizes satisfaction with current relationships with other people.

8. The nurse is caring for a family in a shelter 2 days after the loss of their home due to a fire. The fire caused minor burns to several members of the family but no life-threatening conditions. Which of the following is the *most* important assessment data for the nurse to gather at this time?
1. Availability of insurance coverage for rebuilding the house
 2. Family members' understanding of the extent of their physical injuries
 3. Psychological support resources available from friends or other sources
 4. Family members' grief responses and coping behaviors
9. The client has been close to death for some time and the family asks how the nurse will know when the client has actually died. Which of the following would be the most accurate response from the nurse?
1. When the blood pressure can no longer be measured
 2. When the gag reflex is no longer present
 3. When there is no apical pulse
 4. When the extremities are cool and dark in color
10. In working with a dying client, the nurse demonstrates assisting the client to die with dignity when performing which action?
1. Allows the client to make as many decisions about care as is possible
 2. Shares with the client the nurse's own views about life after death
 3. Avoids talking about dying and focuses on the present
 4. Relieves the client of as much responsibility for self-care as is possible

Meeting the Standards

In this unit, we learned about sensory perception, self-concept, sexuality, spirituality, stress and coping, and loss, grieving, and death. All are essential concepts that a nurse needs to consider to care properly for a client. Often, the nurse finds these topics challenging because they are somewhat abstract and involve the intangible core aspects of what makes us individuals. In the case below, you will explore how two nursing standards guide the nurse in professional practice and in providing safe, quality care.

CLIENT: Christina AGE: 72 CURRENT MEDICAL DIAGNOSIS: Breast cancer

Medical History: Christina was diagnosed with an early-stage common form of breast cancer 4 years ago. She had removal of the lump, followed by radiation therapy and oral chemotherapy. She has no current symptoms of her cancer and is tolerating the chemotherapy without difficulty. She has no other significant health conditions. The 5-year survival projection for women with similar breast cancers is 95% and the 10-year survival rate is 82%.

Personal and Social History: Christina is retired from employment and lives with her retired husband and their cats. Their

socioeconomic status is middle class. They have Social Security, Medicare, and sufficient retirement savings.

Christina is your client in the same-day surgery unit where she is being seen for a biopsy of a new lump in her breast. During your admission interview and assessment, you identify several areas requiring nursing care planning. Christina is very anxious as shown by her elevated blood pressure and pulse, perspiration, and nervous movements. She says to you “I just know this is cancer again. It must be that deodorant I use. Or, maybe it’s the electrical wires near our house. Or, just God punishing me for bad thoughts. What do you think?”

Questions

1. How might you respond to Christina? What have you learned about stress, loss and grieving, spirituality, and other similar concepts in this unit that can assist you in providing a helpful response?

American Nurses Association Standard of Professional Performance #12 is Leadership: *The registered nurse demonstrates leadership in the professional practice setting and the profession. Two of the many competencies are that the nurse (a) oversees the nursing care given by others while retaining accountability for the quality of care given to the health care consumer, and (b) treats others with respect, trust, and dignity.*

When you examine Christina’s breasts in preparing the biopsy site, she avoids meeting your eyes. She says, quietly, “I know you don’t want to hear about my troubles, but I don’t think my husband finds me attractive anymore.”

2. What response might you make that exemplifies the two competencies above and your learning from this unit?

American Nurses Association Standard of Professional Performance #16 is Environmental Health: *The registered nurse practices in an environmentally safe and healthy manner. The competencies include that the registered nurse (a) participates in strategies that promote health and healing, including assessing*

the practice environment for factors such as sound, noise, and light; (b) communicates environmental health risks and exposure reduction strategies to health care consumers, families, colleagues, and communities; and (c) utilizes scientific evidence to determine if a product or treatment is a potential environmental threat.

3. Considering the standard, what categories of possible interventions might you consider for a nursing diagnosis and goal focused on Christina’s need for a healing environment?

Another competency in the Environmental Health standard states that the nurse demonstrates commitment to continuous, lifelong learning and education for self and others.

4. During your care of Christina, you realize that you are insufficiently knowledgeable about breast cancer treatment effects. You wonder about the sensation in the breast after radiation therapy (for both Christina and her husband) and the support systems that would be in place for the many breast cancer survivors who might be worrying about a recurrence. Describe the various ways you might investigate answers to these questions by interacting with your colleagues.

UNIT 10

Promoting Physiological Health

-  **44** Activity and Exercise 1010
-  **45** Sleep 1066
-  **46** Pain Management 1086
-  **47** Nutrition 1127
-  **48** Urinary Elimination 1174
-  **49** Fecal Elimination 1210
-  **50** Oxygenation 1241
-  **51** Circulation 1287
-  **52** Fluid, Electrolyte, and Acid–Base Balance 1308

44 Activity and Exercise

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe four basic elements of normal movement.
2. Differentiate isotonic, isometric, isokinetic, aerobic, and anaerobic exercise.
3. Compare the effects of exercise and immobility on body systems.
4. Identify factors influencing a person's body alignment and activity.
5. Assess activity-exercise pattern, body alignment, gait, appearance and movement of joints, mobility capabilities and limitations, muscle mass and strength, activity tolerance, and problems related to immobility.
6. Develop nursing diagnoses and outcomes related to activity, exercise, and mobility problems.
7. Use safe practices when positioning, moving, transferring, and ambulating clients.
8. Compare and contrast active, passive, and active-assistive range-of-motion (ROM) exercises.
9. Describe client teaching for clients who use mechanical aids for walking.
10. Verbalize the steps used in:
 - a. Moving a client up in bed.
 - b. Turning a client to the lateral or prone position in bed.
 - c. Logrolling a client.
 - d. Assisting a client to sit on the side of the bed.
 - e. Transferring between bed and chair.
 - f. Transferring between bed and stretcher.
 - g. Assisting a client to ambulate.
11. Recognize when it is appropriate to delegate aspects of moving, transferring, and ambulating a client to unlicensed assistive personnel.
12. Demonstrate appropriate documentation and reporting of moving, transferring, and ambulating a client.

INTRODUCTION

Whether we engage our diaphragm muscle to improve oxygenation and immune function, walk a labyrinth to achieve greater peace of mind, or practice yoga while lying in bed, our ability to move is an essential aspect of our well-being. Psychophysiological self-regulation and overall health are affected by our activities. At the 2005–2006 North American Nursing Diagnosis Association (NANDA) Conference, the diagnosis *Sedentary Lifestyle* was approved, underscoring the role of exercise and activity as an essential component of health.

Many *Healthy People 2020* (U.S. Department of Health and Human Services, 2013) objectives pertain to exercise and activity. Moderate exercise is identified as significant to enhancing physical fitness. Examples of exercise and activity objectives include reducing the proportion of adults who engage in no leisure-time physical activity, increasing the proportion of adolescents who participate in daily school physical education, increasing the proportion of adults who meet current federal physical activity guidelines for aerobic physical activity and for muscle strength training, increasing the proportion of trips made by walking and bicycling, and increasing the proportion

of school districts that require or recommend elementary school recess for an appropriate period of time.

A strong, well-developed body of research evidence supports the role of exercise in improving the health status of individuals with cardiovascular disease, pulmonary dysfunction, disabilities of aging, and depression. Integrating well-researched exercise protocols with conventional nursing and medical approaches will result in optimal treatment of these common disorders. Evidence shows that habitual exercise can prevent and even reverse many of the chronic diseases experienced by aging adults. A growing body of research supports the preventive and therapeutic effects of exercise for individuals with hypertension, osteoporosis, coronary heart disease, mental health disorders, diabetes, cancer, arthritis, chronic fatigue syndrome, fibromyalgia, menopause, urinary incontinence, and HIV/AIDS (Autenrieth et al., 2013; Brown, Riddell, Macpherson, Canning, & Kuk, 2013; Farinatti, Borges, Gomes, Lima, & Fleck, 2010).

An **activity-exercise pattern** refers to a person's routine of exercise, activity, leisure, and recreation. It includes (a) activities of daily living (ADLs) that require energy expenditure such as hygiene, dressing, cooking, shopping, eating, working, and home maintenance, and (b) the type, quality, and quantity of exercise, including sports.

Mobility, the ability to move freely, easily, rhythmically, and purposefully in the environment, is an essential part of living. People must move to protect themselves from trauma and to meet their basic needs. Mobility is vital to independence; a fully immobilized person is as vulnerable and dependent as an infant.

People often define their health and physical fitness by their activity because mental well-being and the effectiveness of body functioning depend largely on their mobility status. For example, when a person is upright, the lungs expand more easily, intestinal activity (peristalsis) is more effective, and the kidneys are able to empty completely. In addition, motion is essential for proper functioning of bones and muscles.

The ability to move without pain also influences self-esteem and body image. For most people, self-esteem depends on a sense of independence and a feeling of usefulness or being needed. People with mobility impairments may feel helpless and burdensome to others, and their ability to work and earn a living may be compromised. Painful mobility makes coping even more difficult. Body image can be altered by paralysis, amputations, or any motor impairment. The reaction of others to impaired mobility can also alter self-esteem and body image significantly.

For those with impaired mobility, movement must be fostered to the full extent of capability to facilitate a satisfying life. For example, many individuals who have impairments or use wheelchairs participate in athletics to experience the joys of competition and fitness. Many individuals with paralysis can use a hand control to enter and drive adapted vans or use their mouth to manipulate a paintbrush and create art. No matter what their level of mobility, they must be encouraged to breathe fully, engage their abdominal muscles, and move as much as possible to prevent the physical and psycho-emotional hazards of immobility.

NORMAL MOVEMENT

Normal movement and stability are the result of an intact musculoskeletal system, an intact nervous system, and intact inner ear structures responsible for equilibrium. Body movement requires

coordinated muscle activity and neurologic integration. It involves four basic elements: body alignment (posture), joint mobility, balance, and coordinated movement.

Alignment and Posture

Proper body alignment and posture bring body parts into position in a manner that promotes optimal balance and maximal body function whether the client is standing, sitting, or lying down. A person maintains balance as long as the **line of gravity** (an imaginary vertical line drawn through the body's center of gravity) passes through the **center of gravity** (the point at which all of the body's mass is centered) and the **base of support** (the foundation on which the body rests). In humans, the usual line of gravity begins at the top of the head and falls between the shoulders, through the trunk, slightly anterior to the sacrum, and between the weight-bearing joints and base of support (Figure 44-1 ■).

When the body is well aligned, strain on the joints, muscles, tendons, or ligaments is minimized and internal structures and organs are supported. Proper body alignment enhances lung expansion and promotes efficient circulatory, renal, and gastrointestinal functions. A person's posture is one criterion for assessing general health, physical fitness, and attractiveness. Posture reflects the mood, self-esteem, and personality of an individual, and vice versa.

Abdominal and skeletal muscles function almost continuously, making tiny adjustments that enable an erect or seated posture despite the endless downward pull of gravity. The extensor muscles, often referred to as the *antigravity muscles*, carry the major load as they keep the body upright.

Figure 44-1 ■ The center of gravity and the line of gravity influence standing alignment.

Joint Mobility

Joints are the functional units of the musculoskeletal system. The bones of the skeleton articulate at the joints, and most of the skeletal muscles attach to the two bones at the joint. These muscles are categorized according to the type of joint movement they produce on contraction. Muscles are therefore called flexors, extensors, internal rotators, and the like. The flexor muscles are stronger than the extensor muscles. Thus, when a person is inactive, the joints are pulled into a flexed (bent) position. If this tendency is not counteracted with exercise and position changes, the muscles permanently shorten, and the joint becomes fixed in a flexed position (contracture). Types of joint movement are listed in Table 44–1.

The **range of motion (ROM)** of a joint is the maximum movement that is possible for that joint. Joint range of motion varies from individual to individual and is determined by genetic makeup, developmental patterns, the presence or absence of disease, and the amount of physical activity in which the person normally engages. Table 44–2 shows the various joint movements and the usual ranges of motion.

Balance

The mechanisms involved in maintaining balance and posture are complex and involve informational inputs from the labyrinth (inner ear), from vision (vestibulo-ocular input), and from stretch receptors of muscles and tendons (vestibulospinal input). Mechanisms of equilibrium (sense of balance) respond, frequently without our awareness, to various head movements. The labyrinth consists of the cochlea, vestibule, and semicircular canals. The cochlea is concerned

with hearing, and the vestibule and semicircular canals with equilibrium. Under normal conditions the equilibrium receptors in the semicircular canals and vestibule, collectively called the vestibular apparatus, send signals to the brain that initiate reflexes needed to make required changes in position. The receptors, hairlike cells, respond to displacement of the head in any direction. When the head moves, the fluid flow within the vestibule and semicircular canals stimulates sensory hair cells. Information from these balance receptors goes directly to reflex centers in the brainstem rather than to the cerebral cortex as with other special senses. This enables fast reflexive responses to a body imbalance. **Proprioception** is the term used to describe awareness of posture, movement, and changes in equilibrium and the knowledge of position, weight, and resistance of objects in relation to the body.

Coordinated Movement

Balanced, smooth, purposeful movement is the result of proper functioning of the cerebral cortex, cerebellum, and basal ganglia. The cerebral cortex initiates voluntary motor activity, the cerebellum coordinates the motor activities of movement, and the basal ganglia maintain posture. The cerebral cortex operates movements, not muscles. The cortex, for example, may direct the arm to pick up a cup of coffee. The cerebellum, which operates below the level of consciousness, blends and coordinates the muscles involved in voluntary movement. It does not direct the movement but translates the “instructions” from the cerebral cortex into detailed actions by the many different muscles in the hand, arm, and shoulder. When a client’s cerebellum is injured, movements become clumsy, unsure, and uncoordinated.

TABLE 44–1 Types of Joint Movements

Movement	Action
Flexion	Decreasing the angle of the joint (e.g., bending the elbow)
Extension	Increasing the angle of the joint (e.g., straightening the arm at the elbow)
Hyperextension	Further extension or straightening of a joint (e.g., bending the head backward)
Abduction	Movement of the bone away from the midline of the body
Adduction	Movement of the bone toward the midline of the body
Rotation	Movement of the bone around its central axis
Circumduction	Movement of the distal part of the bone in a circle while the proximal end remains fixed
Eversion	Turning the sole of the foot outward by moving the ankle joint
Inversion	Turning the sole of the foot inward by moving the ankle joint
Pronation	Moving the bones of the forearm so that the palm of the hand faces downward when held in front of the body
Supination	Moving the bones of the forearm so that the palm of the hand faces upward when held in front of the body

FACTORS AFFECTING BODY ALIGNMENT AND ACTIVITY

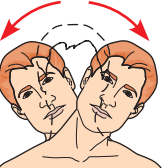

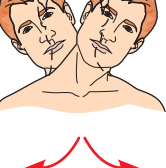

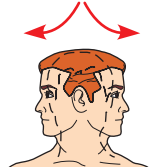

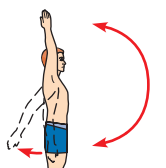

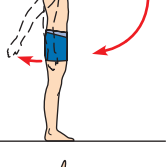

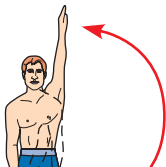

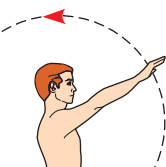

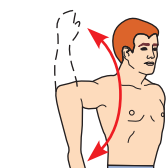

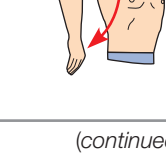

A number of factors affect an individual’s body alignment, mobility, and daily activity level. These include growth and development, nutrition, personal values and attitudes, certain external factors, and prescribed limitations.

Growth and Development

A person’s age and musculoskeletal and nervous system development affect posture, body proportions, body mass, body movements, and reflexes. Newborn movements are reflexive and random. All extremities are generally flexed but can be passively moved through a full range of motion. As the neurologic system matures, control over movement progresses during the first year. Gross motor development precedes fine motor skills. Gross motor development occurs in a head-to-toe fashion, that is, progression from head control, to crawling, to pulling up to a standing position, to standing, and to walking, usually after the first birthday. The contralateral motion of crawling, however brief, is an important building block for walking. Initially, walking involves a wide stance and unsteady gait, thus the term *toddler*. From ages 1 to 5 years, both gross and fine motor skills are refined. For example, preschoolers master riding a tricycle, dancing, running, jumping, using crayons to draw, fastening or using zippers, and brushing their teeth. Immobility can impair the social and motor development of young children.

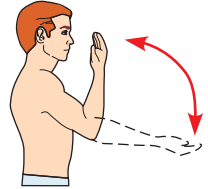

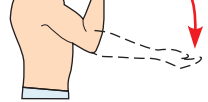

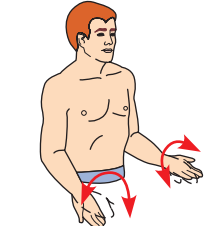

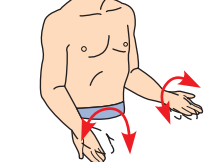

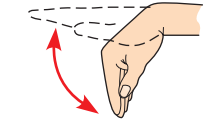

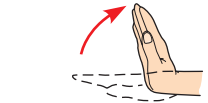

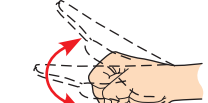

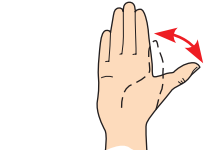

From 6 to 12 years of age, refinement of motor skills continues and exercise patterns for later life are generally determined. Many

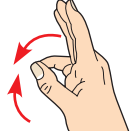

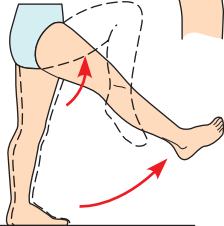

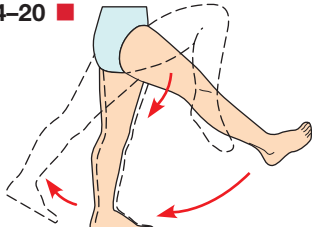

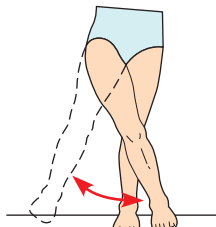

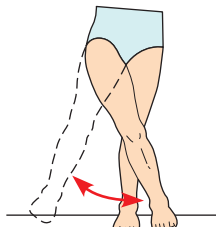

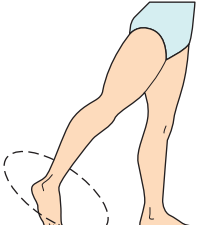

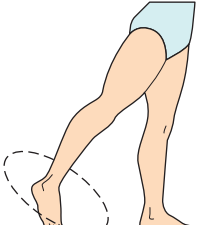

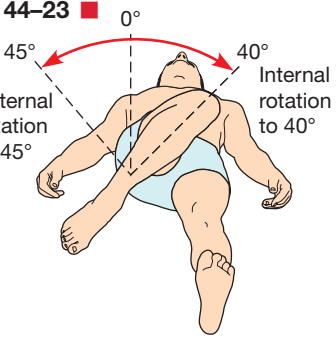

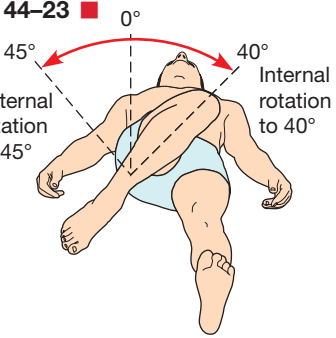

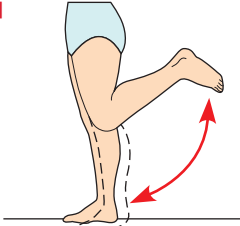

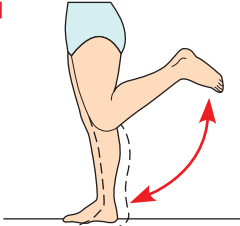

TABLE 44-2 Selected Joint Movements and Example of Corresponding Activity of Daily Living (ADL)

Body Part—Type of Joint/Movement	Normal Range and Example of Corresponding ADL	Illustration
NECK—PIVOT JOINT		
Flexion. Move the head from the upright midline position forward, so that the chin rests on the chest (Figure 44-2 ■).	45° from midline Example: nodding head “yes”	Figure 44-2 ■ 
Extension. Move the head from the flexed position to the upright position (Figure 44-2).	45° from midline Example: nodding head “yes”	Figure 44-3 ■ 
Hyperextension. Move the head from the upright position back as far as possible (Figure 44-2).	45° from midline	Figure 44-3 ■
Lateral flexion. Move the head laterally to the right and left shoulders (Figure 44-3 ■).	40° from midline	Figure 44-4 ■ 
Rotation. Turn the face as far as possible to the right and left (Figure 44-4 ■).	70° from midline Example: shaking head “no”	Figure 44-4 ■ 
SHOULDER—BALL-AND-SOCKET JOINT		
Flexion. Raise each arm from a position by the side forward and upward to a position beside the head (Figure 44-5 ■).	180° from the side Example: reaching to turn on overhead light	Figure 44-5 ■ 
Extension. Move each arm from a vertical position beside the head forward and down to a resting position at the side of the body (Figure 44-5).	180° from vertical position beside the head	Figure 44-6 ■ 
Hyperextension. Move each arm from a resting side position to behind the body (Figure 44-5).	50° from side position	Figure 44-6 ■
Abduction. Move each arm laterally from a resting position at the sides to a side position above the head, palm of the hand either toward or away from the head (Figure 44-6 ■).	180° Example: reaching to bedside stand on same side of bed as arm	Figure 44-7 ■ 
Adduction (anterior). Move each arm from a position at the sides across the front of the body as far as possible (Figure 44-6). The elbow may be straight or bent.	50° Example: reaching across body toward opposite side of bed	Figure 44-7 ■
Circumduction. Move each arm forward, up, back, and down in a full circle (Figure 44-7 ■).	360°	Figure 44-8 ■ 
External rotation. With each arm held out to the side at shoulder level and the elbow bent to a right angle, fingers pointing down, move the arm upward so that the fingers point up (Figure 44-8 ■).	90° Example: reaching over opposite shoulder to scratch upper back	Figure 44-8 ■ 
Internal rotation. With each arm held out to the side at shoulder level and the elbow bent to a right angle, fingers pointing up, bring the arm forward and down so that the fingers point down (Figure 44-8).	90° Example: reaching to scratch same side lower back	Figure 44-8 ■ 

(continued)

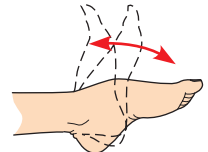

TABLE 44-2 Selected Joint Movements and Example of Corresponding Activity of Daily Living (ADL)—*continued*

Body Part—Type of Joint/Movement	Normal Range and Example of Corresponding ADL	Illustration
ELBOW—HINGE JOINT		
Flexion. Bring each lower arm forward and upward so that the hand is at the shoulder (Figure 44-9 ■).	150° Example: eating, bathing, shaving	Figure 44-9 ■ 
Extension. Bring each lower arm forward and downward, straightening the arm (Figure 44-9).	150° Example: eating, bathing, shaving	
Rotation for supination. Turn each hand and forearm so that the palm is facing upward (Figure 44-10 ■).	70° to 90°	Figure 44-10 ■ 
Rotation for pronation. Turn each hand and forearm so that the palm is facing downward (Figure 44-10).	70° to 90°	
WRIST—CONDYLOID JOINT		
Flexion. Bring the fingers of each hand toward the inner aspect of the forearm (Figure 44-11 ■).	80° to 90° Example: eating, bathing, shaving, writing	Figure 44-11 ■ 
Extension. Straighten each hand to the same plane as the arm (Figure 44-11).	80° to 90° Example: eating, bathing, shaving	
Hyperextension. Bend the fingers of each hand back as far as possible (Figure 44-12 ■).	70° to 90°	Figure 44-12 ■ 
Radial flexion (abduction). Bend each wrist laterally toward the thumb side with hand supinated (Figure 44-13 ■).	0° to 20°	Figure 44-13 ■ 
Ulnar flexion (adduction). Bend each wrist laterally toward the fifth finger with the hand supinated (Figure 44-13).	30° to 50°	
HAND AND FINGERS: METACARPOPHALANGEAL JOINTS—CONDYLOID; INTERPHALANGEAL JOINTS—HINGE		
Flexion. Make a fist with each hand (Figure 44-14 ■).	90° Example: squeezing, gripping, writing	Figure 44-14 ■ 
Extension. Straighten the fingers of each hand (Figure 44-14).	90°	
Hyperextension. Bend the fingers of each hand back as far as possible (Figure 44-14).	30°	
Abduction. Spread the fingers of each hand apart (Figure 44-15 ■).	20°	Figure 44-15 ■ 
Adduction. Bring the fingers of each hand together (Figure 44-15).	20° Example: writing, gripping, eating, many hobbies involving fine motor coordination (e.g., art, music)	
THUMB—SADDLE JOINT		
Flexion. Move each thumb across the palmar surface of the hand toward the fifth finger (Figure 44-16 ■).	90°	Figure 44-16 ■ 
Extension. Move each thumb away from the hand (Figure 44-16).	90°	
Abduction. Extend each thumb laterally (Figure 44-17 ■).	30°	Figure 44-17 ■ 
Adduction. Move each thumb back to the hand (Figure 44-17).	30°	

Body Part—Type of Joint/Movement	Normal Range and Example of Corresponding ADL	Illustration
<p>Opposition. Touch each thumb to the top of each finger of the same hand. The thumb joint movements involved are abduction, rotation, and flexion (Figure 44-18 ■).</p>		<p>Figure 44-18 ■</p> 
<p>HIP—BALL-AND-SOCKET JOINT Flexion. Move each leg forward and upward. The knee may be extended or flexed (Figure 44-19 ■).</p>	<p>Knee extended, 90°; knee flexed, 120° Example: walking, leg lifts in front of the body</p>	<p>Figure 44-19 ■</p> 
<p>Extension. Move each leg back beside the other (Figure 44-20 ■).</p>	<p>90° to 120° Example: walking, lining the leg up with the body</p>	<p>Figure 44-20 ■</p> 
<p>Hyperextension. Move each leg back behind the body (Figure 44-20).</p>	<p>30° to 50° Example: walking; lying on side, reach the leg behind the body</p>	<p>Figure 44-21 ■</p> 
<p>Abduction. Move each leg out to the side (Figure 44-21 ■).</p>	<p>45° to 50° Example: moving leg away from body</p>	<p>Figure 44-21 ■</p> 
<p>Adduction. Move each leg back to the other leg and beyond in front of it (Figure 44-21).</p>	<p>20° to 30° beyond other leg Example: moving leg over the other leg toward the middle of the body</p>	<p>Figure 44-22 ■</p> 
<p>Circumduction. Move each leg backward, up, to the side, and down in a circle (Figure 44-22 ■).</p>	<p>360° Example: leg circles clockwise and counterclockwise</p>	<p>Figure 44-22 ■</p> 
<p>Internal rotation. Flex knee and hip to 90°. Place the foot away from the midline. Move the thigh and knee <i>toward</i> the midline (Figure 44-23 ■).</p>	<p>40°</p>	<p>Figure 44-23 ■</p> 
<p>External rotation. Flex knee and hip to 90°. Place the foot toward the midline. Move the thigh and knee <i>away</i> from the midline (Figure 44-23).</p>	<p>45°</p>	<p>Figure 44-23 ■</p> 
<p>KNEE—HINGE JOINT</p>	<p>120° to 130° Example: knee bends, walking</p>	<p>Figure 44-24 ■</p> 
<p>Extension. Straighten each leg, returning the foot to its position beside the other foot (Figure 44-24).</p>	<p>120° to 130° Example: straightening leg from bent position, walking</p>	<p>Figure 44-24 ■</p>

TABLE 44-2 Selected Joint Movements and Example of Corresponding Activity of Daily Living (ADL)—*continued*

Body Part—Type of Joint/Movement	Normal Range and Example of Corresponding ADL	Illustration
ANKLE—HINGE JOINT		
Extension (plantar flexion). Point the toes of each foot downward (Figure 44-25 ■).	20° Example: pressing toes away from face, walking	Figure 44-25 ■ 
Flexion (dorsiflexion). Point the toes of each foot upward (Figure 44-25).	45° to 50° Example: pulling toes toward face, walking	
FOOT—GLIDING		
Eversion. Turn the sole of each foot laterally (Figure 44-26 ■).	5° Example: foot circles clockwise and counterclockwise	Figure 44-26 ■ 
Inversion. Turn the sole of each foot medially (Figure 44-26).	5° Example: foot circles clockwise and counterclockwise	
	Example: walking, wiggling toes	
TOES: INTERPHALANGEAL JOINTS—HINGE; METATARSOPHALANGEAL JOINTS—HINGE; INTERTARSAL JOINTS—GLIDING		
Flexion. Curl the toe joints of each foot downward (Figure 44-27 ■).	35° to 60°	Figure 44-27 ■ 
Extension. Straighten the toes of each foot (Figure 44-27).	35° to 60°	
TRUNK—GLIDING JOINT		
Flexion. Bend the trunk toward the toes (Figure 44-28 ■).	70° to 90° Example: touching toes	Figure 44-28 ■ 
Extension. Straighten the trunk from a flexed position (Figure 44-28).		
Hyperextension. Bend the trunk backward (Figure 44-28).	20° to 30° Example: gentle supported back bend with hands on buttocks	Figure 44-29 ■ 
Lateral flexion. Bend the trunk to the right and to the left (Figure 44-29 ■).	35° on each side Example: gently allow right hand to slide down right side of thigh, repeat on left side	
Rotation. Turn the upper part of the body from side to side (Figure 44-30 ■).	30° to 45° Example: gently swing torso right and left, maintaining forward hip alignment	Figure 44-30 ■ 

schools provide physical education and competitive sports programs to enhance physical activity. Posture in school-age children is usually excellent. In adolescence, growth spurts and behaviors such as carrying heavy book bags on one shoulder and extended computer use may result in postural changes that often persist into adulthood.

Adults between 20 and 40 years of age generally have few physical changes affecting mobility, with the exception of pregnant women. Pregnancy alters the body's center of gravity and affects balance. The most recent recommendations from the American College of Obstetricians and Gynecologists (2011) suggest that healthy pregnant women should exercise 30 minutes or more with moderate intensity on most if not all days of the week. Thorough clinical evaluations should be completed prior to recommending any exercise regimen. In addition, exercise can prevent gestational diabetes, even in clients who are very obese. Additional studies support the long-term benefits of exercise during pregnancy to control excess weight gain, thus preventing long-term obesity after delivery. Leaner babies may also be at lower risk for obesity later in life.

As age advances, muscle tone and bone density decrease, joints lose flexibility, reaction time slows, and bone mass decreases, particularly in women who have osteoporosis. **Osteoporosis** is a condition in which the bones become brittle and fragile due to calcium depletion. Osteoporosis is common in older women and primarily affects the weight-bearing joints of the lower extremities and the anterior aspects of spinal bones, causing compression fractures of the vertebrae and hip fractures. All of these changes affect older adults' posture, gait, and balance. Posture becomes forward leaning and stooped, which shifts the center of gravity forward. To compensate for this shift, the knees flex slightly for support and the base of support is widened. Gait becomes wide based, short stepped, and shuffling.

A strong body of research supports the benefits of regular activity for older adults to maintain and regain strength, flexibility, cardiovascular fitness, and bone density. Other health benefits are well documented, including reduction in falls, mood stabilization, reduction in obesity, and diabetes management (Seco et al., 2013).

Nutrition

Both undernutrition and overnutrition can influence body alignment and mobility. Poorly nourished people may have muscle weakness and fatigue. Vitamin D deficiency causes bone deformity during growth. Inadequate calcium intake and vitamin D synthesis and intake increase the risk of osteoporosis. Obesity can distort movement and stress joints, adversely affecting posture, balance, and joint health.

Personal Values and Attitudes

Whether people value regular exercise is often the result of family influences. In families that incorporate regular exercise into their daily routine or spend time together in activities, children learn to value physical activity. Sedentary families, on the other hand, participate in sports only as spectators, and this lifestyle is often transmitted to their children. With the increase in TV, computer, and video activities, youth are increasingly sedentary with associated declines in health. Values about physical appearance also influence some people's participation in regular exercise. People who value a muscular build or physical attractiveness may participate in regular exercise programs to produce the appearance they desire.

Choice of physical activity or type of exercise is also influenced by values. Choices may be influenced by geographic location and cultural role expectations. For many, thinking of exercise more as "recreational movement," "enhancement of well-being," and "an essential part of daily self-care" may help overcome perceptions that exercise is drudgery. Options include informal and fun activities such as dancing to music. Motivational states influence our behavior and choices, and vary widely from day to day. Exercise behavior may be improved by addressing individuals' awareness of their physiological response to activity and exercise. The design of **individualized exercise prescriptions** that tailor exercise mode and dose and address these varying states with each person will ensure greater adherence to an exercise program (Allen & Morelli, 2011; Katz, 2012). Prescriptions should include frequency of the activity, intensity, and time (the FIT model). In those who are building toward a fitness goal, these parameters will change over time to increase the client's level of conditioning. Nurses must assess each client for potentially motivating factors such as the following: degree of fun or challenge of any given activity; use of music; opportunities for socializing and group cohesion and having an exercise partner; positive sensations of the exercise experience; pleasurable feelings associated with increased stress reduction; increased energy and fitness; mastering the activity; goal setting and progress; daily logs or weekly written schedules; competition with oneself or others; promotion of a sense of accomplishment; weight management; emphasis on self-talk about how exercise will prevent fatigue, depression, weight gain, or anxiety; and the need to explore less intense and challenging, noncompetitive activities.

Nurses, taking into account motivation to participate, medical conditions, level of fitness, and safety issues, can use individualized exercise prescriptions to encourage exercise and activity in all of their clients. Clients who experience orthostatic hypotension, impaired equilibrium, and gait disturbance should begin exercising in supervised environments. For example, a frail or sedentary person may need to begin with a prescription that emphasizes stretching, strengthening, and development of balance rather than aerobic training. For apparently active and healthy people, the prescription can immediately include moderate aerobic conditioning, strength training, and stretching.

External Factors

Many external factors affect a person's mobility. Excessively high temperatures and high humidity discourage activity, whereas comfortable temperatures and low humidity are conducive to activity. Proper hydration needs vary according to the individual, health status, activity levels, and environment. Quality water is the best fluid to replace loss incurred through metabolic processes and exercise. Drinking 1 to 2 cups of water is usually adequate for shorter bouts of exercise. For longer bouts such as marathons, drinking 2 cups of water 2 hours prior to the event and then replacing fluids with a sports drink that contains sodium during and after can be beneficial.

The availability of recreational facilities also influences activity; for example, lack of money may prohibit a client from joining an exercise club or gymnasium or from purchasing needed equipment. Neighborhood safety promotes outdoor activity, whereas an unsafe environment discourages people from going outdoors. Adolescents, in particular, may spend many hours sitting at computers, watching television, or playing video games rather than engaging in physical activities.

Prescribed Limitations

Limitations to movement may be medically prescribed for some health problems. To promote healing, devices such as casts, braces, splints, and traction are often used to immobilize body parts. Clients who are short of breath may be advised not to walk up stairs. Bed rest may be the therapeutic choice for certain clients, for example, to relieve edema, to reduce metabolic and oxygen needs, to promote tissue repair, or to decrease pain.

The term **bed rest** varies in meaning to some extent. In some agencies, bed rest means strict confinement to bed or “complete” bed rest. Others may allow the client to use a bedside commode or have bathroom privileges. Nurses need to familiarize themselves with the meaning of bed rest in their practice setting. In any case, the effects of limiting activity are immediate, and therapeutic positioning is important to prevent further complications and improve client outcomes. There is rarely a need for complete bed rest.

EXERCISE

People participate in exercise programs to decrease risk factors for chronic diseases and to increase their health and well-being.

Functional strength is another goal of exercise, and is defined as the ability of the body to perform work. **Activity tolerance** is the type and amount of exercise or ADLs an individual is able to perform without experiencing adverse effects.

Types of Exercise

Exercise involves the active contraction and relaxation of muscles. Exercises can be classified according to the type of muscle contraction (isotonic, isometric, or isokinetic) and according to the source of energy (aerobic or anaerobic).

Isotonic (dynamic) exercises are those in which the muscle shortens to produce muscle contraction and active movement. Most physical conditioning exercises—running, walking, swimming, cycling, and other such activities—are isotonic, as are ADLs and active ROM exercises (those initiated by the client). Examples of isotonic bed exercises are pushing or pulling against a stationary object, using a trapeze to lift the body off the bed, lifting the buttocks off the bed by pushing with the hands against the mattress, and pushing the body to a sitting position.

Isotonic exercises increase muscle tone, mass, and strength and maintain joint flexibility and circulation. During isotonic exercise, both heart rate and cardiac output quicken to increase blood flow to all parts of the body.

Isometric (static or setting) exercises are those in which muscle contraction occurs without moving the joint (muscle length does not change). These exercises involve exerting pressure against a solid object and are useful for strengthening abdominal, gluteal, and quadriceps muscles used in ambulation; for maintaining strength in immobilized muscles in casts or traction; and for endurance training. An example of an isometric bed exercise would be squeezing a towel or pillow between the knees while at the same time tightening the muscles in the fronts of the thighs by pressing the knees backwards (see Figure 44–31 ■), and holding for several seconds. These are often called “quad sets.” Isometric exercises produce a mild increase in heart rate and cardiac output, but no appreciable increase in blood flow to other parts of the body.

Isokinetic (resistive) exercises involve muscle contraction or tension against resistance. During isokinetic exercises, the person

Figure 44–31 ■ Example of an isometric exercise for the knees and legs. The client sits or lies on a flat surface with the legs straight out. Using a rolled towel between the knees, the client pushes the knees together and tightens the muscles in the front of the thighs by forcing the knees downward and holding for 10 seconds.

tenses (isometric) against resistance. Special machines or devices provide the resistance to the movement. These exercises are used in physical conditioning and are often done to build up certain muscle groups.

Aerobic exercise is activity during which the amount of oxygen taken into the body is greater than that used to perform the activity. Aerobic exercises use large muscle groups that move repetitively. Aerobic exercises improve cardiovascular conditioning and physical fitness. Assessment of physical fitness is discussed in Chapter 16 ∞. The accompanying Client Teaching feature describes frequency, duration, and types of activity recommended for healthy adults.

Intensity of exercise can be measured in three ways:

1. **Target heart rate.** The goal is to work up to and sustain a target heart rate during exercise, based on the person's age. To determine target heart rate, first calculate the person's maximum heart rate by subtracting his or her current age in years from 220. Then obtain the target heart rate by taking 60% to 85% of the maximum. Because heart rates vary among individuals, the tests that follow are replacing this measure.
2. **Talk test.** This test is easier to implement and keeps most people at 60% of maximum heart rate or more. When exercising, the person should experience labored breathing, yet still be able to carry on a conversation.
3. **Borg scale of perceived exertion** (Borg, 1998). This scale measures “how difficult” the exercise feels to the person in terms of heart and lung exertion. The scale progresses from 1 to 20 with the following markers: 7 = very, very light; 9 = very light; 11 = fairly light; 13 = somewhat hard; 15 = hard; 17 = very hard; and 19 = very, very hard.

“Very, very hard” corresponds closely to 100% of maximum heart rate. “Very light” is close to 40%. Most people need to strive for the “somewhat hard” level (13/20), which corresponds to 75% of maximum heart rate.

Anaerobic exercise involves activity in which the muscles cannot draw out enough oxygen from the bloodstream, and anaerobic pathways are used to provide additional energy for a short time. This type of exercise is used in endurance training for athletes such as weight lifting and sprinting.

CLIENT TEACHING

Guidelines and Minimal Requirements for Physical Activity

FREQUENCY AND DURATION

- *Aerobic*: Cumulative 30 minutes or more daily (can be divided throughout the day) of “moderate intensity” movement as measured by talk test and perceived exertion scale.
- *Stretching*: Should be added onto that minimum requirement so that all parts of the body are stretched each day.
- *Strength training*: Should be added onto these minimum requirements so that all muscle groups are addressed at least three times a week, with a day of rest after training.

TYPE OF EXERCISE

- *Aerobic*: Elliptical exercisers, walking, biking, gardening, dancing, and swimming are recommended for all individuals,

including beginners and older adults. Activities that are more strenuous include jogging, running, Spinning®, power yoga, bouncing, boxing, and jumping rope.

- *Stretching*: Yoga, Pilates, qigong, and many other flexibility programs are effective.
- *Strength training*: Resistance can be provided with weights, bands, balls, apparatus, and body weight.

SAFETY

- Stress the importance of balance and prevention of falls, proper clothing to ensure thermal safety, checking equipment for proper function, wearing a helmet and other protective gear, using reflective devices at night, and carrying identification and emergency information.

Culturally Responsive Care

PATIENT-CENTERED CARE

Therapeutic Movement Modalities from Eastern Cultures

Therapeutic movement modalities from Eastern cultures are finding a place in evidence-based health care. In particular, Hatha yoga, qigong, and t'ai chi are receiving wide attention for improving strength and balance as well as treating a wide variety of health problems. Hatha yoga, developed in ancient Hindu culture, is a series of physical exercises, breath control, and meditation that tone and strengthen the whole person—body, mind, and spirit (Figure 44–32 ■). The beauty of yoga is that it can be fully practiced by those who must use a wheelchair or remain in bed.

Qigong is a Chinese discipline that involves breathing and gentle movements of mostly arms and torso. The regular practice of qigong is intended to generate as well as conserve energy to maintain health or treat illness.

Figure 44–32 ■ Woman in a yoga stretch.
Dorling Kindersley Limited.

T'ai chi was derived from qigong and combines physical fitness, meditation, and self-defense. Although developed as a martial art, it is practiced today mostly for health promotion. In China, it is common to see people of all ages, including older adults, practicing these movement disciplines outdoors in public parks (Figure 44–33 ■).

In several studies investigating the immune effects of qigong practice, levels of white blood cells, monocytes, and lymphocytes increased significantly after training. In an investigation of clients who had hypertension, both systolic and diastolic blood pressure and norepinephrine, metanephrine, and epinephrine levels were significantly reduced in the group given qigong training versus those in the control group. Ventilatory functions were also improved in the qigong group.

Nurses can independently recommend that clients who are able to do so consider initiating these movement modalities. Through appropriate referrals to group classes in the community as well as the use of videotapes in homes and long-term care facilities, clients can take charge of their own health in ways that are empowering, holistic, and free of negative side effects. Nurses should assess each individual for readiness, safety issues, balance, and ability to engage in any physical activity.

Figure 44–33 ■ Men and women practicing t'ai chi outdoors in Leshan, China.

Benefits of Exercise

In general, regular exercise is essential for maintaining mental and physical health.

MUSCULOSKELETAL SYSTEM

The size, shape, tone, and strength of muscles (including the heart muscle) are maintained with mild exercise and increased with strenuous exercise. With strenuous exercise, muscles **hypertrophy** (enlarge), and the efficiency of muscular contraction increases. Hypertrophy is commonly seen in the arm muscles of a tennis player, the leg muscles of a skater, and the arm and hand muscles of a carpenter.

Joints lack a discrete blood supply. It is through activity that joints receive nourishment. Exercise increases joint flexibility, stability, and range of motion. A growing number of randomized, controlled clinical trials have shown that exercise interventions significantly reduce weakness, frailty, depression, and the risk and incidence of falling in older adults (Dang, 2010; Rose & Hernandez, 2010).

Bone density and strength are maintained through weight bearing. The stress of weight-bearing and high-impact movement maintains a balance between osteoblasts (bone-building cells) and osteoclasts (bone-resorption and breakdown cells). Examples of non-weight-bearing exercise include swimming and bicycling.

CARDIOVASCULAR SYSTEM

The American Heart Association (2013) places great emphasis on physical activity by recommending at least 150 minutes per week of moderate exercise or 75 minutes per week of vigorous exercise, or a combination of moderate and vigorous activity. Adequate moderate-intensity exercise (40% to 60% of maximum capacity such as walking a mile in 15 to 20 minutes) increases the heart rate, the strength of heart muscle contraction, and the blood supply to the heart and muscles through increased cardiac output. Exercise also promotes heart health by mediating the harmful effects of stress. The types of exercise that will provide cardiac benefit vary. They include aerobic exercise such as walking and cycling. Research evidence for modalities that were formerly considered outside of mainstream health care supports the benefits of yoga practice on cardiovascular health. Statistically significant effects include lowering systolic and diastolic blood pressure, improved oxygen uptake, improved heart rate variability, improved circulation, and self-reported stress reduction (Monson, 2010).

RESPIRATORY SYSTEM

Ventilation (air circulating into and out of the lungs) and oxygen intake increase during exercise, thereby improving gas exchange. More toxins are eliminated with deeper breathing, and problem solving and emotional stability are enhanced due to increased oxygen to the brain. Adequate exercise also prevents pooling of secretions in the bronchi and bronchioles, decreasing breathing effort and risk of infection. Attention to exercising muscles of respiration (by deep breathing) throughout an activity as well as rest enhances oxygenation (improving stamina) and circulation of lymph (improving immune function). A strong body of evidence supports the use of lower extremity exercise forms (e.g., walking, treadmill, stationary bike, stair climbing) complemented by strength exercises of the upper body for treating individuals with chronic obstructive pulmonary disease (COPD) (Divo & Pinto-Plata, 2012). The number of research reports citing the benefits of yogic breathing and postures for people with asthma are increasing in the literature (Sharma, Haider, & Bose, 2012).

GASTROINTESTINAL SYSTEM

Exercise improves the appetite and increases gastrointestinal tract tone, facilitating peristalsis. Activities such as rowing, swimming, walking, and sit-ups work the abdominal muscles and can help relieve constipation. Exercise has been shown to improve symptoms of irritable bowel syndrome and other digestive disorders (Anastasi, Capili, & Chang, 2013).

METABOLIC/ENDOCRINE SYSTEM

Exercise elevates the metabolic rate, thus increasing the production of body heat and waste products and calorie use. During strenuous exercise, the metabolic rate can increase to as much as 20 times the normal rate. This elevation lasts after exercise is completed. Exercise increases the use of triglycerides and fatty acids, resulting in a reduced level of serum triglycerides, glycosylated hemoglobin (HgbA_{1C}) levels, and cholesterol. Weight loss and exercise stabilize blood sugar and make cells more responsive to insulin.

URINARY SYSTEM

With adequate exercise, which promotes efficient blood flow, the body excretes wastes more effectively. In addition, stasis (stagnation) of urine in the bladder is usually prevented, which in turn decreases the risk for urinary tract infections (UTIs).

IMMUNE SYSTEM

As respiratory and musculoskeletal effort increase with exercise and as gravity is enlisted with postural changes, lymph fluid is more efficiently pumped from tissues into lymph capillaries and vessels throughout the body. Circulation through lymph nodes where destruction of pathogens and removal of foreign antigens can occur is also improved.

Although moderate exercise seems to enhance immunity, a pattern of strenuous exercise may reduce immune function, leaving a window of opportunity for infection during the recovery phase. Adequate rest is important after vigorous training to allow the body to recover (Gleeson & Walsh, 2012).

PSYCHONEUROLOGIC SYSTEM

Mental or affective disorders such as depression or chronic stress may affect a person's desire to move. The depressed person may lack enthusiasm for taking part in any activity and may even lack energy for usual hygiene practices. Lack of visible energy is seen in a slumped posture with head bowed. Chronic stress can deplete the body's energy reserves to the point that fatigue discourages the desire to exercise, even though exercise can energize the person and facilitate coping. By contrast, individuals with eating disorders may exercise excessively in an effort to prevent weight gain.

A growing body of evidence supports the role of exercise in elevating mood and relieving stress and anxiety across the life span. Solid data examining relationships between both aerobic and nonaerobic styles of exercise support the use of this modality to relieve symptoms of depression. The mechanism of action is thought to be a result of one or more of the following: Exercise increases levels of metabolites for neurotransmitters such as norepinephrine and serotonin; exercise releases endogenous opioids, thus increasing levels of endorphins; exercise increases levels of oxygen to the brain and other body systems, inducing euphoria; and through muscular exertion (especially with movement modalities such as yoga and tai chi) the body releases stored stress associated with accumulated

emotional demands. Regular exercise also improves quality of sleep for most individuals.

COGNITIVE FUNCTION

Current research supports the positive effects of exercise on cognitive functioning, in particular decision-making and problem-solving processes, planning, and paying attention. Physical exertion induces cells in the brain to strengthen and build neuronal connections. Brain Gym (educational kinesiology) is a series of easy, mostly cross-lateral movements that enhance right- and left-brain integration, thus improving mood, learning, problem solving, and performance in individuals of all ages. These contralateral movements have been shown to help individuals with attention deficit disorder (ADD), attention deficit/hyperactivity disorder (ADHD), learning disorders, and mood disorders.

SPIRITUAL HEALTH

Yoga-style exercise improves the mind–body–spirit connection, relationship with God, and physical well-being by establishing balance in the internal and external environment. The combination of mind, body, and breath awareness is likely to have an impact on psychophysiological functioning. The emphasis on breathing in is thought to soothe the nervous and cardiorespiratory systems, promoting relaxation and preparedness for a contemplative experience.

The **relaxation response (RR)**, first described by Dr. Herbert Benson, is beneficial for counteracting some of the harmful effects

of stress on the body and mind. The RR is a healthful physiological relaxation that can be elicited through recitation of a word or phrase or prayer while sitting quietly and relaxing your muscles (Varvogli & Darviri, 2011).

Progressive muscle relaxation techniques involve contracting and then releasing groups of muscles throughout the body until all parts of the body feel relaxed. These movements are subtle and, along with relaxation breathing, can be done by almost anyone at any time, regardless of mobility or fitness status, providing potent stress relief and neurocardiovascular health benefits. Slowly walking a labyrinth (a circular mandala) can induce a meditative state, decreasing heart and respiratory rates, lowering blood pressure, and reducing insomnia. Many hospitals, hospices, and churches have labyrinths in garden and atrium spaces. Canvas labyrinths can be purchased and spread out on large surfaces such as a gymnasium. Even using a finger to slowly and mindfully trace and retrace a path to the center and back out of the mandala pictured in Figure 44–34 ■ can serve as a contemplative activity that will trigger slowed heart and respiratory rates.

EFFECTS OF IMMOBILITY

Mobility and activity tolerance are affected by any disorder that impairs the ability of the nervous system, musculoskeletal system, cardiovascular system, respiratory system, and vestibular apparatus. Congenital problems such as hip dysplasia, spina bifida, cerebral palsy, and the muscular dystrophies affect motor functioning.

Figure 44–34 ■ Mandala in the floor of Chartres Cathedral, France.

Disorders of the nervous system such as Parkinson's disease, multiple sclerosis, central nervous system tumors, cerebrovascular accidents (strokes), infectious processes (e.g., meningitis), and head and spinal cord injuries can leave muscle groups weakened, paralyzed (**paresis**), **spastic** (with too much muscle tone), or **flaccid** (without muscle tone). Musculoskeletal disorders affecting mobility include strains, sprains, fractures, joint dislocations, amputations, and joint replacements. Inner ear infections and dizziness can impair balance. Many other acute and chronic illnesses that limit the supply of oxygen and nutrients needed for muscle contraction and movement can seriously affect activity tolerance. Examples include chronic obstructive lung disease, anemia, congestive heart failure, and angina.

Individuals who have inactive lifestyles or who are faced with inactivity because of illness or injury are at risk for many problems that can affect major body systems. Whether immobility causes any problems often depends on the duration of the inactivity, the client's health status, and the client's sensory awareness. The most obvious signs of prolonged immobility are often manifested in the musculoskeletal system, and the deconditioning effects can be observed even after a matter of days. Clients experience a significant decrease in muscular strength and agility whenever they do not maintain a moderate amount of physical activity. In addition, immobility adversely affects the cardiovascular, respiratory, metabolic, urinary, and psychoneurologic systems. Nurses need to understand these effects and encourage client movement as much as possible. Early ambulation after illness or surgery is an essential measure to prevent complications.

CLINICAL ALERT!

A review of studies on effects of bed rest in clients with different disorders revealed that bed rest for treatment of medical conditions is associated with worse outcomes than early mobilization. In general, there are few indications for bed rest, and bed rest may delay recovery or actually harm clients (Lipshutz & Gropper, 2013).

Musculoskeletal System

- **Disuse osteoporosis.** Without the stress of weight-bearing activity, the bones demineralize. They are depleted chiefly of calcium, which gives the bones strength and density. Regardless of the amount of calcium in a person's diet, the demineralization process, known as *osteoporosis*, continues with immobility. The bones become spongy and may gradually deform and fracture easily.
- **Disuse atrophy.** Unused muscles **atrophy** (decrease in size), losing most of their strength and normal function.
- **Contractures.** When the muscle fibers are not able to shorten and lengthen, eventually a **contracture** (permanent shortening of the muscle) forms, limiting joint mobility. This process eventually involves the tendons, ligaments, and joint capsules; it is irreversible except by surgical intervention. Joint deformities such as **foot drop** (Figure 44–35 ■), wrist drop, and external hip rotation occur when a stronger muscle dominates the opposite muscle.
- **Stiffness and pain in the joints.** Without movement, the collagen (connective) tissues at the joint become **ankylosed** (permanently immobile). In addition, as the bones demineralize, excess calcium may deposit in the joints, contributing to stiffness and pain.

Figure 44–35 ■ Plantar flexion contracture (foot drop).

Cardiovascular System

- **Diminished cardiac reserve.** Decreased mobility creates an imbalance in the autonomic nervous system, resulting in a preponderance of sympathetic activity over cholinergic activity that increases heart rate. Rapid heart rate reduces diastolic pressure, coronary blood flow, and the capacity of the heart to respond to any metabolic demands above the basal levels. Because of this diminished cardiac reserve, the immobilized person may experience tachycardia with even minimal exertion.
- **Increased use of the Valsalva maneuver.** The **Valsalva maneuver** refers to holding the breath and straining against a closed glottis. For example, clients tend to hold their breath when attempting to move up in a bed or sit on a bedpan. This builds up sufficient pressure on the large veins in the thorax to interfere with the return blood flow to the heart and coronary arteries. When the client exhales and the glottis again opens, pressure is suddenly released, and a surge of blood flows to the heart. Cardiac arrhythmias can result if the client has preexisting cardiac disease.
- **Orthostatic (postural) hypotension.** **Orthostatic hypotension** is a common result of immobilization. Under normal conditions, sympathetic nervous system activity causes automatic vasoconstriction in the blood vessels in the lower half of the body when a mobile person changes from a horizontal to a vertical posture. Vasoconstriction prevents pooling of the blood in the legs and effectively maintains central blood pressure to ensure adequate perfusion of the heart and brain. During any prolonged immobility, however, this reflex becomes dormant. When the immobile person attempts to sit or stand, this reconstricting mechanism fails to function properly in spite of increased adrenalin output. The blood pools in the lower extremities, and central blood pressure drops. Cerebral perfusion is seriously compromised, and the person feels dizzy or light-headed and may even faint. This sequence is usually accompanied by a sudden and marked increase in heart rate, the body's effort to protect the brain from an inadequate blood supply.
- **Venous vasodilation and stasis.** The skeletal muscles of an active person contract with each movement, compressing the blood vessels in those muscles and helping to pump the blood back to the heart against gravity. The tiny valves in the leg veins aid in venous return to the heart by preventing backward flow of blood and pooling. In an immobile person, the skeletal muscles do not contract sufficiently, and the muscles atrophy. The skeletal muscles can no longer assist in pumping blood back to the heart against gravity. Blood pools in the leg veins, causing vasodilation and engorgement. The valves in the veins can no longer work effectively to prevent backward flow of blood and pooling (Figure 44–36 ■). This phenomenon is known as incompetent valves. As the blood continues to pool in the veins, its greater volume increases venous

Figure 44-36 ■ Leg veins: A, in a mobile person; B, in an immobile person.

blood pressure, which can become much higher than that exerted by the tissues surrounding the vessel.

- **Dependent edema.** When the venous pressure is sufficiently great, some of the serous part of the blood is forced out of the blood vessel into the interstitial spaces surrounding the blood vessel, causing edema. Edema is most common in parts of the body positioned below the heart. Dependent edema is most likely to occur around the sacrum or heels of a client who sits up in bed or in the feet and lower legs of a client who sits in a chair. Edema further impedes venous return of blood to the heart, causing more pooling and more edema. Edematous tissue is uncomfortable and more susceptible to injury than normal tissue.
- **Thrombus formation.** Three factors collectively predispose a client to the formation of a **thrombophlebitis** (a clot that is loosely attached to an inflamed vein wall): impaired venous return to the heart, hypercoagulability of the blood (sometimes caused by medications such as oral contraceptives), and injury to a vessel wall.

A **thrombus** (clot) is particularly dangerous if it breaks loose from the vein wall to enter the general circulation as an **embolus** (an object that has moved from its place of origin, causing obstruction to circulation elsewhere). Large emboli that enter the pulmonary circulation may occlude the vessels that nourish the lungs to cause an infarcted (dead) area of the lung. If the infarcted area is large, pulmonary function may be seriously compromised, or death may ensue. Emboli traveling to the coronary vessels or brain can produce a similarly dangerous outcome.

CLINICAL ALERT!

Prolonged inactivity (such as bed rest or sleeping during a long plane ride) in combination with oral contraceptive use can lead to dangerous clot formation in deep leg veins, even in otherwise healthy young women. Smoking increases this risk. Regular movement, stretching, and keeping legs uncrossed are recommended. Monitor for tenderness, redness or discoloration, warmth, and/or swelling in the legs.

Respiratory System

- **Decreased respiratory movement.** In a recumbent, immobile client, ventilation of the lungs is passively altered. The body presses against the rigid bed and curtails chest movement. The abdominal organs push against the diaphragm, restricting lung movement and making it difficult to expand the lungs fully. An immobile recumbent person rarely sighs, partly because overall muscle atrophy also affects the respiratory muscles and partly because there is no stimulus of activity. Without these periodic stretching movements, the cartilaginous intercostal joints may become fixed in an expiratory phase of respiration, further limiting the potential for maximal ventilation. These changes produce shallow respirations and reduce **vital capacity** (the maximum amount of air that can be exhaled after a maximum inhalation).
- **Pooling of respiratory secretions.** Secretions of the respiratory tract are normally expelled by changing positions or posture and by coughing. Inactivity allows secretions to pool by gravity (Figure 44-37 ■), interfering with the normal diffusion of oxygen and carbon dioxide in the alveoli. The ability to cough up secretions may also be hindered by loss of respiratory muscle tone, dehydration (which thickens secretions), or sedatives that depress the cough reflex. Poor oxygenation and retention of carbon dioxide in the blood can, if allowed to continue, predispose the client to respiratory acidosis, a potentially lethal disorder.
- **Atelectasis.** When ventilation is decreased, pooled secretions may accumulate in a dependent area of a bronchiole and effectively block it. Because of changes in regional blood flow, bed rest decreases the amount of surfactant produced. (Surfactant enables the alveoli to remain open.) The combination of decreased surfactant and blockage of a bronchiole with mucus can cause **atelectasis** (the collapse of a lobe or of an entire lung) distal to

Figure 44-37 ■ Pooling of secretions in the lungs of an immobile person.

the mucous blockage. Immobile older, postoperative clients are at greatest risk of atelectasis.

- **Hypostatic pneumonia.** Pooled secretions provide excellent media for bacterial growth. Under these conditions, a minor upper respiratory infection can evolve rapidly into a severe infection of the lower respiratory tract. Pneumonia caused by static respiratory secretions can severely impair oxygen–carbon dioxide exchange in the alveoli and is a fairly common cause of death among weakened, immobile individuals, especially heavy smokers.

Metabolic System

- **Decreased metabolic rate.** **Metabolism** refers to the sum of all the physical and chemical processes by which living substance is formed and maintained and by which energy is made available for use by the body. The **basal metabolic rate** is the minimal energy expended for the maintenance of these processes, expressed in calories per hour per square meter of body surface. In immobile clients, the basal metabolic rate and gastrointestinal motility and secretions of various digestive glands decrease as the energy requirements of the body decrease.
- **Negative nitrogen balance.** In an active person, a balance exists between protein synthesis (**anabolism**) and protein breakdown (**catabolism**). Immobility creates a marked imbalance, and the catabolic processes exceed the anabolic processes. Catabolized muscle mass releases nitrogen. Over time, more nitrogen is excreted than is ingested, producing a negative nitrogen balance. The negative nitrogen balance represents a depletion of protein stores that are essential for building muscle tissue and for wound healing.
- **Anorexia.** Loss of appetite (**anorexia**) occurs because of the decreased metabolic rate and the increased catabolism that accompany immobility. Reduced caloric intake is usually a response to the decreased energy requirements of the inactive person. If protein intake is reduced, the nitrogen imbalance may become more pronounced, sometimes so severely that malnutrition ensues.
- **Negative calcium balance.** A negative calcium balance occurs as a direct result of immobility. Greater amounts of calcium are extracted from bone than can be replaced. The absence of weight bearing and of stress on the musculoskeletal structures is the direct cause of the calcium loss from bones. Weight bearing and stress are also required for calcium to be replaced in bone.

Urinary System

- **Urinary stasis.** In a mobile client, gravity plays an important role in the emptying of the kidneys and the bladder. The shape and position of the kidneys and active kidney contractions are important in completely emptying the urine from the calyces, renal pelvis, and ureters (Figure 44–38 A ■). The shape and position of the urinary bladder (the detrusor muscle) and active bladder contractions are also important in achieving complete emptying (Figure 44–39 A ■).
- When the client remains in a horizontal position, gravity impedes the emptying of urine from the kidneys and the urinary bladder. To urinate, the client who is supine (in a back-lying position) must push upward, against gravity (Figures 44–38 B and 44–39 B). The renal pelvis may fill with urine before it is pushed into the ureters. Emptying is not as complete, and **urinary stasis** (stoppage or slowdown of flow) occurs after a few days of bed rest. Because of the overall decrease in muscle tone during immobilization,

Figure 44–38 ■ Pooling of urine in the kidney: A, The client is in an upright position. B, The client is in a back-lying position.

Figure 44–39 ■ Pooling of urine in the urinary bladder: A, The client is in an upright position. B, The client is in a back-lying position.

including the tone of the detrusor muscle, bladder emptying is further compromised.

- **Renal calculi.** In a mobile person, calcium in the urine remains dissolved because calcium and citric acid are balanced in appropriately acidic urine. With immobility and the resulting excessive amounts of calcium in the urine, this balance is no longer maintained. The urine becomes more alkaline, and the calcium salts precipitate out as crystals to form renal **calculi** (stones). In an immobile client in a horizontal position, the renal pelvis filled with stagnant, alkaline urine is an ideal location for calculi to form. The stones usually develop in the renal pelvis and pass through the ureters into the bladder. As the stones pass along the long, narrow ureters, they cause extreme pain and bleeding and can sometimes obstruct the urinary tract.
- **Urinary retention.** The immobile client may suffer from **urinary retention** (accumulation of urine in the bladder), bladder distention, and occasionally **urinary incontinence**

(involuntary urination). The decreased muscle tone of the urinary bladder inhibits its ability to empty completely. In addition, the discomfort of using a bedpan or urinal, the embarrassment and lack of privacy associated with this function, and the unnatural position for urination combine to make it difficult for the client to relax the perineal muscles sufficiently to urinate while lying in bed.

- When urination is not possible, the bladder gradually becomes distended with urine. The bladder may stretch excessively, eventually inhibiting the urge to void. When bladder distention is considerable, some involuntary urinary “dribbling” may occur (retention with overflow). This does not relieve the urinary distention, because most of the stagnant urine remains in the bladder.
- **Urinary infection.** Static urine provides an excellent medium for bacterial growth. The flushing action of normal, frequent urination is absent, and urinary distention often causes minute tears in the bladder mucosa, allowing infectious organisms to enter. The increased alkalinity of the urine caused by the hypercalcuria supports bacterial growth. The organism most commonly causing urinary tract infections is *Escherichia coli*, which normally resides in the colon. The normally sterile urinary tract may be contaminated by improper perineal care, the use of an indwelling urinary catheter, or occasionally **urinary reflux** (backward flow). During reflux, contaminated urine from an overly distended bladder backs up into the renal pelvis to contaminate the kidney pelvis as well.

Gastrointestinal System

Constipation is a frequent problem for immobilized clients because of decreased peristalsis and colon motility. The overall skeletal muscle weakness affects the abdominal and perineal muscles used in defecation. When the stool becomes very hard, more strength is required to expel it. The immobile client may lack this strength. This can lead to impaction.

A client’s unnatural and uncomfortable position on a bedpan does not facilitate elimination. The backward-leaning posture does not promote effective use of the muscles used in defecation. Some people are reluctant to use the bedpan in the presence of others. The embarrassment, lack of privacy, dependence on others to assist with the bedpan, and disruption of normal bowel habits may cause the individual to postpone or ignore the urge for elimination. Repeated postponement eventually suppresses the urge and weakens the defecation reflex.

Some clients may make excessive use of the Valsalva maneuver by straining at stool in an attempt to expel the hard stool. This effort dangerously increases intra-abdominal and intrathoracic pressures and places undue stress on the heart and circulatory system.

Integumentary System

- **Reduced skin turgor.** The skin can atrophy as a result of prolonged immobility. Shifts in body fluids between the fluid compartments can affect the consistency and health of the dermis and subcutaneous tissues in dependent parts of the body, eventually causing a gradual loss in skin elasticity.
- **Skin breakdown.** Normal blood circulation relies on muscle activity. Immobility impedes circulation and diminishes the supply of nutrients to specific areas. As a result, skin breakdown and formation of pressure (decubitus) ulcers can occur.

Psychoneurologic System

Due to a decline in production of mood-elevating substances such as endorphins, people experience negative effects on mood when unable to engage in physical activity. People who are unable to carry out the usual activities related to their roles (e.g., as employee, husband, mother, or athlete) become aware of an increased dependence on others. These factors lower the person’s self-esteem. Frustration and the decrease in self-esteem may in turn provoke exaggerated emotional reactions. Emotional reactions vary considerably. Some individuals become apathetic and withdrawn, some regress, and some become angry and aggressive.

Because the immobilized client’s participation in life becomes much narrower and the variety of stimuli decreases, the client’s perception of time intervals deteriorates. Problem-solving and decision-making abilities may deteriorate as a result of lack of intellectual stimulation and the stress of the illness and immobility. In addition, the loss of control over events can cause anxiety.

●○○ NURSING MANAGEMENT

Assessing

Assessment relative to a client’s activity and exercise should be routinely addressed and includes a nursing history and a physical examination of body alignment, gait, appearance and movement of joints, capabilities and limitations for movement, muscle mass and strength, activity tolerance, problems related to immobility, and physical fitness.

The nurse collects information from the client, from other nurses, and from the client’s records. The examination and history are important sources of information about disabilities affecting the client’s mobility and activity status, such as contractures, edema, pain in the extremities, or generalized fatigue.

Nursing History

An activity and exercise history is usually part of the comprehensive nursing history. Examples of interview questions to elicit these data are shown in the accompanying Assessment Interview. If the client indicates a recent pattern change or difficulties with mobility, a more detailed history is required. This detailed history should include the specific nature of the problem, when it first began, its frequency, its causes if known, how the problem affects daily living, what the client is doing to cope with the problem, and whether these methods have been effective.

Physical Examination

Conduct the physical examination focusing on activity and exercise patterns. The exam includes assessment of body alignment, gait, appearance and movement of joints, capabilities and limitations for movement, muscle mass and strength, activity tolerance, and problems related to immobility.

Body Alignment

Assessment of body alignment includes an inspection of the client while the client stands. The purpose of body alignment assessment is to identify:

- Normal developmental variations in posture
- Posture and learning needs to maintain good posture

ASSESSMENT INTERVIEW Activity and Exercise

DAILY ACTIVITY LEVEL

- What activities do you carry out during a routine day?
- Are you able to carry out the following tasks independently?
 - a. Eating
 - b. Dressing and grooming
 - c. Bathing
 - d. Toileting
 - e. Ambulating
 - f. Using a wheelchair
 - g. Transferring in and out of bed, bath, and car
 - h. Cooking
 - i. House cleaning
 - j. Shopping
- Where problems exist in your ability to carry out such tasks:
 - a. Would you rate yourself as partially or totally dependent?
 - b. How is the task achieved (by family, friend, agency, or use of specialized equipment)?

ACTIVITY TOLERANCE

- What types of activities make you tired?

- Do you ever experience dizziness, shortness of breath, marked increase in respiratory rate, or other problems following mild or moderate activity?

EXERCISE

- What type of exercise do you carry out to enhance your physical fitness?
- What is the frequency and length of this exercise session?
- Do you believe exercise is beneficial to your health? Explain.

FACTORS AFFECTING MOBILITY

- *Environmental factors.* Do stairs, lack of railings or other assistive devices, or an unsafe neighborhood impede your mobility or exercise regimen?
- *Health problems.* Do any of the following health problems affect your muscle strength or endurance: heart disease, lung disease, stroke, cancer, neuromuscular problems, musculoskeletal problems, visual or mental impairments, trauma, or pain?
- *Financial factors.* Are your finances adequate to obtain equipment or other aids that you require to enhance your mobility?

- Factors contributing to poor posture, such as fatigue, pain, compression fractures, or low self-esteem
- Muscle weakness or other motor impairments.

To assess alignment, the nurse inspects the client from lateral (Figure 44–40 A ■), anterior, and posterior perspectives. From the anterior and posterior views, the nurse should observe whether:

- The shoulders and hips are level
- The toes point forward
- The spine is straight, not curved to either side.

The “slumped” posture (Figure 44–40 B) is the most common problem that occurs when people stand. The neck is flexed

far forward, the abdomen protrudes, the pelvis is thrust forward to create **lordosis** (an exaggerated anterior/inward curvature of the lumbar spine), and the knees are hyperextended. Low back pain and fatigue occur quickly in people with poor posture.

Gait

The characteristic pattern of a person’s **gait** (walk) is assessed to determine the client’s mobility and risk for injury due to falling. Two phases of normal gait are swing and stance (Figure 44–41 ■). When one leg is in the swing phase, the other is in the stance phase. In the *stance phase*, (a) the heel of one foot strikes the ground, and (b) body weight is spread over the ball of that foot while the other heel pushes off and leaves the ground. In the *swing phase*, the leg from behind moves in front of the body.

Figure 44–40 ■ A standing person with A, good trunk alignment; B, poor trunk alignment. The arrows indicate the direction in which the pelvis is tilted.

Figure 44–41 ■ The swing and stance phases of a normal gait.

The nurse assesses gait as the client walks into the room or asks the client to walk a distance of 10 feet down a hallway and observes for the following:

- Chin is level, gaze is straight ahead, sternum is lifted, and shoulders are down and back, relaxed away from the ears.
- Heel strikes the ground before the toe. It is here, where both feet are taking some body weight, that the spine is most rotated.
- Feet are dorsiflexed in the swing phase.
- Arm opposite the swing-through foot moves forward at the same time.
- Gait is smooth, coordinated, and rhythmic, with even weight borne on each foot. Hips gently sway with spinal rotation; the body moves forward smoothly, stopping and starting with ease.

The nurse may also assess **pace** (the number of steps taken per minute), which often slows with age and disability. A normal walking pace is 70 to 100 steps per minute. The pace of an older person may slow to about 40 steps per minute.

The nurse should also note the client's need for a prosthesis or assistive device, such as a cane or walker. For a client who uses assistive aids, the nurse assesses gait without the device and compares the assisted and unassisted gaits.

Appearance and Movement of Joints

Physical examination of the joints involves inspection, palpation, assessment of range of active motion, and if active motion is not possible, assessment of range of passive motion. The nurse should assess the following:

- Any joint swelling or redness, which could indicate the presence of an injury or an inflammation
- Any deformity, such as a bony enlargement or contracture, and symmetry of involvement.
- The muscle development associated with each joint and the relative size and symmetry of the muscles on each side of the body.
- Any reported or palpable tenderness.
- **Crepitation** (palpable or audible crackling or grating sensation produced by joint motion and frequently experienced in joints that have suffered repeated trauma over time).
- Increased temperature over the joint. Palpate the joint using the backs of the fingers and compare the temperature with that of the symmetric joint.
- Degree of joint movement. Ask the client to move selected body parts as shown in Table 44–2. If indicated, measure the extent of movement with a goniometer, a device that measures the angle of the joint in degrees. See Figure 1 in Skill 30-16, page 579.

Assessment of range of motion should not be unduly fatiguing, and the joint movements need to be performed smoothly, slowly, and rhythmically. No joint should be forced. Uneven, jerky movement and forcing can injure the joint and its surrounding muscles and ligaments.

Capabilities and Limitations for Movement

The nurse needs to obtain data that may indicate hindrances or restrictions to the client's movement and the need for assistance, including the following:

- How the client's illness influences the ability to move and whether the client's health contraindicates any exertion, position, or movement.

- Encumbrances to movement, such as an intravenous (IV) line in place or a heavy cast.
- Mental alertness and ability to follow directions. Check whether the client is receiving medications that hinder the ability to walk safely. Narcotics, sedatives, tranquilizers, and some antihistamines cause drowsiness, dizziness, weakness, and orthostatic hypotension.
- Balance and coordination.
- Presence of orthostatic hypotension before transfers. Specifically, assess for any increase in pulse rate, marked fall in blood pressure, dizziness, light-headedness, and dimming of vision when the client moves from a supine to a vertical posture.
- Degree of comfort. People who have pain may not want to move and may require an analgesic before they are moved.
- Vision. Is it adequate to prevent falls?

The nurse also assesses the amount of assistance the client requires for the following:

- Moving in the bed. In particular, observe for the amount of assistance the client requires for turning:
 - a. From a supine position to a lateral position
 - b. From a lateral position on one side to a lateral position on the other
 - c. From a supine position to a sitting position in bed.
- Rising from a lying position to a sitting position on the edge of the bed. Healthy people can normally rise without support from the arms.
- Rising from a chair to a standing position. Normally this can be done without pushing with the arms.
- Coordination and balance. Determine the client's abilities to hold the body erect, to bear weight and keep balance in a standing position on both legs or only one, to take steps, and to push off from a chair or bed.

Muscle Mass and Strength

Before the client undertakes a change in position or attempts to ambulate, it is essential for the nurse to assess the client's strength and ability to move. Providing appropriate assistance lowers the risk of muscle strain and body injury to both the client and nurse. Assessment of upper extremity strength is especially important for clients who use ambulation aids, such as walkers and crutches. For information on how to determine muscle mass and strength in lower and upper extremities, see Chapter 30 .

Activity Tolerance

By determining an appropriate activity level for a client, the nurse can predict whether the client has the strength and endurance to participate in activities that require similar expenditures of energy. This assessment is useful in encouraging increasing independence in people who (a) have a cardiovascular or respiratory disability, (b) have been completely immobilized for a prolonged period, (c) have decreased muscle mass or a musculoskeletal disorder, (d) have experienced inadequate sleep, (e) have experienced pain, or (f) are depressed, anxious, or unmotivated.

The most useful measures in predicting activity tolerance are heart rate, strength, and rhythm; respiratory rate, depth, and

ANATOMY & PHYSIOLOGY REVIEW

Upper and Lower Body Integration and the Spine's Role in Locomotion

It is important to be aware of the connection between the upper and lower body in terms of function, comfort, and mobility. The iliopsoas muscles (hip flexors) allow us to stand upright and are crucial for spinal alignment and locomotion. Prolonged sitting and inactivity can shorten these muscles, compromising mobility, function, and comfort in the back, hips, and legs. The shoulder blades and surrounding muscles are a major part of the shoulder girdle and allow the arms to be in relationship with the back. Muscular imbalance in the shoulder girdle will cause dysfunctional movement patterns throughout the body, including the spine. Balanced strength in the pelvic muscles enhances back stability and alignment of the feet and legs. Muscular imbalance in the pelvis will also cause dysfunctional movement patterns throughout the body, including the cervical and thoracic spine. All of these considerations affect total body alignment, comfort, and gait. Proper alignment and function lead to greater efficiency of movement and conservation of energy.

It is theorized that gait originates in the spine rather than in the legs. This “spinal engine” theory (developed by S. A. Gracovetsky) rejects the notion that locomotion is a function of leg movement with the trunk being passively carried along. Rather, motion in the spine and surrounding tissues precedes that of the legs, comprising the basic engine of locomotion. The contralateral swinging of each leg with the opposite arm (e.g., the right arm swings forward with the left leg and vice versa) constitutes the rhythm of a normal gait with free motion in the shoulders and hips. The coordinated and fluid connection between upper and lower body motion indicates overall balance, energy efficiency, and comfort in movement.

Nursing Implications: Nurses should keep upper–lower body connection and spinal rotation in mind when evaluating gait, and encourage clients to walk with flowing contralateral movement between upper and lower limbs and a loose, rhythmic swing in the hips.

The iliopsoas muscle is frequently regarded as a single muscle because it is a blending of two muscles, the psoas and the iliacus. The psoas originates on the lumbar vertebrae and attaches to the femur. The iliacus originates on the pelvic crest and attaches to the femur. The connection between the spine and legs is evident when visualizing the iliopsoas muscles.

Spinal rotation precedes locomotion.

QUESTIONS

1. Why might someone with a foot or knee problem develop low back pain?
2. Why is contralateral movement of the upper and lower limbs important in a fluid, balanced gait?

See student resource website for answers.

rhythm; and blood pressure. These data are obtained at the following times:

- Before the activity starts (baseline data), while the client is at rest
- During the activity
- Immediately after the activity stops
- Three minutes after the activity has stopped and the client has rested.

The activity should be stopped immediately in the event of any physiological change indicating the activity is too strenuous or prolonged for the client. These changes include the following:

- Sudden facial pallor (paleness)
- Feelings of dizziness or weakness
- Change in level of consciousness
- Heart rate or respiratory rate that significantly exceeds baseline or preestablished levels
- Change in heart or respiratory rhythm from regular to irregular
- Weakening of the pulse
- Dyspnea, shortness of breath, or chest pain
- Diastolic blood pressure change of 10 mmHg or more.

If, however, the client tolerates the activity well, and if the client's heart rate returns to baseline levels within 5 minutes after the

activity ceases, the activity is considered safe. This activity, then, can serve as a standard for predicting the client's tolerance for similar activities.

Problems Related to Immobility

When collecting data pertaining to the problems of immobility, the nurse uses the assessment methods of inspection, palpation, and auscultation; checks results of laboratory tests; and takes measurements, including body weight, fluid intake, and fluid output. Specific techniques for assessing immobility problems and abnormal assessment findings related to the complications of immobility are listed in Table 44–3.

It is extremely important to obtain and record baseline assessment data soon after the client first becomes immobile. These baseline data serve as the standard against which all data collected throughout the period of immobilization are compared.

Because a major nursing responsibility is to prevent the complications of immobility, the nurse needs to identify clients at risk of developing such complications before problems arise. Clients at risk include those who (a) are poorly nourished; (b) have decreased sensitivity to pain, temperature, or pressure; (c) have existing cardiovascular, pulmonary, or neuromuscular problems; and (d) have an altered level of consciousness.

TABLE 44–3 Assessing Problems of Immobility

Assessment	Problem
<p>MUSCULOSKELETAL SYSTEM Measure arm and leg circumferences. Palpate and observe body joints. Take goniometric measurements of joint ROM.</p>	Decreased circumference due to decreased muscle mass Stiffness or pain in joints Decreased joint ROM, joint contractures
<p>CARDIOVASCULAR SYSTEM Auscultate the heart. Measure blood pressure. Palpate and observe sacrum, legs, and feet. Palpate peripheral pulses. Measure calf muscle circumferences. Observe calf muscles for redness, tenderness, and swelling.</p>	Increased heart rate Orthostatic hypotension Peripheral dependent edema, increased peripheral vein engorgement Weak peripheral pulses Edema Thrombophlebitis
<p>RESPIRATORY SYSTEM Observe chest movements. Auscultate chest.</p>	Asymmetric chest movements, dyspnea Diminished breath sounds, crackles, wheezes, and increased respiratory rate
<p>METABOLIC SYSTEM Measure height and weight. Palpate skin.</p>	Weight loss due to muscle atrophy and loss of subcutaneous fat Generalized edema due to low blood protein levels
<p>URINARY SYSTEM Measure fluid intake and output. Inspect urine. Palpate urinary bladder.</p>	Dehydration Cloudy, dark urine; high specific gravity Distended urinary bladder due to urinary retention
<p>GASTROINTESTINAL SYSTEM Observe stool. Auscultate bowel sounds.</p>	Hard, dry, small stool Decreased bowel sounds due to decreased intestinal motility
<p>INTEGUMENTARY SYSTEM Inspect skin.</p>	Break in skin integrity
<p>PSYCHONEUROLOGIC SYSTEM Observe behaviors, affect, and cognition. Monitor developmental skills in children.</p>	Anger, flat affect, crying, confusion, anxiety, decline in cognitive function, or signs such as sleep and appetite disturbances warrant further evaluation

Diagnosing

Mobility problems may be appropriate as the diagnostic label or as the etiology for other nursing diagnoses.

NANDA International (Herdman & Kamitsuru, 2014) includes the following nursing diagnostic labels for activity and exercise problems:

- **Activity Intolerance:** insufficient physiological or psychological energy to endure or complete required or desired daily activities. Wilkinson (2014) suggests specifying the level of endurance. Levels include:
 - Level I:** Walks regular pace on level ground but becomes more short of breath than normal when climbing one or more flights of stairs.
 - Level II:** Walks one city block or 500 feet on level ground or climbs one flight of stairs slowly without stopping.
 - Level III:** Walks no more than 50 feet on level ground without stopping and is unable to climb one flight of stairs without stopping.
 - Level IV:** Dyspnea and fatigue at rest.
- **Risk for Activity Intolerance:** vulnerable to experiencing insufficient physiological or psychological energy to endure or complete required or desired daily activities, which may compromise health.
- **Impaired Physical Mobility:** limitation in independent, purposeful physical movement of the body or of one or more extremities. More specific versions of this diagnosis are
 - Impaired Bed Mobility*
 - Impaired Transfer Ability*
 - Impaired Walking*
 - Impaired Wheelchair Mobility*
 - Impaired Sitting*
- **Sedentary Lifestyle:** reports a habit of life that is characterized by a low physical activity level.
- **Risk for Disuse Syndrome:** vulnerable to deterioration of body systems as the result of prescribed or unavoidable musculoskeletal inactivity, which may compromise health. A clinical example of this nursing diagnosis is shown in the Nursing Care Plan and the Concept Map on pages 1061–1062.

Depending on the data obtained, problems with mobility often affect other areas of human functioning and indicate other diagnoses. In these instances, the mobility problem becomes the etiology. The etiology needs to be described more explicitly in terms such as reduced ROM, neuromuscular impairment or musculoskeletal impairment of upper and lower extremities, or joint pain. Examples in which *Impaired Physical Mobility* is the etiology follow:

- *Fear (of falling)*
- *Ineffective Coping*
- *Situational Low Self-Esteem*
- *Powerlessness*
- *Risk for Falls.*

When problems associated with prolonged immobility arise, many other diagnoses may be necessary. Examples include, but are not limited to, the following:

- *Ineffective Airway Clearance* if there is stasis of pulmonary secretions
- *Risk for Infection* if there is stasis of urinary or pulmonary secretions
- *Risk for Injury* if orthostatic hypotension is present
- *Disturbed Sleep Pattern* if there is a lack of daytime physical activity

- *Risk for Situational Low Self-Esteem* if there is functional impairment and/or role disturbance.

Planning

When planning for desired outcomes, Nursing Outcomes Classification (NOC) labels that pertain to exercise and activity can be helpful and include the following: activity tolerance; ambulation; balance; body positioning; coordinated movement; endurance; fall prevention behavior; fatigue level; immobility consequences, both physiological and psycho-cognitive; joint movement; mobility; physical fitness; play participation; and self-care (Moorhead, Johnson, Maas, & Swanson, 2013).

Positioning, transferring, and ambulating clients are almost always independent nursing functions. The primary care practitioner usually orders specific body positions only after surgery, anesthesia, or trauma involving the nervous and musculoskeletal systems. All clients should have an activity order written by their primary care practitioner when they are admitted to the agency for care.

As part of planning, the nurse is responsible for identifying those clients who need assistance with body alignment and determining the degree of assistance they need. The nurse must be sensitive to the client's need to function as independently as possible yet provide assistance when the client needs it.

Most clients require some nursing guidance and assistance to learn about, achieve, and maintain proper body mechanics. The nurse should also plan to teach clients applicable skills. For example, a client with a back injury needs to learn how to get out of bed safely and comfortably, a client with an injured leg needs to learn how to transfer from bed to wheelchair safely, and a client with a newly acquired walker needs to learn how to use it safely. Nurses often teach family members or caregivers safe moving, lifting, and transfer techniques in the home setting.

The goals established for clients will vary according to the diagnosis and defining characteristics related to each individual. Examples of overall goals for clients with actual or potential problems related to mobility or activity follow.

The client will have:

- Increased tolerance for physical activity
- Restored or improved capability to ambulate and/or participate in ADLs
- Absence of injury from falling or improper use of body mechanics
- Enhanced physical fitness
- Absence of any complications associated with immobility.

Examples of desired outcomes, interventions, and activities are provided in the Nursing Care Plan and Concept Map on pages 1061–1062.

Planning for Home Care

Clients who have been hospitalized for activity or mobility problems often need continued care in the home. In preparation for discharge, the nurse needs to determine the client's actual and potential health problems, strengths, and resources. The accompanying Home Care Assessment describes the specific assessment data required before establishing a discharge plan for clients with mobility or activity problems. A major aspect of discharge planning involves instructional needs of the client and family. See Client Teaching features throughout this chapter.

Home Care Assessment Mobility and Activity Problems

SAFETY

CLIENT AND ENVIRONMENT

- Capabilities or tolerance for required and desired activities: self-care (feeding, bathing, toileting, dressing, grooming, home maintenance, shopping, cooking); recreational activities
- Mobility aids required: cane, walker, crutches, wheelchair, transfer boards
- Equipment required if immobilized: special bed, side rails, pressure-reducing mattress, assistive lifting equipment
- Current level of knowledge: body mechanics for use of mobility aids; specific exercises prescribed
- Home mobility hazard appraisal: adequacy of lighting; presence of handrails; safety of pathways and stairs; congested areas; unanchored rugs, mats, or electrical cords, and any other obstacles to safe movement; structural adjustments needed for wheelchair access

FAMILY OR CAREGIVER

- Caregiver availability, skills, and willingness to assist: assess learning needs and develop appropriate teaching plan,

primary people able to assist client with self-care, movement, shopping, and so on; physical and emotional status to assist with care

- Family role changes and coping: effect on financial status, parenting and spousal roles, social roles
- Availability of caregiver support: other support people available for occasional duties such as shopping, transportation, house-keeping, cooking, budgeting; refer to community agencies for respite care, where appropriate

COMMUNITY

- Resources: availability and familiarity with sources of medical equipment and assistive lifting equipment, financial assistance, homemaker services, hygienic care; Meals-on-Wheels; spiritual counselors and visitors; sources of respite for caregiver.

CLIENT TEACHING**Home Care Activity and Exercise****MAINTAINING MUSCULOSKELETAL FUNCTION**

- Teach the systematic performance of passive or assistive ROM exercises to maintain joint mobility.
- Demonstrate, as appropriate, the proper way to perform isotonic, isometric, or isokinetic exercises to maintain muscle mass and tone (collaborate with the physical therapist about these). Incorporate ADLs into exercise program if appropriate.
- Provide a written schedule for the type, frequency, and duration of exercises; encourage the use of a progress graph or chart to facilitate adherence with the therapy.
- Offer an ambulation schedule.
- Instruct in the availability of assistive ambulatory devices and correct use of them.
- Discuss pain control measures required before exercise.

PREVENTING INJURY

- Provide assistive devices for moving and transferring, whenever possible, and teach safe transfer and ambulation techniques.
- Discuss safety measures to avoid falls (e.g., locking wheelchairs, wearing appropriate footwear, using rubber tips on crutches, keeping the environment safe, and using mechanical

aids such as raised toilet seat, grab bars, urinal, and bedpan or commode to facilitate toileting).

- Teach ways to prevent postural hypotension.

MANAGING ENERGY TO PREVENT FATIGUE

- Discuss activity and rest patterns and develop a plan as indicated; intersperse rest periods with activity periods.
- Discuss ways to minimize fatigue such as performing activities more slowly and for shorter periods, resting more often, and using more assistance as required.
- Provide information about available resources to help with ADLs and home maintenance management.
- Teach ways to increase energy (e.g., increasing intake of high-energy foods, ensuring adequate rest and sleep, controlling pain, sharing feelings with a trusted listener).
- Teach techniques to monitor activity tolerance as appropriate.

REFERRALS

- Provide appropriate information about accessing community resources: home care agencies, physical and occupational therapy agencies, local YMCAs and other agencies that provide structured exercise and movement programs, and sources of adaptive equipment.

Implementing

Nurses can initiate and apply a wide variety of exercise and activity interventions as needed to address a multitude of client concerns. Nursing Interventions Classification (NIC) labels that pertain to exercise and activity include the following: activity therapy; cardiac care; rehabilitation; constipation management; exercise promotion (strength and stretching); exercise therapy (ambulation, balance, joint mobility, muscle control); fall prevention; health education; mood management; pelvic muscle exercise; pressure ulcer prevention; progressive muscle relaxation; recreation therapy; self-care assistance; self-esteem enhancement; simple relaxation therapy; sleep enhancement; sports-injury prevention; teaching: prescribed activity/exercise; therapeutic play; and weight management and weight reduction (Bulechek, Butcher, Dochterman, & Wagner, 2013).

Nursing strategies to maintain or promote body alignment and mobility involve positioning clients appropriately, moving and turning clients in bed, transferring clients, providing ROM exercises,

ambulating clients with or without mechanical aids, and strategies to prevent the complications of immobility. Whenever positioning, moving, and ambulating clients, nurses must use proper body mechanics and assistive lifting/moving equipment to avoid musculoskeletal strain and injury.

Using Body Mechanics

Body mechanics is the term used to describe the efficient, coordinated, and safe use of the body to move objects and carry out the ADLs. When a person moves, the center of gravity shifts continuously in the direction of the moving body parts. Balance depends on the interrelationship of the center of gravity, the line of gravity, and the base of support. The closer the line of gravity is to the center of the base of support, the greater the person's stability (Figure 44–42 A ■). Conversely, the closer the line of gravity is to the edge of the base of support, the more precarious the balance (Figure 44–42 B). If the line of gravity falls outside the base of support, the person falls (Figure 44–42 C).

Figure 44-42 ■ A, Balance is maintained when the line of gravity falls close to the base of support. B, Balance is precarious when the line of gravity falls at the edge of the base of support. C, Balance cannot be maintained when the line of gravity falls outside the base of support.

The broader the base of support and the lower the center of gravity, the greater the stability and balance. Body balance, therefore, can be greatly enhanced by (a) widening the base of support and (b) lowering the center of gravity, bringing it closer to the base of support. The base of support is easily widened by spreading the feet farther apart. The center of gravity is readily lowered by flexing the hips and knees until a squatting position is achieved. The importance of these alterations cannot be overemphasized for nurses.

Until recently, nurses believed that “correct” body mechanics would facilitate the safe and efficient use of appropriate muscle groups to maintain balance, reduce the energy required, reduce fatigue, and decrease the risk of injury for both nurses and clients, especially during transferring, lifting, and repositioning. In reality, more than 30 years of evidence show that:

- Educating nurses in body mechanics alone will *not* prevent job-related injuries.
- Back belts have *not* been shown to be effective in reducing back injury.
- Nurses who are physically fit are at *no* less risk of injury. Research has shown that physical fitness may *increase* the risk of injury because of being asked to help others four times more often (American Nurses Association [ANA], n.d.).
- The formerly widely accepted National Institute for Occupational Safety and Health (NIOSH) “lifting equation,” which recommended that workers observe a limit of 51 pounds of lifting, *cannot* be safely applied to nursing practice.
- The long-term benefits of using the proper equipment (e.g., mechanical lifts) far outweigh the costs related to injuries.
- Staff will use equipment when they have participated in the decision-making process for purchasing the equipment

In the field of nursing, work-related musculoskeletal disorders (MSDs), such as back and shoulder injuries, persist as the leading and most costly U.S. occupational health problem. In fact, during 2011, workers in the health care/social assistance workplace suffered a higher rate of MSDs than construction, mining, or manufacturing workers (Bureau of Labor Statistics, 2013). Moreover, 62% of 4,614 nurses who

responded to a 2011 ANA health and safety survey reported that one of their top concerns was disabling musculoskeletal injury. Eight out of ten said that musculoskeletal pain was a frequent occurrence and that they continued to work despite the pain (ANA, 2011). Manually moving and lifting clients often cause MSDs. Increasingly, health care facilities are focusing on “no lift” policies for their employees, and 35 pounds of client weight should be the maximum a nurse should attempt. This limit should be further reduced if the health care worker is lifting in a restricted space, sitting or kneeling, twisting, one-handed, or with arms extended; if working longer than 8 hours; or if the client is combative, cannot follow direction, or has physical or medical conditions that impact his or her being lifted or moved (ANA, 2013, p. 13). If the weight to be lifted exceeds 35 pounds or the other conditions exist, assistive devices should be used. These devices include floor-based and ceiling lifts, slings, sit-to-stand assist devices, sliding boards, friction-reducing devices, transfer sheets or power-assist, air-cushioned mattresses, and lateral transfer and transport chairs.

The ANA has been involved in the effort to protect nurses from MSDs for many years and has taken the official position of supporting actions and policies that result in the elimination of manual handling of clients in order to establish a safe environment for nurses and clients. Safe patient handling and mobility (SPHM) programs can greatly reduce health care worker injuries. Prompted by ANA’s Handle with Care Campaign that started in 2003, 11 states have enacted “safe patient handling” laws related to the implementation of SPHM programs. However, there is no consistency among these 11 states. For example, one state requires replacing manual lifting with lifting devices and another state requires health care facilities to develop a comprehensive safe patient handling plan (ANA, n.d.).

Recently, the Centers for Medicare and Medicaid Services (CMS), the Institute of Medicine (IOM), the World Health Organization (WHO), the National Quality Foundation (NQF), and the ANA supported the concepts of universal standards and an interdisciplinary approach to SPHM (ANA, 2013). As a result, a workgroup of national subject-matter experts from multiple health care disciplines was formed. Two years later in 2013, this workgroup published *Safe Patient Handling and Mobility Interprofessional National Standards*

Across the Care Continuum. The workgroup focused on ensuring that the standards would be helpful and realistic for health care workers in all health care settings and focused on evidence-based outcomes without being prescriptive (ANA, 2013).

These standards are voluntary performance standards to help health care facilities establish policies and procedures. It is the hope, however, that similar to the requirement of universal precautions, the Safe Patient Handling and Mobility Standards will become required instead of optional (“Safe lifting,” 2013). To this end, the ANA is working with congressional bill sponsors in support of national legislation.

Until all work settings provide safe environments in which nurses have the equipment they need, content pertaining to body mechanics will be included here. Readers are encouraged to support “no manual lift” and “no solo lift” policies in their workplaces, and to become involved in legislation and equipment purchase initiatives. Nurses must participate in this shift in safety awareness, and are encouraged to support the Safe Patient Handling and Mobility Standards of the ANA and to keep abreast of congressional action on bills to enforce safer client handling.

CLINICAL ALERT!

Back injuries are caused by force, repetition, and awkward positions. The most common injuries among health care workers are low back pain, herniated disks, strained muscles, pulled and/or torn ligaments, and disk degradation.

Lifting

It is important to remember that nurses should **not** lift more than 35 pounds without assistance from proper equipment and/or other individuals. Types of assistive equipment include mobile-powered or mechanical lifts, ceiling-mounted lifts, sit-to-stand powered lifts, friction-reducing devices, and transfer chairs. See Figure 44–43 ■ through Figure 44–48 ■.

Pulling and Pushing

When pulling or pushing an object, a person maintains balance with least effort when the base of support is increased in the direction in which the movement is to be produced or opposed. For example, when

Figure 44–43 ■ A mobile electric lift functions to lift clients from bed, chair, toilet, and floor.

Figure 44–44 ■ A ceiling-mounted lift.

pushing an object, a person can enlarge the base of support by moving the front foot forward. When pulling an object, a person can enlarge the base of support by (a) moving the rear leg back if the person is facing the object or (b) moving the front foot forward if the person is facing away from the object. It is easier and safer to pull an object toward one’s own center of gravity than to push it away, because a person can exert more control of the object’s movement when pulling it.

Figure 44–45 ■ A sit-to-stand power lift allows for client transfers from bed to chair. The client must be cognitive and provide some muscle tone in at least one leg and the trunk. A mobile floor-based hydraulic lift functions to lift clients from bed, chair, toilet, and floor.

Figure 44-46 ■ The Slipp® Patient Mover is a client-moving device that reduces the nurse's exposure to back injuries and maximizes client comfort.

Wright Products, Inc.

Figure 44-47 ■ An air transfer system. Once inflated, the client can be transferred laterally or repositioned on a frictionless air surface.

CLINICAL ALERT!

Lateral-assist devices such as horizontal air transfer mattresses and transfer chairs are essential equipment for most client care areas. They help prevent acute and chronic back pain and disability. Observing principles of body mechanics is recommended even when using assistive equipment, because any lifting and forceful movement is potentially injurious, especially when repeated over time.

Pivoting

Pivoting is a technique in which the body is turned in a way that avoids twisting of the spine. To pivot, place one foot ahead of the other, raise the heels very slightly, and put the body weight on the balls of the feet. When the weight is off the heels, the frictional surface is decreased and the knees are not twisted when turning. Keeping the body aligned, turn (pivot) about 90 degrees in the desired direction. The foot that was forward will now be behind.

Preventing Back Injury

Nurses provide clients with the opportunity to change positions, expand their lungs, or change their environments as appropriate. It is important, however, that nurses not jeopardize their own health while

Figure 44-48 ■ Transfer chair that can transfer the client laterally from bed to stretcher without lifting and then can convert to a sitting or reclining position to transport the client through the facility.

caring for clients. Client positioning, lifting, and transferring are significant risk factors for back injuries. As mentioned earlier, 35 pounds of client weight should be the maximum a nurse should attempt.

Two movements to avoid because of their potential for causing back injury are twisting (rotation) of the thoracolumbar spine and acute flexion of the back with hips and knees straight (stooping). Undesirable twisting of the back can be prevented by squarely facing the direction of movement, whether pushing, pulling, or sliding, and moving the object directly toward or away from one's center of gravity. Guidelines for preventing back injuries are presented in Client Teaching.

CLIENT TEACHING

Preventing Back Injuries

- Understand that the use of body mechanics will not necessarily prevent injury if manually handling a load greater than 35 pounds without the use of assistive devices.
- Avoid lifting anything greater than 35 pounds. Use assistive equipment, get help from coworkers, and participate in the purchasing/ordering process of appropriate assistive equipment for your work setting.
- Become consciously aware of your posture and body mechanics.
- When standing for a period of time, periodically move legs and hips, and flex one hip and knee and rest your foot on an object if possible.
- When sitting, keep your knees slightly higher than your hips.
- Use a firm mattress and soft pillow that provide good body support at natural body curvatures.
- Exercise regularly to maintain overall physical condition and regulate weight; include exercises that strengthen the pelvic, abdominal, and spinal muscles.
- Avoid movements that cause pain or require spinal flexion with straight legs (e.g., toe-touching and sit-ups) or spinal rotation (twisting).
- When moving an object, spread your feet apart to provide a wide base of support.
- Wear comfortable low-heeled shoes that provide good foot support and reduce the risk of slipping, stumbling, or turning your ankle.

Positioning Clients

Positioning a client in good body alignment and changing the position regularly (every 2 hours) and systematically are essential aspects of nursing practice. Clients who can move easily automatically reposition themselves for comfort. Such people generally require minimal positioning assistance from nurses, other than guidance about ways to maintain body alignment and to exercise their joints. However, people who are weak, frail, in pain, paralyzed, or unconscious rely on nurses to provide or assist with position changes. For all clients, it is important to assess the skin and provide skin care before and after a position change.

Any position, correct or incorrect, can be detrimental if maintained for a prolonged period. Frequent change of position helps to prevent muscle discomfort, undue pressure resulting in pressure ulcers, damage to superficial nerves and blood vessels, and contractures. Position changes also maintain muscle tone and stimulate postural reflexes.

When the client is not able to move independently or assist with moving, *the preferred method is for two or more nurses to move or turn the client and use assistive equipment.* Appropriate assistance reduces the risk of muscle strain and body injury to both the client and nurse, and is likely to protect the dignity and comfort of the client.

When positioning clients in bed, the nurse can do a number of things to ensure proper alignment and promote client comfort and safety:

- Make sure the mattress is firm and level yet has enough give to fill in and support natural body curvatures. A sagging mattress, a mattress that is too soft, or an underfilled waterbed used over a prolonged period can contribute to the development of hip flexion

contractures and low back strain and pain. Bed boards made of plywood and placed beneath a sagging mattress are increasingly recommended for clients who have back problems or are prone to them. Some bed boards are hinged across the middle so that they will bend as the head of the bed is raised. It is particularly important in the home setting to inspect the mattress for support.

- Ensure that the bed is clean and dry. Wrinkled or damp sheets increase the risk of pressure ulcer formation. Make sure extremities can move freely whenever possible. For example, the top bedclothes need to be loose enough for clients to move their feet.
- Place support devices in specified areas according to the client's position. Box 44–1 lists commonly used support devices. Use only those support devices needed to maintain alignment and to prevent stress on the client's muscles and joints. If the client is capable of movement, too many devices limit mobility and increase the potential for muscle weakness and atrophy.
- Avoid placing one body part, particularly one with bony prominences, directly on top of another body part. Excessive pressure can damage veins and predispose the client to thrombus formation. Pressure against the popliteal space may damage nerves and blood vessels in this area. Pillows can provide needed cushioning.
- Avoid friction and shearing. Friction is a force acting parallel to the skin surface. For example, sheets rubbing against skin create friction. Friction can abrade the skin (i.e., remove the superficial layers), making it more prone to breakdown. Shearing force is a combination of friction and pressure. It occurs commonly when a client assumes a sitting position in bed. In this position, the body tends to slide downward toward the foot of the bed. This downward movement is transmitted to the sacral bone and the deep tissues. At the same time, the skin over the sacrum tends not to

BOX 44–1 Support Devices

- *Pillows.* Different sizes are available. Used for support or elevation of an arm or leg. Specially designed dense pillows can be used to elevate the upper body. Pillows can also be used as a trochanter roll by placing the pillow from the client's iliac crest to midthigh. This prevents external rotation of the leg when the client is in a supine position.
- *Mattresses.* There are two types of mattresses: ones that fit on the bed frame (e.g., standard bed mattress) and mattresses that fit on the standard bed mattress (e.g., egg-crate mattress). Mattresses should be evenly supportive.
- *Suspension or heel guard boot.* These are made of a variety of substances. They usually have a firm exterior and padding

of foam to protect the skin. They prevent foot drop and relieve pressure on heels.

- *Footboard.* A flat panel often made of plastic or wood. It keeps the feet in dorsiflexion to prevent plantar flexion.
- *Hand roll.* Can be made by rolling a washcloth. Purpose is to keep hand in a functional position and prevent finger contractures.
- *Abduction pillow.* A triangular-shaped foam pillow that maintains hip abduction to prevent hip dislocation following total hip replacement.

A, Suspension boot; B, heel guard.

Maintaining postoperative abduction following total hip replacement.

move because of the adherence between the skin and the bed linens. The skin and superficial tissues are thus relatively unmoving in relation to the bed surface, whereas the deeper tissues are firmly attached to the skeleton and move downward. This causes a shearing force in the area where the deeper tissues and the superficial tissues meet. The force damages the tissues in this area.

- Plan a *systematic 24-hour schedule* for position changes. Frequent position changes are essential to prevent pressure ulcers in immobilized clients. Such clients should be repositioned every 2 hours throughout the day and night and more frequently when there is a risk for skin breakdown. This schedule is usually outlined on the client's nursing care plan.
- Always obtain information from the client to determine which position is most comfortable and appropriate. Seeking information from the client about what feels best is a useful guide when aligning clients and is an essential aspect of evaluating the effectiveness of an alignment intervention. Sometimes a client who appears well aligned may be experiencing real discomfort. Both appearance, in relation to alignment criteria, and comfort are important in achieving effective alignment.

Fowler's Position

Fowler's position, or a semisitting position, is a bed position in which the head and trunk are raised 45° to 60° relative to the bed (visualize a 90° right angle to orient your thinking) and the knees may or may not be flexed. Nurses may need to clarify the meaning of the term *Fowler's position* in their particular setting. Typically, Fowler's position refers to a 45° angle of elevation of the upper body.

Semi-Fowler's position (Figure 44–49 ■) is when the head and trunk are raised 15 to 45 degrees. This position is sometimes called low Fowler's and typically means 30 degrees of elevation. In

Figure 44–49 ■ A, Semi-Fowler's (low-Fowler's) position (supported); B, Fowler's position (supported). The amount of support depends on the needs of the individual client.

high-Fowler's position, the head and trunk are raised 60° to 90°, and most often means the client is sitting upright at a right angle to the bed (Table 44–4).

Fowler's position is the position of choice for people who have difficulty breathing and for some people with heart problems. When the client is in this position, gravity pulls the diaphragm downward, allowing greater chest expansion and lung ventilation.

A common error nurses make when aligning clients in Fowler's position is placing an overly large pillow or more than one pillow

TABLE 44–4 Fowler's Position

Unsupported Position	Problem to Be Prevented	Corrective Measure*
Bed-sitting position with upper part of body elevated 30° to 90° commencing at hips	Posterior flexion of lumbar curvature	Pillow at lower back (lumbar region) to support lumbar region
Head rests on bed surface	Hyperextension of neck	Pillows to support head, neck, and upper back
Arms fall at sides	Shoulder muscle strain, possible dislocation of shoulders, edema of hands and arms with flaccid paralysis, flexion contracture of the wrist	Pillow under forearms to eliminate pull on shoulder and assist venous blood flow from hands and lower arms
Legs lie flat and straight on lower bed surface	Hyperextension of knees	External rotation of hips
Small pillow under thighs to flex knees	Trochanter roll lateral to femur (Figure 44–50 ■)	Heels rest on bed surface
Pressure on heels	Pillow under lower legs	Feet are in plantar flexion
Plantar flexion of feet (foot drop)	Footboard to provide support for dorsiflexion	

*The amount of correction depends on the needs of the individual client.

Figure 44–50 ■ Making a trochanter roll: (1) Fold the towel in half lengthwise. (2) Roll the towel tightly, starting at one narrow edge and rolling within approximately 30 cm (1 ft) of the other edge. (3) Invert the roll. Then palpate the greater trochanter of the femur and place the roll with the center at the level of the greater trochanter; place the flat part of the towel under the client; then roll the towel snugly against the hip. The amount of support depends on the needs of the individual client.

Figure 44-51 ■ Orthopneic position.

behind the client’s head. This promotes the development of neck flexion contractures. If a client desires several head pillows, the nurse should encourage the client to rest without a pillow for several hours each day to extend the neck fully and counteract the effects of poor neck alignment.

Orthopneic Position

In the **orthopneic position**, the client sits either in bed or on the side of the bed with an overbed table across the lap (Figure 44-51 ■). This position facilitates respiration by allowing maximum chest expansion. It is particularly helpful to clients who have problems exhaling, because they can press the lower part of the chest against the edge of the overbed table.

Dorsal Recumbent Position

In the **dorsal recumbent (back-lying) position** (Figure 44-52 ■), the client’s head and shoulders are slightly elevated on a small pillow. In some agencies, the terms *dorsal recumbent* and *supine* are used interchangeably; strictly speaking, however, in the **supine or dorsal position** the head and shoulders are not elevated. In both positions, the client’s forearms may be elevated on pillows or placed at

Figure 44-52 ■ Dorsal recumbent position (supported).

the client’s sides. Supports are similar in both positions, except for the head pillow (Table 44-5). The dorsal recumbent position is used to provide comfort and to facilitate healing following certain surgeries or anesthetics (e.g., spinal).

Prone Position

In the **prone position**, the client lies on the abdomen with the head turned to one side (Figure 44-53 ■). The hips are not flexed. Both children and adults often sleep in this position, sometimes with one or both arms flexed over their heads. It is the only bed position that allows full extension of the hip and knee joints. When used periodically, the prone position helps to prevent flexion contractures of the hips and knees, thereby counteracting a problem caused by all other bed positions. The prone position also promotes drainage from the mouth and is especially useful for unconscious clients or those clients recovering from surgery of the mouth or throat (Table 44-6).

The prone position poses some distinct disadvantages. The pull of gravity on the trunk produces a marked lordosis in most people, and the neck is rotated laterally to a significant degree. For this reason, the prone position may not be recommended for people with problems of the cervical or lumbar spine. This position also causes plantar flexion. Some clients with cardiac or respiratory problems find the prone position confining and suffocating because chest expansion is inhibited during respirations. *The prone position should be used only when the client’s back is correctly aligned, only for short periods, and only for people with no evidence of spinal abnormalities.* As a result, this position is not often used.

Lateral Position

In the **lateral (side-lying) position** (Figure 44-54 ■), the client lies on one side of the body. Flexing the top hip and knee and placing this leg in front of the body creates a wider, triangular base of support and achieves greater stability. The greater the flexion of the top hip and knee, the greater the stability and balance in this position. This

Figure 44-53 ■ Prone position (supported).

TABLE 44-5 Dorsal Recumbent Position

Unsupported Position	Problem to Be Prevented	Corrective Measure*
Head is flat on bed surface	Hyperextension of neck in thick-chested client	Pillow of suitable thickness under head and shoulders if necessary for alignment
Lumbar curvature of spine is apparent	Posterior flexion of lumbar curvature	Roll or small pillow under lumbar curvature
Legs may be externally rotated	External rotation of legs	Roll or sandbag placed laterally to trochanter of femur (optional)
Legs are extended	Hyperextension of knees	Small pillow under thigh to flex knee slightly
Feet assume plantar flexion position	Plantar flexion (foot drop)	Footboard or rolled pillow to support feet in dorsiflexion
Heels on bed surface	Pressure on heels	Pillow under lower legs

*The amount of correction depends on the needs of the individual client.

TABLE 44-6 Prone Position

Unsupported Position	Problem to Be Prevented	Corrective Measure*
Head is turned to side and neck is slightly flexed	Flexion or hyperextension of neck	Small pillow under head unless contraindicated because of promotion of mucous drainage from mouth
Body lies flat on abdomen accentuating lumbar curvature	Hyperextension of lumbar curvature; difficulty breathing; pressure on breasts (women); pressure on genitals (men)	Small pillow or roll under abdomen just below diaphragm
Toes rest on bed surface; feet are in plantar flexion	Plantar flexion (foot drop)	Allow feet to fall naturally over end of mattress, or support lower legs on a pillow so that toes do not touch the bed

*The amount of correction depends on the needs of the individual client.

Figure 44-54 ■ Lateral position (supported).

flexion reduces lordosis and promotes good back alignment. For this reason, the lateral position is good for resting and sleeping clients. The lateral position helps to relieve pressure on the sacrum and heels in people who sit for much of the day or who are confined to bed and rest in Fowler's or dorsal recumbent positions much of the time. In the lateral position, most of the body's weight is borne by the lateral aspect of the lower scapula, the lateral aspect of the ilium, and the greater trochanter of the femur. People who have sensory or motor deficits on one side of the body usually find that lying on the uninvolved side is more comfortable (Table 44-7).

Sims' Position

In **Sims' (semiprone) position** (Figure 44-55 ■), the client assumes a posture halfway between the lateral and the prone positions. The lower arm is positioned behind the client, and the upper arm is flexed at the shoulder and the elbow. Both legs are flexed in front of the client. The upper leg is more acutely flexed at both the hip and the knee than is the lower one.

Sims' position may be used for unconscious clients because it facilitates drainage from the mouth and prevents aspiration of fluids. It is also used for paralyzed clients because it reduces pressure over the

Figure 44-55 ■ Sims' position (supported).

sacrum and greater trochanter of the hip. It is often used for clients receiving enemas and occasionally for clients undergoing examinations or treatments of the perineal area. Many people, especially pregnant women, find Sims' position comfortable for sleeping. Clients with sensory or motor deficits on one side of the body usually find that lying on the uninvolved side is more comfortable (Table 44-8).

Moving and Turning Clients in Bed

Although healthy clients usually take for granted that they can change body position and go from one place to another with little effort, all people may have difficulty moving, even in bed. How much assistance clients require depends on their own ability to move and their

TABLE 44-7 Lateral Position

Unsupported Position	Problem to Be Prevented	Corrective Measure*
Body is turned to side, both arms in front of body, weight resting primarily on lateral aspects of scapula and ilium	Lateral flexion and fatigue of sternocleidomastoid muscles	Pillow under head and neck to provide good alignment
Upper arm and shoulder are rotated internally and adducted	Internal rotation and adduction of shoulder and subsequent limited function; impaired chest expansion	Pillow under upper arm to place it in good alignment; lower arm should be flexed comfortably
Upper thigh and leg are rotated internally and adducted	Internal rotation and adduction of femur; twisting of the spine	Pillow under leg and thigh to place them in good alignment; shoulders and hips should be aligned

*The amount of correction depends on the needs of the individual client.

TABLE 44–8 Sims' (Semiprone) Position

Unsupported Position	Problem to Be Prevented	Corrective Measure*
Head rests on bed surface; weight is borne by lateral aspects of cranial and facial bones	Lateral flexion of neck	Pillow supports head, maintaining it in good alignment unless drainage from the mouth is required
Upper shoulder and arm are internally rotated	Internal rotation of shoulder and arm; pressure on chest, restricting expansion during breathing	Pillow under upper arm to prevent internal rotation
Upper leg and thigh are adducted and internally rotated	Internal rotation and adduction of hip and leg	Pillow under upper leg to support it in alignment
Feet assume plantar flexion	Foot drop	Sandbags to support feet in dorsiflexion

*The amount of correction depends on the needs of the individual client.

health status. Nurses should be sensitive to both the need of clients to function independently and their need for assistance to move. Correct body alignment for the client must also be maintained so that undue stress is not placed on the musculoskeletal system.

When assisting a client to move, the nurse needs to use appropriate numbers of staff and assistive devices (such as those shown in previous Figures 44–43 through 44–48) to avoid injury to self and client. Having enough staff and assistive devices also helps to ensure client comfort and modesty. Hydraulic lifts are examples of assistive equipment that take the place of manual lifts and transfers. A lift can be used to transfer clients between the bed and a wheelchair, the bed and the bathtub, and the bed and a stretcher. A lift consists of a base on casters, a hydraulic mechanical pump, a mast boom, and a sling. The sling may consist of a one-piece or two-piece canvas seat. The one-piece seat stretches from the client's head to the knees. The two-piece seat has one canvas strap to support the client's buttocks and thighs and a second strap extending up to the axillae to support the back. It is important to be familiar with the model used and the practices that accompany use. Before using the lift, the nurse ensures that it is in working order and that the hooks, chains, straps, and canvas seat are in good repair. Most agencies recommend that two nurses operate a lift. Check agency policy.

CLINICAL ALERT!

Studies confirm that repositioning clients in bed, specifically pulling a client toward the head of the bed, is one of the most significant causes of back injuries and back pain among caregivers in the health care industry (Fragala, 2011, p. 65).

Actions and rationales applicable to moving and lifting clients include the following:

- Before moving a client, assess the degree of exertion permitted, the client's physical abilities (e.g., muscle strength, presence of paralysis) and ability to assist with the move, ability to understand instructions, degree of comfort or discomfort when moving, client's weight, presence of orthostatic hypotension (particularly important when client will be standing), and your own strength and ability to move the client.

- If indicated, use pain relief modalities or medication prior to moving the client.
- Prepare any needed assistive devices and supportive equipment (e.g., mechanical lifts, friction-reducing slide sheet, pillows, trochanter roll).
- Plan around encumbrances to movement such as an IV or urinary catheter.
- Be alert to the effects of any medications the client takes that may impair alertness, balance, strength, or mobility.
- Obtain required assistance from other individuals.
- Explain the procedure to the client and listen to any suggestions the client or support people have.
- Provide privacy.
- Perform hand hygiene.
- Raise the height of the bed *to bring the client close to your center of gravity*.
- Lock the wheels on the bed, and raise the rail on the side of the bed opposite you *to ensure client safety*.
- Face in the direction of the movement *to prevent spinal twisting*.
- Assume a broad stance *to increase stability and provide balance*.
- Lean your trunk forward, and flex your hips, knees, and ankles *to lower your center of gravity, increase stability, and ensure use of large muscle groups during movements*.
- Tighten your gluteal, abdominal, leg, and arm muscles *to prepare them for action and prevent injury*.
- Rock from the front leg to the back leg when pulling or from the back leg to the front leg when pushing *to overcome inertia, counteract the client's weight, and help attain a balanced, smooth motion*.
- After moving the client, determine and document the client's comfort (presence of anxiety, dizziness, or pain), body alignment, tolerance of the activity (e.g., check pulse rate, blood pressure), ability to assist, use of support devices, and safety precautions required (e.g., side rails).

Also see Skills 44–1 through 44–4 on moving and turning clients in bed and helping them sit up on the edge of the bed. *Note:* The Assessment, Planning, Delegation, and Equipment sections as listed in Skill 44-1 are the same for each of these four procedures and are not repeated. The Evaluation section at the end of Skill 44–4 is also the same for all four procedures and, hence, is not repeated.

Moving a Client Up in Bed

PURPOSE

- To assist clients who have slid down in bed from the Fowler's position to move up in bed.

ASSESSMENT

Before moving a client, assess the following:

- Client's physical abilities to assist with the move (e.g., muscle strength, presence of paralysis)
- Client's ability to understand instructions and willingness to participate
- Client's degree of comfort or discomfort when moving. If needed, administer analgesics or perform other pain relief measures prior to the move (see Chapter 46 ∞)
- Client's weight
- The availability of equipment and other personnel to assist you.

PLANNING

Review the client record to determine if previous nurses have recorded information about the client's ability to move. Use proper assistive equipment and additional personnel whenever needed. Ensure that the client understands instructions, and provide an interpreter as needed. Determine the number of personnel and type of equipment needed to safely perform the positional change to prevent injury to staff and client.

Equipment

- Assistive devices such as an overhead trapeze, friction-reducing device, or a mechanical lift

DELEGATION

The skills of moving and turning clients in bed can be delegated to unlicensed assistive personnel (UAP). The nurse should make sure that any needed equipment and additional personnel are available to reduce risk of injury to the health care personnel. Emphasize the need for the UAP to report changes in the client's condition that require assessment and intervention by the nurse.

IMPLEMENTATION

Preparation

Determine:

- Assistive devices that will be required
- Encumbrances to movement such as an IV or an indwelling urinary catheter
- Medications the client is receiving, because certain medications may hamper movement or alertness of the client
- Assistance required from other health care personnel.

Performance

- Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Listen to any suggestions made by the client or support people.
- Perform hand hygiene and observe other appropriate infection prevention procedures.
- Provide for client privacy.
- Adjust the bed and the client's position.
 - Adjust the head of the bed to a flat position or as low as the client can tolerate. **Rationale:** *Moving the client upward against gravity requires more force and can cause back strain.*
 - Raise the bed to a height appropriate for personnel safety (i.e., at the caregiver's elbows).
 - Lock the wheels on the bed and raise the rail on the side of the bed opposite you.
 - Remove all pillows, then place one against the head of the bed. **Rationale:** *This pillow protects the client's head from inadvertent injury against the top of the bed during the upward move.*
- For the client who is able to reposition without assistance:
 - Place the bed in flat or reverse Trendelenburg's position (as tolerated by the client). Stand by and instruct the client to move self. Assess if the client is able to move without causing friction to the skin.
 - Encourage the client to reach up and grasp the upper side rails with both hands, bend knees, and push off with the feet and pull up with the arms simultaneously.
 - Ask if a positioning device is needed (e.g., pillow).
- For the client who is partially able to assist:
 - For a client who weighs less than 200 pounds: Use a friction-reducing device and two assistants. **Rationale:** *Moving a client up in bed is not a one-person task. During any client handling, if the caregiver is required to lift more than 35 lb of a client's weight, then the client should be considered fully dependent and assistive devices should be used. This reduces risk of injury to the caregiver.*
 - For a client who weighs between 201–300 pounds: Use a friction-reducing slide sheet and four assistants OR an air transfer system and two assistants. **Rationale:** *Moving a client up in bed is not a one-person task. During any client handling, if the caregiver is required to lift more than 35 lb of a client's weight, then the client should be considered fully dependent and assistive devices should be used. This reduces risk of injury to the caregiver.*
 - For a client who weighs more than 300 pounds: Use an air transfer system and two assistants OR a total transfer lift.
 - Ask the client to flex the hips and knees and position the feet so that they can be used effectively for pushing. **Rationale:** *Flexing the hips and knees keeps the entire lower leg off the bed surface preventing friction during movement, and ensures use of the large muscle groups in the client's legs when pushing, thus increasing the force of movement.*
 - Place the client's arms across the chest. Ask the client to flex the neck during the move and keep the head off the bed surface. **Rationale:** *This keeps the arms and head off the bed surface and minimizes friction during movement.*
 - Use the friction-reducing device and assistants to move client up in bed. Ask the client to push on the count of three.

Moving a Client Up in Bed—continued

7. Position yourself appropriately, and move the client.
 - Face the direction of the movement, and then assume a broad stance with the foot nearest the bed behind the forward foot and weight on the forward foot. Lean your trunk forward from the hips. Flex the hips, knees, and ankles.
 - Tighten your gluteal, abdominal, leg, and arm muscles and rock from the back leg to the front leg and back again. Then, shift your weight to the front leg as the client pushes with the heels so that the client moves toward the head of the bed.
8. For the client who is unable to assist:
 - Use the ceiling lift with supine sling or mobile floor-based lift and two or more caregivers. Follow manufacturer's guidelines for using the lift. **Rationale:** *Moving a client up in bed is not a one-person task. During any client handling, if the caregiver is required to lift more than 35 lb of a client's weight, then the client should be considered to be fully dependent, and assistive devices should be used. This reduces risk of injury to caregiver.*
9. Ensure client comfort.
 - Elevate the head of the bed and provide appropriate support devices for the client's new position.
 - See the sections on positioning clients earlier in this chapter.
10. Document all relevant information. Record:
 - Time and change of position moved from and position moved to
 - Any signs of pressure areas
 - Use of support devices
 - Ability of client to assist in moving and turning
 - Response of client to moving and turning (e.g., anxiety, discomfort, dizziness).

SKILL 44-1

Turning a Client to the Lateral or Prone Position in Bed

PURPOSE

- Movement to the lateral (side-lying) position may be necessary when placing a bedpan beneath the client, when changing the client's bed linen, or when repositioning the client.

IMPLEMENTATION

Preparation

Determine:

- Assistive devices that will be required (e.g., friction-reducing device or mechanical lift)
- Encumbrances to movement such as an IV or an indwelling urinary catheter
- Medications the client is receiving, because certain medications may hamper movement or alertness of the client
- Assistance required from other health care personnel.

Rationale: *Moving a client is not a one-person task. During any client handling, if the caregiver is required to lift more than 35 lb of a client's weight, then the client should be considered to be fully dependent and assistive devices should be used. This reduces risk of injury to caregiver.*

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Position yourself and the client appropriately before performing the move. Other individual(s) stands on the opposite side of the bed.
 - Adjust the head of the bed to a flat position or as low as the client can tolerate. **Rationale:** *This provides a position of comfort for the client.*
 - Raise the bed to a height appropriate for personnel safety (i.e., at the caregiver's elbows).
 - Lock the wheels on the bed.
 - Move the client closer to the side of the bed opposite the side the client will face when turned. **Rationale:** *This ensures that the client will be positioned safely in the center of the bed after turning.* Use a friction-reducing device or mechanical lift (depending on level of client assistance required) to pull the client to the side of the bed. Adjust the client's head and reposition the legs appropriately.
5. Roll the client to the lateral position. The second person(s) standing on the opposite side of the bed helps roll the client from the other side.
 - Place one hand on the client's far hip and the other hand on the client's far shoulder. **Rationale:** *This position of the hands supports the client at the two heaviest parts of the body, providing greater control in movement during the roll.*
 - Position the client on his or her side with arms and legs positioned and supported properly. **2**

- 1 External rotation of the shoulder prevents the arm from being caught beneath the client's body when the client is turned.

SKILL 44-2

Turning a Client to the Lateral or Prone Position in Bed—continued

SKILL 44-2

2 Lateral position with pillows in place.

Variation: Turning the Client to a Prone Position

To turn a client to the prone position, follow the preceding steps, with two exceptions:

- Instead of abducting the far arm, keep the client's arm alongside the body for the client to roll over. **Rationale:** *Keeping the arm alongside the body prevents it from being pinned under the client when the client is rolled.*
- Roll the client completely onto the abdomen. **Rationale:** *It is essential to move the client as close as possible to the edge of the bed before the turn so that the client will be lying on the center of the bed after rolling. Never pull a client across the bed while the client is in the prone position. Rationale: Doing so can injure a woman's breasts or a man's genitals.*

6. Document all relevant information. Record:

- Time and change of position moved from and position moved to
- Any signs of pressure areas
- Use of support devices
- Ability of client to assist in moving and turning
- Response of the client to moving and turning (e.g., anxiety, discomfort, dizziness).

Logrolling a Client

SKILL 44-3

PURPOSE

- **Logrolling** is a technique used to turn a client whose body must at all times be kept in straight alignment (like a log). An example is the client with back surgery or a spinal injury. Considerable care must be taken to prevent additional injury.

This technique requires two nurses or, if the client is large, three nurses. For the client who has a cervical injury, one nurse must maintain the client's head and neck alignment.

IMPLEMENTATION

Preparation

Determine:

- Assistive devices that will be required
- Encumbrances to movement such as an IV or a urinary catheter
- Medications the client is receiving, because certain medications may hamper movement or alertness of the client
- Assistance required from other health care personnel. At least 2–3 additional people are needed to perform this skill safely.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Position yourselves and the client appropriately before the move.
 - Place the client's arms across the chest. **Rationale:** *Doing so ensures that they will not be injured or become trapped under the body when the body is turned.*
5. Pull the client to the side of the bed.
 - Use a friction-reducing device to facilitate logrolling. First, stand with another nurse on the same side of the bed. Assume a broad stance with one foot forward, and grasp the rolled edge of the friction-reducing device. On a signal, pull the client toward both of you. 1
 - One nurse counts: "One, two, three, go." Then, at the same time, all staff members pull the client to the side of the bed by shifting their weight to the back foot. **Rationale:** *Moving the client in unison maintains the client's body alignment.*

6. One person moves to the other side of the bed, and places supportive devices for the client when turned.

- Place a pillow where it will support the client's head after the turn. **Rationale:** *The pillow prevents lateral flexion of the neck and ensures alignment of the cervical spine.*
- Place one or two pillows between the client's legs to support the upper leg when the client is turned. **Rationale:** *This pillow prevents adduction of the upper leg and keeps the legs parallel and aligned.*

1 Using a friction-reducing slide sheet, the nurses pull the sheet with the client on it to the edge of the bed.

Logrolling a Client—continued

7. Roll and position the client in proper alignment.
 - Go to the other side of the bed (farthest from the client), and assume a stable stance.
 - Reaching over the client, grasp the friction-reducing device, and roll the client toward you. ②
 - One nurse counts: “One, two, three, go.” Then, at the same time, all nurses roll the client to a lateral position.
 - The second nurse (behind the client) helps turn the client and provides pillow supports to ensure good alignment in the lateral position.
 - Support the client’s head, back, and upper and lower extremities with pillows.
 - Raise the side rails and place the call bell within the client’s reach.
8. Document all relevant information. Record:
 - Time and change of position moved from and position moved to
 - Any signs of pressure areas
 - Use of support devices
 - Ability of client to assist in moving and turning
 - Response of client to moving and turning (e.g., anxiety, discomfort, dizziness).

② The nurse on the right uses the far edge of the slide sheet to roll the client toward him; the nurse on the left remains behind the client and assists with turning.

SKILL 44-3

Assisting a Client to Sit on the Side of the Bed (Dangling)

PURPOSE

- The client assumes a sitting position on the edge of the bed before walking, moving to a chair or wheelchair, eating, or performing other activities.

IMPLEMENTATION

Preparation

Determine:

- Assistive devices that will be required
- Encumbrances to movement such as an IV or a urinary catheter
- Medications the client is receiving, because certain medications may hamper movement or alertness of the client
- Assistance required from other health care personnel.

Performance

1. Prior to performing the procedure, introduce self and verify the client’s identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Position yourself and the client appropriately before performing the move.
 - Assist the client to a lateral position facing you, using an assistive device depending on client assistance needs.
 - Raise the head of the bed slowly to its highest position.

Rationale: This decreases the distance that the client needs to move to sit up on the side of the bed.
 - Position the client’s feet and lower legs at the edge of the bed. **Rationale:** This enables the client’s feet to move easily off the bed during the movement, and the client is aided by gravity into a sitting position.

- Stand beside the client’s hips and face the far corner of the bottom of the bed (the angle in which movement will occur). Assume a broad stance, placing the foot nearest the client and head of the bed forward. Lean your trunk forward from the hips. Flex your hips, knees, and ankles.
5. Move the client to a sitting position, using an assistive device depending on client assistance needs.
 - Place the arm nearest to the head of the bed under the client’s shoulders and the other arm over both of the client’s thighs near the knees. **Rationale:** Supporting the client’s shoulders prevents the client from falling backward during the movement. Supporting the client’s thighs reduces friction of the thighs against the bed surface during the move and increases the force of the movement.
 - Tighten your gluteal, abdominal, leg, and arm muscles.
 - Pivot on the balls of your feet in the desired direction facing the foot of the bed while pulling the client’s feet and legs off the bed. **Rationale:** Pivoting prevents twisting of the nurse’s spine. The weight of the client’s legs swinging downward increases downward movement of the lower body and helps make the client’s upper body vertical.
 - Keep supporting the client until the client is well balanced and comfortable. **Rationale:** This movement may cause some clients to become light-headed or dizzy.
 - Assess vital signs (e.g., pulse, respirations, and blood pressure) as indicated by the client’s health status.

SKILL 44-4

Assisting a Client to Sit on the Side of the Bed (Dangling)—continued

6. Document all relevant information. Record:
- Ability of the client to assist in moving and turning
 - Type of assistive device, if one was used
 - Response of the client to moving and turning (e.g., anxiety, discomfort, dizziness).

EVALUATION

- Check the skin integrity of the pressure areas from the previous position. Relate findings to previous assessment data if available. Conduct follow-up assessment for previous and/or new skin breakdown areas.
- Check for proper alignment after the position change. Do a visual check and ask the client for a comfort assessment.
- Determine that all required safety precautions (e.g., side rails) are in place.
- Determine client's tolerance of the activity (e.g., vital signs before and after dangling), particularly the first time the client changes position.
- Report significant changes to the primary care practitioner.

Note: This skill describes the process to use for a client who is able to perform the task independently and only needs standby assistance for steadying, or a client who requires minimum assistance in which the client can perform the task with or without friction-reducing assistive devices and the health care worker provides 25% of the work. For clients who require moderate assistance (requiring no more than 50% assistance by the caregiver) or maximum assistance (requiring more than 50% assistance by the caregiver), a lateral chair or mobile or ceiling-mounted transfer system is required.

LIFESPAN CONSIDERATIONS Positioning, Moving, and Turning Clients

INFANTS

- Position infants on their back for sleep, even after feeding. There is little risk of regurgitation and choking, and the rate of sudden infant death syndrome (SIDS) is significantly lower in infants who sleep on their backs.
- The skin of newborns can be fragile and may be abraded or torn (sheared) if the infant is pulled across a bed.

CHILDREN

- Carefully inspect the dependent skin surfaces of all infants and children confined to bed at least three times in each 24-hour period.

OLDER ADULTS

- In clients who have had cerebrovascular accidents (strokes), there is a risk of shoulder displacement on the paralyzed side from improper moving or repositioning techniques. Use care when moving, positioning in bed, and transferring. Pillows or foam devices are helpful to support the affected arm and shoulder and prevent injury.
- Decreased subcutaneous fat and thinning of the skin place older adults at risk for skin breakdown. Repositioning approximately every 2 hours (more or less, depending on the unique needs of the individual client) helps reduce pressure on bony prominences and avoid tissue trauma.

Home Care Considerations Positioning, Moving, and Turning Clients

PATIENT-CENTERED CARE

- Assess the height of the bed and the client's leg length to ensure that self-movements in and out of the bed are smooth.
 - When making a home visit, it is particularly important to inspect the mattress for support. A sagging mattress, a mattress that is too soft, or an underfilled waterbed used over a prolonged period can contribute to the development of hip flexion contractures and low back strain and pain. Bed boards made of plywood and placed beneath a sagging mattress are increasingly recommended for clients who have back problems or are prone to them.
 - Assess the caregivers' knowledge and application of body mechanics to prevent injury.
 - Demonstrate how to turn and position the client in bed. Observe the caregiver performing a return demonstration.
- Reevaluate this technique periodically to reinforce correct application of body mechanics.
- Teach caregivers the basic principles of body alignment and how to check for proper alignment after the client has been changed to a new position.
 - Warn caregivers of the dangers of lifting and repositioning and encourage the use of assistive devices and a "no solo lift" policy.
 - Teach the caregiver to check the client's skin for redness and integrity after repositioning the client. Stress the importance of informing the nurse about the length of time skin redness remains over pressure areas after the client has been repositioned. Emphasize that reddened areas should not be massaged because doing so may lead to tissue trauma.

Transferring Clients

Many clients require some assistance in transferring between bed and chair or wheelchair, between wheelchair and toilet, and between bed and stretcher. Before transferring any client, however, the nurse must determine the client's physical and mental capabilities to participate

in the transfer technique. In addition, the nurse must analyze and organize the activity.

A gait belt, sometimes called a transfer or walking belt, has traditionally been used to transfer a client from one position to another and for ambulation (Figure 44-56 ■). A gait belt can have handles

Figure 44-56 ■ Gait belt.
Courtesy Posey Company.

that allow the nurse to control movement of the client during the transfer or during ambulation (Figure 44-57 A and B ■). Rockefeller and Proctor (2011) point out that the long-held belief that the use of gait belts improves safety for both clients and caregivers is based on tradition and not on evidence-based research. The few studies that have been done indicate that using a gait belt for transfer falls into either a moderate- or high-risk category for low back disorders. Gait belts are not appropriate for all clients. They are suitable for clients who can bear weight and require only minimal assistance. The gait belt with handles is easier to grasp. Gait belts should not be used to lift a client off the floor or for bariatric clients. In addition, they should not be relied on for use with clients who are at high risk for falls (Rockefeller & Proctor, 2011, p. 33).

A sliding board is another device that can be used to transfer a client between a bed and chair. Boards are often made of low-friction materials or with movable sliding sections. Some clients may be able to transfer themselves using a sliding/transfer board. If a caregiver is needed, the client is either pushed or pulled across the transfer board using a slide sheet. Clients must have sitting balance. See Skill 44-5 for transferring a client between a bed and a chair, and Skill 44-6 for transferring a client between a bed and a stretcher. *Note:* The Evaluation section at the end of Skill 44-6 also applies to Skill 44-5.

General guidelines for transfer techniques include the following:

- Plan what to do and how to do it. Determine the space in which the transfer will take place (bathrooms, for instance, are usually cramped), the number of assistants (one or two) needed to accomplish the transfer safely, and the client's capabilities (e.g., size, weight, cognition, balance, cooperation).

A

B

Figure 44-57 ■ A, Gait belt with add-on handles; B, gait belt with handles.

Images provided courtesy Posey Company, Arcadia, California.

- Obtain essential equipment before starting (e.g., gait/transfer belt; friction-reducing device, such as a slide sheet, slide board, or air transfer system; wheelchair; stretcher; lift) and check that all equipment is functioning correctly. The gait/transfer belt is meant only to increase control of the client's movements; if the client requires lifting, a mechanical lifting device should be used.
- Remove obstacles from the area used for the transfer.
- Explain the transfer to the client, including what the client should do.
- Explain the transfer to the nursing personnel who are helping; specify who will give directions (one person needs to be in charge).
- Always support or hold the client rather than the equipment and ensure the client's safety and dignity.
- During the transfer, explain step by step what the client should do, for example, "Move your right foot forward."
- Make a written plan of the transfer, including the client's tolerance (e.g., pulse and respiratory rates).

Because wheelchairs and stretchers are unstable, they can predispose the client to falls and injury. Guidelines for the safe use of wheelchairs and stretchers are shown in the accompanying Practice Guidelines.

PRACTICE GUIDELINES

Wheelchair Safety

- Always lock the brakes on both wheels of the wheelchair when the client transfers in or out of it.
- Raise the footplates before transferring the client into the wheelchair.
- Lower the footplates after the transfer, and place the client's feet on them.
- Ensure the client is positioned well back in the seat of the wheelchair.
- Use seat belts that fasten behind the wheelchair to protect confused clients from falls. *Note:* Seat belts are a form of restraint and must be used in accordance with policies and procedures that apply to the use of restraints (see Chapter 32).
- Back the wheelchair into or out of an elevator, rear large wheels first.
- Place your body between the wheelchair and the bottom of an incline.

CLINICAL ALERT!

Air, foam, and gel cushions that distribute weight evenly (*not* doughnut-type cushions) are essential for clients confined to a wheelchair and must be checked frequently to ensure they are intact. Strict continence management is also important for preventing skin breakdown. Maintaining tire pressure will prevent added resistance and energy expenditure. Periodically monitor the client's upper extremities for pain and overuse syndromes.

PRACTICE GUIDELINES

Safe Use of Stretchers

- Lock the wheels of the bed and stretcher before the client transfers in or out of them.
- Fasten safety straps across the client on a stretcher, and raise the side rails.
- Never leave a client unattended on a stretcher unless the wheels are locked and the side rails are raised on both sides and/or the safety straps are securely fastened across the client.
- Always push a stretcher from the end where the client's head is positioned. This position protects the client's head in the event of a collision.
- If the stretcher has two swivel wheels and two stationary wheels:
 - a. Always position the client's head at the end with the stationary wheels and
 - b. Push the stretcher from the end with the stationary wheels. The stretcher is maneuvered more easily when pushed from this end.
- Maneuver the stretcher when entering the elevator so that the client's head goes in first.

Transferring Between Bed and Chair

PURPOSE

- A client may need to be transferred between the bed and a wheelchair or chair, the bed and the commode, or a wheelchair and the toilet. There are numerous variations in the technique.

Which variation the nurse selects depends on factors related to the client and the environment that are assessed prior to beginning the transfer.

ASSESSMENT

Before transferring a client, assess the following:

- The client's body size
- Ability to follow instructions
- Ability to bear weight
- Ability to position/reposition feet on floor
- Ability to push down with arms and lean forward
- Ability to achieve independent sitting balance
- Activity tolerance
- Muscle strength
- Joint mobility
- Presence of paralysis
- Level of comfort
- Presence of orthostatic hypotension
- The technique with which the client is familiar
- The space in which the transfer will need to be maneuvered (bathrooms, for example, are usually cramped)
- The number of assistants (one or two) needed to accomplish the transfer safely.

PLANNING

Review the client record to determine if previous nurses have recorded information about the client's ability to transfer. Implement pain relief measures so that they are effective when the transfer begins. The

decision must be made at this time regarding the client's ability to participate. If the client can safely participate in the transfer, a gait/transfer belt or sliding board can be used; if not, a powered standing assist lift or full-body lift would be safer for the client and nurse.

Transferring Between Bed and Chair—continued

Equipment

- Robe or appropriate clothing
- Slippers or shoes with nonskid soles
- Gait/transfer belt
- Chair, commode, wheelchair as appropriate to client need
 - Slide board, if appropriate
 - Lift, if appropriate

IMPLEMENTATION

Preparation

- Plan what to do and how to do it.
- Obtain essential equipment before starting (e.g., gait/transfer belt, wheelchair), and check that all equipment is functioning correctly.
- Remove obstacles from the area so clients do not trip. Make sure there are no spills or liquids on the floor on which clients could slip.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain the transfer process to the client. During the transfer, explain step by step what the client should do, for example, "Move your right foot forward."
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Position the equipment appropriately.
 - Lower the bed to its lowest position so that the client's feet will rest flat on the floor. Lock the wheels of the bed.
 - Place the wheelchair parallel to the bed and as close to the bed as possible. 1 Put the wheelchair on the side of the bed that allows the client to move toward his or her stronger side. Lock the wheels of the wheelchair and raise the footplate.
5. Prepare and assess the client.
 - Assist the client to a sitting position on the side of the bed (see Skill 44-4).
 - Assess the client for orthostatic hypotension before moving the client from the bed.
 - Assist the client in putting on a bathrobe and nonskid slippers or shoes.
 - Place a gait/transfer belt snugly around the client's waist. Check to be certain that the belt is securely fastened.
6. Give explicit instructions to the client. Ask the client to:
 - Move forward and sit on the edge of the bed (or surface on which the client is sitting) with feet placed flat on the floor. **Rationale:** This brings the client's center of gravity closer to the nurse's.
 - Lean forward slightly from the hips. **Rationale:** This brings the client's center of gravity more directly over the base of support and positions the head and trunk in the direction of the movement.
 - Place the foot of the stronger leg beneath the edge of the bed (or sitting surface) and put the other foot forward. **Rationale:** In this way, the client can use the stronger leg muscles to stand and power the movement. A broader base of support makes the client more stable during the transfer.
 - Place the client's hands on the bed surface (or available stable area) so that the client can push while standing. **Rationale:** This provides additional force for the movement and reduces the potential for strain on the nurse's back. The client should not grasp your neck for support. **Rationale:** Doing so can injure the nurse.

DELEGATION

The skill of transferring a client can be delegated to UAP who have demonstrated safe transfer technique for the involved client. It is important for the nurse to assess the client's capabilities and communicate specific information about what the UAP should report back to the nurse.

1 The wheelchair is placed parallel to the bed and as close to the bed as possible. Note that placement of the nurse's feet mirrors that of the client's feet.

7. Position yourself correctly.
 - Stand directly in front of the client and to the side requiring the most support. Hold the gait/transfer belt with the nearest hand; the other hand supports the back of the client's shoulder. Lean your trunk forward from the hips. Flex your hips, knees, and ankles. Assume a broad stance, placing one foot forward and one back. Brace the client's feet with your feet to prevent the client from sliding forward or laterally. Mirror the placement of the client's feet, if possible. **Rationale:** This helps prevent loss of balance during the transfer.
8. Assist the client to stand, and then move together toward the wheelchair or sitting area to which you wish to transfer the client.
 - On the count of three or the verbal instructions of "Ready—steady—stand" and on the count of three or the word "Stand," ask the client to push down against the mattress/side of the bed while you transfer your weight from one foot to the other (while keeping your back straight) and stand upright moving the client forward (directly toward your center of gravity) into a standing position. (If the client requires more than a very small degree of pulling, even with the assistance of two nurses, a mechanical device should be obtained and used.)
 - Support the client in an upright standing position for a few moments. **Rationale:** This allows the nurse and the client to extend the joints and provides the nurse with an opportunity to ensure that the client is stable before moving away from the bed.
 - Together, pivot on your foot farthest from the chair, or take a few steps toward the wheelchair, bed, chair, commode, or car seat.
9. Assist the client to sit.
 - Move the wheelchair forward or have the client back up to the wheelchair (or desired seating area) and place the legs against the seat. **Rationale:** Having the client place the legs against the wheelchair seat minimizes the risk of the client falling when sitting down.

Transferring Between Bed and Chair—continued

- Make sure the wheelchair brakes are on.
- Have the client reach back and feel/hold the arms of the wheelchair.
- Stand directly in front of the client. Place one foot forward and one back.
- Tighten your grasp on the transfer belt, and tighten your gluteal, abdominal, leg, and arm muscles.
- Have the client sit down while you bend your knees/hips and lower the client onto the wheelchair seat.

10. Ensure client safety.

- Ask the client to push back into the wheelchair seat.
Rationale: *Sitting well back on the seat provides a broader base of support and greater stability and minimizes the risk of falling from the wheelchair. A wheelchair or bedside commode can topple forward when the client sits on the edge of the seat and leans far forward.*
- Remove the gait/transfer belt.
- Lower the footplates, and place the client's feet on them, if applicable.

Variation: Transferring with a Belt and Two Nurses

- Even if a client is able to partially bear weight and is cooperative, it still may be safer to transfer a client with the assistance of two nurses. If so, you should position yourselves on both sides of the client, facing the same direction as the client. Flex your hips, knees, and ankles. Grasp the client's transfer belt with the hand closest to the client, and with the other hand support the client's elbows.
- Coordinating your efforts, all three of you stand simultaneously, pivot, and move to the wheelchair. Reverse the process to lower the client onto the wheelchair seat.

Variation: Transferring a Client with an Injured Lower Extremity

When the client has an injured lower extremity, movement should always occur toward the client's unaffected (strong) side. For example, if the client's right leg is injured and the client is sitting on the edge of the bed preparing to transfer to a wheelchair, position the wheelchair on the client's left side. **Rationale:** *In this way, the client can use the unaffected leg most effectively and safely.*

2 Using a slide board.

Variation: Using a Slide Board

For clients who cannot stand but are able to cooperate and possess sufficient upper body strength, use a slide board to help them move without nursing assistance. **2 Rationale:** *This method not only promotes client's sense of independence but also preserves your energy.*

11. Document relevant information:

- Client's ability to bear weight and pivot
- Number of staff needed for transfer and safety measures/precautions used
- Length of time up in chair
- Client response to transfer and being up in chair or wheelchair.

Note: This skill describes the process to use for a client who is able to perform the task independently and only needs standby assistance for steadying. For clients who require moderate or maximum assistance, a lateral chair or a mobile or ceiling-mounted transfer system is required.

Transferring Between Bed and Stretcher

PURPOSE

- The stretcher, or gurney, is used to transfer supine clients from one location to another. Whenever the client is capable of accomplishing the transfer from bed to stretcher independently, either by lifting onto it or by rolling onto it, the client should be encouraged to do so. If the client cannot move onto the stretcher independently and weighs less than 200 pounds, a friction-reducing device (i.e., slide sheet) and/or a lateral transfer board **1** or an air transfer system should be used, and at least two caregivers are needed to assist with the transfer. Some friction-reducing devices have handles or long straps to avoid awkward stretching by the caregivers when pulling the client during the lateral transfer. For clients between 201 and 300 pounds, a slide sheet or transfer board and four caregivers or an air transfer system and two caregivers should be used. For clients who weigh more than 300 pounds, two caregivers and either an air transfer system or a ceiling lift with supine sling should be used. Depending on the client's condition (e.g., neck immobilizer, IVs, drains, chest tube), additional assistants may be needed.

1 A lateral transfer board. The friction-reducing material rolls when transferring clients in a supine position.

Transferring Between Bed and Stretcher—continued

ASSESSMENT

Before transferring a client, assess the following:

- The client's body size and weight
- Ability to follow instructions
- Activity tolerance
- Level of comfort
- The space in which the transfer is maneuvered
- The number of assistants (one to four) needed to accomplish the transfer safely.

PLANNING

Review the client record to determine if previous nurses have recorded information about how the client tolerated similar transfers. If indicated, implement pain-relief measures so that they are effective when the transfer begins.

DELEGATION

The skill of transferring a client can be delegated to UAP who have demonstrated safe transfer technique for the involved client. It is important for the nurse to assess the number of staff needed, assistive devices needed, and the client's ability to assist and to communicate specific information about what the UAP should report to the nurse.

IMPLEMENTATION

Preparation

Obtain the necessary equipment and nursing personnel to assist in the transfer.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Explain the transfer to the nursing personnel who are helping and specify who will give directions (one person needs to be in charge).
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Adjust the client's bed in preparation for the transfer.
 - Lower the head of the bed until it is flat or as low as the client can tolerate.
 - Place the friction-reducing device under the client.
 - Raise the bed so that it is slightly higher (i.e., 1/2 in.) than the surface of the stretcher. **Rationale:** *It is easier for the client to move down a slant.*
 - Ensure that the wheels on the bed are locked.
 - Place the stretcher parallel to the bed next to the client and lock the stretcher wheels.
 - Fill the gap that exists between the bed and the stretcher loosely with the bath blankets (optional).
5. Transfer the client securely to the stretcher.
 - If the client can transfer independently, encourage him or her to do so and stand by for safety.
 - If the client is partially able or not able to transfer:
 - One caregiver needs to be at the side of the client's bed, between the client's shoulder and hip.
 - The second and third caregivers should be at the side of the stretcher: one positioned between the client's

shoulder and hip and the other between the client's hip and lower legs.

- All caregivers should position their feet in a walking stance.
- Ask the client to flex the neck during the move, if possible, and place the arms across the chest.

Rationale: *This prevents injury to those body parts.*

- On a planned command, the caregivers at the stretcher's side pull (shifting weight to the rear foot), and the caregiver at the bedside pushes the client toward the stretcher (shifting weight to the front foot).

6. Ensure client comfort and safety.

- Make the client comfortable, unlock the stretcher wheels, and move the stretcher away from the bed.
- Immediately raise the stretcher side rails and/or fasten the safety straps across the client. **Rationale:** *Because the stretcher is high and narrow, the client is in danger of falling unless these safety precautions are taken.*

Variation: Using a Transfer Board

The transfer board is a lacquered or smooth polyethylene board measuring 45 to 55 cm (18 to 22 in.) by 182 cm (72 in.) with handholds along its edges. Transfer mattresses are also available, as are mechanical assistive devices. It is imperative to have enough people assisting with the transfer to prevent injury to staff as well as clients. Turn the client to a lateral position away from you, position the board close to the client's back, and roll the client onto the board. Pull the client and board across the bed to the stretcher. Safety belts may be placed over the chest, abdomen, and legs.

7. Document relevant information:

- Equipment used
- Number of people needed for transfer and safety measures/precautions used
- Destination if reason for transfer is transport from one location to another.

EVALUATION

- Compare client capabilities such as weight bearing, pivoting ability, and strength and control during previous transfers.
- Report any significant deviations from normal to the primary care practitioner.
- Note use of appropriate safety measures (e.g., transfer belt, locking wheels of bed and stretcher) by UAP during transfer process.

LIFESPAN CONSIDERATIONS Transferring Clients**INFANTS**

The infant who is lying down, on the side or supine, can be placed in either a bassinet or crib for transport. If the bassinet has a bottom shelf, it can be used for carrying the IV pump or monitor.

CHILDREN

- The toddler should be transported in a high-top crib with the side rails up and the protective top in place. Stretchers should not be used because the mobile toddler may roll or fall off.

OLDER ADULTS

- Because conditions of older adults can change from day to day, always assess the situation to ensure that you have the right

equipment and enough people to assist when transferring a client.

- Use special caution with older clients to prevent skin tears or bruising during a transfer or when using a hydraulic lift.
- Write the method used to transfer each client—equipment used, best position, and number of people needed to assist in transfer. This can be part of the care plan and also be available in the client's room as a guide to all personnel caring for the client.
- Avoid sudden position changes. They can cause orthostatic hypotension and increase the risk of fainting and falls.

Home Care Considerations Transferring from Bed to a Chair**PATIENT-CENTERED CARE**

- The caregiver and client should practice transfer technique(s), using appropriate equipment as needed, in the hospital or long-term care setting before being discharged.
- Assess furniture in the home. Does the client's favorite chair have arms for ease of using and sitting? Examine the fabric—is

it rough? Will it cause skin abrasions? If the client will be using a wheelchair, is there enough space in the bedroom and bathroom for a safe transfer?

- Observe client and caregiver transfer technique in the home setting to reinforce prior teaching.

Providing ROM Exercises

Clients who experience restrictions in activity are at risk for impaired joint mobility. Promoting exercise to maintain a client's muscle tone and joint mobility is an essential function of nursing personnel. When clients are ill, they may need to perform ROM exercises until they can regain their normal activity levels.

Active ROM exercises are isotonic exercises in which the client moves each joint in the body through its complete range of movement, maximally stretching all muscle groups within each plane over the joint. These exercises maintain or increase muscle strength and endurance and help to maintain cardiorespiratory function in an immobilized client. They also prevent deterioration of joint capsules, ankylosis, and contractures (permanent shortening of the muscle).

Full ROM does not occur spontaneously in the immobilized individual who independently achieves ADLs, moves about in bed, transfers between bed and wheelchair or chair, or ambulates a short distance, because only a few muscle groups are maximally stretched during these activities. Although the client may successfully achieve some active ROM movements of the upper extremities while combing the hair, bathing, and dressing, the immobilized client is very unlikely to achieve any active ROM movements of the lower extremities when these are not used in the normal functions of standing and walking about. For this reason, most clients who use a wheelchair and many ambulatory clients need active ROM exercises until they regain their normal activity levels.

At first, the nurse may need to teach the client and family to perform the needed ROM exercises; eventually, the client may be able to accomplish these independently. Instructions for the client performing active ROM exercises are shown in the accompanying Client Teaching.

During **passive ROM exercises**, another person moves each of the client's joints through its complete range of movement, maximally stretching all muscle groups within each plane over each joint. Because the client does not contract the muscles, passive ROM exercises are of no value in maintaining muscle strength but are useful in

maintaining joint flexibility. For this reason, passive ROM exercises should be performed only when the client is unable to accomplish the movements actively.

Passive ROM exercises should be accomplished for each movement of the arms, legs, and neck that the client is unable to achieve actively. As with active ROM exercises, passive ROM exercises should be accomplished to the point of slight resistance, but not beyond, and never to the point of discomfort. The movements should be systematic, and the same sequence should be followed during each exercise session. Each exercise should be repeated, at the client's tolerance, from three to five times. The series of exercises should be done twice daily. Performing one series of exercises along with the bath is helpful. Passive ROM exercises are accomplished most effectively when the client lies supine in bed. General guidelines for providing passive exercises are shown in the accompanying Practice Guidelines.

During active-assistive ROM exercises, the client uses a stronger, opposite arm or leg to move each of the joints of a limb incapable of active motion. The client learns to support and move the weak arm or leg with the strong arm or leg as far as possible. Then the nurse continues the movement passively to its maximal degree. This activity

CLIENT TEACHING**Active ROM Exercises**

- Perform each ROM exercise as taught to the point of slight resistance, but not beyond, and never to the point of discomfort.
- Perform the movements systematically, using the same sequence during each session.
- Perform each exercise three times.
- Perform each series of exercises twice daily.

OLDER ADULTS

- For older adults, it is not essential to achieve full range of motion in all joints. Instead, emphasize achieving a sufficient range of motion to carry out ADLs, such as walking, dressing, combing hair, showering, and preparing a meal.

increases active movement on the strong side of the client's body and maintains joint flexibility on the weak side. Such exercise is especially useful for clients who have had a stroke and are hemiplegic (paralyzed on one half of the body).

CLINICAL ALERT!

Clients who require passive ROM exercises after a disability should have a goal of progressing to active-assistive ROM exercises and, finally, to active ROM exercises.

AMBULATING CLIENTS

Ambulation (the act of walking) is a function that most people take for granted. However, when clients are ill they are often confined to bed and are thus nonambulatory. The longer clients are in bed, the more difficulty they have walking. In fact, evidence continues to support that early, routine mobilization of critically ill clients is safe, improves muscle

strength and functional independence, and reduces hospital length of stay (Dammeyer, Dickinson, Packard, Baldwin, & Ricklemann, 2013).

Even 1 or 2 days of bed rest can make a client feel weak, unsteady, and shaky when first getting out of bed. A client who has had surgery, is elderly, or has been immobilized for a longer time will feel more pronounced weakness. The potential problems of immobility are far less likely to occur when clients become ambulatory as soon as possible. The nurse can assist clients to prepare for ambulation by helping them become as independent as possible while in bed. Nurses should encourage clients to perform ADLs, maintain good body alignment, and carry out active ROM exercises to the maximum degree possible yet within the limitations imposed by their illness and recovery program.

Preambulatory Exercises

Clients who have been in bed for long periods often need to perform muscle tone exercises to strengthen the muscles used for walking before attempting to walk. One of the most important muscle groups is

PRACTICE GUIDELINES

Providing Passive ROM Exercises

- Ensure that the client understands the reason for doing ROM exercises.
- If there is a possibility of hand swelling, make sure rings are removed.
- Clothe the client in a loose gown, and cover the body with a bath blanket.
- Use correct body mechanics when providing ROM exercises to avoid muscle strain or injury to both yourself and the client.
- Position the bed at an appropriate height.
- Expose only the limb being exercised to avoid embarrassing the client and to maintain warmth.
- Support the client's limbs above and below the joint as needed to prevent muscle strain or injury (Figure 44–58 ■). This may also be done by cupping joints in the palm of your hand or cradling limbs along your forearm (Figure 44–59 ■). If a joint is painful (e.g., arthritic), support the limb in the muscular areas above and below the joint.
- Use a firm, comfortable grip when handling the limb.
- Move the body parts smoothly, slowly, and rhythmically. Jerky movements cause discomfort and, possibly, injury. Fast movements can cause spasticity (sudden, prolonged involuntary muscle contraction) or rigidity (stiffness or inflexibility).
- Avoid moving or forcing a body part beyond the existing range of motion. Muscle strain, pain, and injury can result. This is particularly important for people with flaccid (limp) paralysis, whose muscles can be stretched and joints dislocated without their awareness.
- If muscle spasticity occurs during movement, stop the movement temporarily, but continue to apply slow, gentle pressure on the part until the muscle relaxes; then proceed with the motion.

Figure 44–58 ■ Supporting a limb above and below the joint for passive exercise.

- If a contracture is present, apply slow firm pressure, without causing pain, to stretch the muscle fibers.
- If rigidity occurs, apply pressure against the rigidity, and continue the exercise slowly.
- Teach client's caregiver the purposes and technique of performing passive ROM at home if appropriate.
- Avoid hypertension of joints in older adults if joints are arthritic.
- Use the exercises as an opportunity to also assess skin condition.

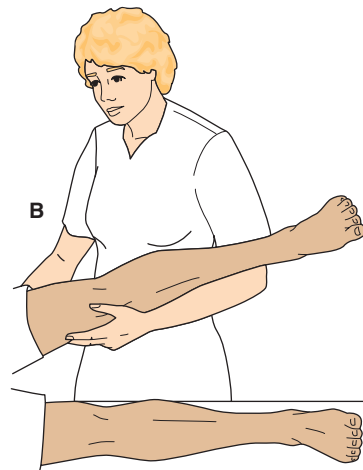

Figure 44–59 ■ Holding limbs for support during passive exercise: A, cupping; B, cradling.

Figure 44–60 ■ Tensing the quadriceps femoris muscles before ambulation.

the quadriceps femoris, which extends the knee and flexes the thigh. This group is also important for elevating the legs, for example, for walking upstairs. These exercises are frequently called quadriceps drills or sets. To strengthen these muscles, the client consciously tenses them, drawing the kneecap upward and inward. The client pushes the popliteal space of the knee against the bed surface, relaxing the heels on the bed surface (Figure 44–60 ■). On the count of 1, the muscles are tensed; they are held during the counts of 2, 3, 4; and they are relaxed at the count of 5. The exercise should be done within the client's tolerance, that is, without fatiguing the muscles. Carried out several times an hour during waking hours, this simple exercise significantly strengthens the muscles used for walking.

Assisting Clients to Ambulate

Clients who have been immobilized for even a few days may require assistance with ambulation. The amount of assistance will depend on the client's condition, including age, health status, and length of

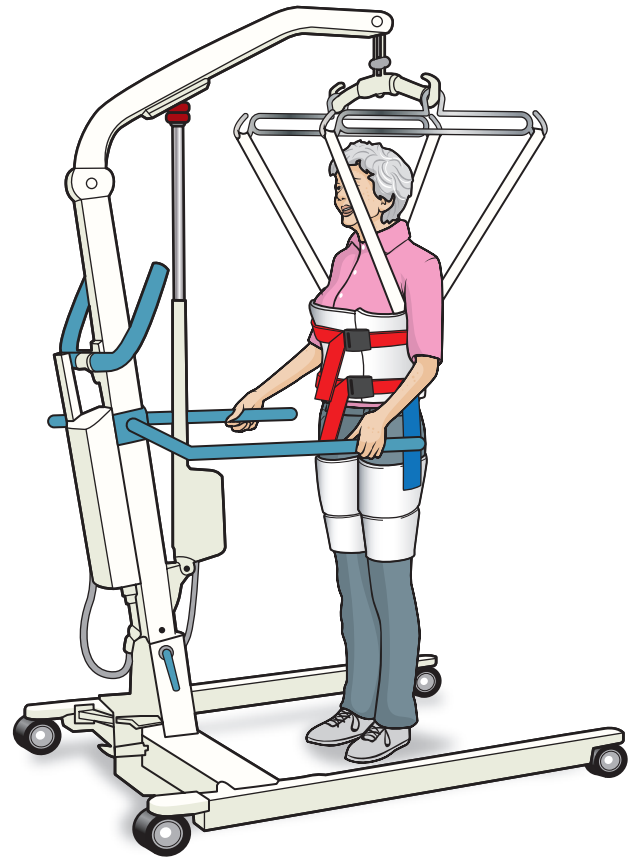

Figure 44–61 ■ Promoting ambulation by using a lift with an ambulation sling.

inactivity. Assistance may mean walking alongside the client while providing standby support for safety (Skill 44–7); providing instruction to the client about the use of assistive devices such as a cane, walker, or crutches; or using a sit-to-stand lift with ambulation capability or a lift with an ambulation sling (Figure 44–61 ■).

Evidence-Based Practice Is Early Mobilization of Critically Ill Clients Effective and Safe?

EVIDENCE-BASED PRACTICE

Critically ill clients have been traditionally placed on bed rest during their stay in an intensive care unit (ICU) with their activity progression to sitting and standing occurring once they are transferred to a nursing unit. This delay in activity increases the risk for immobility complications. Recent studies have challenged this practice and have shown that critically ill clients in medical and surgical ICUs benefit from early mobilization. No studies, however, have investigated the safety or effectiveness of early mobilization in critically ill clients who have sustained traumatic or burn injuries. As a result, Clark, Lowman, Griffin, Matthews, and Reiff (2013) conducted a quality improvement project at their medical center to assess the effects of an early mobilization protocol on complication rates, ventilator days, and ICU and hospital lengths of stay for clients admitted to a trauma and burn ICU (TBICU). The early mobility program team consisted of physicians, surgeons, RNs, respiratory therapists, and physical therapists. This team developed a protocol for early mobilization in a TBICU that consisted of four levels of progressive mobility. Specific contraindications for the initiation of early mobility at level 2 and higher were also identified. The nursing standard of care included positioning of the client every 2 hours and daily routine passive range of motion (PROM) as determined by the physical therapist. The nursing and physical therapy managers conducted educational instructional sessions to discuss PROM and common positioning and ROM limitations seen in the TBICU population. They also reviewed and

reinforced the positive outcomes of previous early mobilization studies. A retrospective study was conducted with clinical and demographic data collected for clients admitted to the TBICU from May 2008 through April 2010. The 1,044 clients admitted from May 2008 through April 2009 were categorized as pre-early mobility program and the 1,132 clients admitted from May 2009 through April 2010 were categorized as post-early mobility program. When comparing the two groups, the post-early mobility program group had the following findings: The overall hospital length of stay was significantly shorter by 2.4 days and there was a decrease in airway, pulmonary, and vascular complications (e.g., pneumonia and deep venous thrombosis). No adverse events were reported related to the early mobility program. Ventilator days and TBICU length of stay were not significantly decreased. The study concluded that early mobilization of clients in a TBICU was safe and effective.

IMPLICATIONS

This quality improvement study/project added to the recent evidence demonstrating the safety and importance of mobilizing clients early in ICUs. The authors pointed out the importance of the collaborative teamwork to develop the protocol and also in the implementation of the early mobility program. Nurses, physical therapists, respiratory therapists, and physicians worked together to prioritize clients' mobility needs.

CLIENT TEACHING

Controlling Postural Hypotension

- Rest with the head of the bed elevated 8 to 12 inches. This position makes the position change on rising less severe.
- Avoid sudden changes in position. Arise from bed in three stages:
 - a. Sit up in bed for 1 minute.
 - b. Sit on the side of the bed with legs dangling for 1 minute.
 - c. Stand with care, holding onto the edge of the bed or another nonmovable object for 1 minute.
- Never bend down all the way to the floor or stand up too quickly after stooping.
- Postpone activities such as shaving and hair grooming for at least 1 hour after rising.
- Wear elastic stockings at night to inhibit venous pooling in the legs.
- Be aware that the symptoms of hypotension are most severe at the following times:
 - a. 30 to 60 minutes after a heavy meal
 - b. 1 to 2 hours after taking an antihypertension medication.
- Get out of a hot bath very slowly, because high temperatures can lead to venous pooling.
- Use a rocking chair to improve circulation in the lower extremities. Even mild leg conditioning can strengthen muscle tone and enhance circulation.
- Refrain from any strenuous activity that results in holding the breath and bearing down. This Valsalva maneuver slows the heart rate, leading to subsequent lowering of blood pressure.

Assisting a Client to Ambulate**PURPOSE**

- To provide a safe condition for the client to walk with whatever support is needed

ASSESSMENT**Assess**

- Length of time in bed and the amount and type of activity the client was last able to tolerate
- Baseline vital signs
- Range of motion of joints needed for ambulating (e.g., hips, knees, ankles)
- Muscle strength of lower extremities
- Need for ambulation aids (e.g., cane, walker, crutches, lift with ambulation sling)

- Client's intake of medications (e.g., narcotics, sedatives, tranquilizers, and antihistamines) that may cause drowsiness, dizziness, weakness, and orthostatic hypotension and seriously hinder the client's ability to walk safely
- Presence of joint inflammation, fractures, muscle weakness, or other conditions that impair physical mobility
- Ability to understand directions
- Level of comfort

PLANNING

Implement pain relief measures so that they are effective. The amount of assistance needed while ambulating will depend on the client's condition, for example, age, health status, length of inactivity, and emotional readiness. Review any previous experiences with ambulation and the success of such efforts. Plan the length of the walk with the client, considering the nursing or primary care practitioner's orders and the medical condition of the client. Be prepared to shorten the walk according to the client's activity tolerance.

DELEGATION

Ambulation of clients is frequently delegated to UAP. However, the nurse should conduct an initial assessment of the client's abilities in order to direct other personnel in providing appropriate assistance. Any unusual events that arise from assisting the client in ambulation must be validated and interpreted by the nurse.

INTERPROFESSIONAL PRACTICE

Assisting a client to ambulate may be within the scope of practice for specific health care providers. For example, in addition to nurses, physical therapists may help a client to ambulate. Although the physical therapist may verbally communicate their findings and plan to the health care team members, the nurse must also know where to locate their documentation in the client's medical record.

Equipment

- Assistive devices required for safe ambulation of client (e.g., gait/transfer belt, walker, cane, sit to stand assist device, lift with ambulation sling)
- Wheelchair for following client, or chairs along the route if the client needs to rest
- Portable oxygen tank if the client needs it

IMPLEMENTATION**Preparation**

Be certain that others are available to assist you if needed. Also, plan the route of ambulation that has the fewest hazards and a clear path for ambulation.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client how you are going to assist, why ambulation is necessary, and how he or she can participate. Discuss how this activity relates to the overall plan of care. Stress that the client must keep the

nurse informed as to how the activity is being tolerated as it progresses.

2. Perform hand hygiene and observe appropriate infection prevention procedures.
3. Ensure that the client is appropriately dressed to walk and has shoes or slippers with nonskid soles.
4. Prepare the client for ambulation.
 - Have the client sit up in bed for at least 1 minute prior to preparing to dangle legs.
 - Assist the client to sit on the edge of the bed and allow dangling for at least 1 minute.

Assisting a Client to Ambulate—continued

- Assess the client carefully for signs and symptoms of orthostatic hypotension (dizziness, light-headedness, or a sudden increase in heart rate) prior to leaving the bedside. **Rationale:** *Allowing for gradual adjustment can minimize drops in blood pressure (and fainting) that occur with shifts in position from lying to sitting, and sitting to standing.*
 - Assist the client to stand by the side of the bed for at least 1 minute until he or she feels secure.
 - Carefully attend to any IV tubing, catheters, or drainage bags. Keep urinary drainage bags below level of the client's bladder. **Rationale:** *To prevent backflow of urine into bladder and risk of infection.*
 - If the client is a high safety risk (e.g., cannot follow commands, medical instability, lack of experience with assistive device, neurologic deficits), use a lift with ambulation sling and 1-2 caregivers.
 - If the client is a high safety risk and has upper extremity strength and is able to grasp with at least one hand, use a lift with ambulation sling or a sit-to-stand lift with ambulation capability and 1-2 caregivers.
 - If the client is a low safety risk (e.g., able to follow commands, medically stable, and experienced with assistive device), use a gait/transfer belt for standby assist as needed and assistive devices as needed (e.g., crutches, walker, cane) and 1-2 caregivers. Make sure the belt is pulled snugly around the client's waist and fastened securely. Grasp the belt at the client's back, and walk behind and slightly to one side of the client. ①
5. Ensure client safety while assisting the client to ambulate.
- Encourage the client to ambulate independently if he or she is able, but walk beside the client's weak side, if appropriate. If the client has a lightweight IV pole because of infusing

fluids, he or she may find that holding onto the pole while ambulating helps with balance. If the pole or other equipment is cumbersome in any way, the nurse must push it to match the client's pace, securing any assistance necessary in order to move smoothly with the client.

- Remain physically close to the client in case assistance is needed at any point.
 - If it is the client's first time out of bed following surgery, injury, or an extended period of immobility, or if the client is weak or unstable, have an assistant follow you and the client with a wheelchair in the event that it is needed quickly.
 - Encourage the client to assume a normal walking stance and gait as much as possible. Ask the client to straighten the back and raise the head so that the eyes are looking forward in a normal horizontal plane. **Rationale:** *Clients who are unsure of their ability to ambulate tend to look down at their feet, which makes them more likely to fall.*
6. Protect the client who begins to fall while ambulating.
- If a client begins to experience the signs and symptoms of orthostatic hypotension or extreme weakness, quickly assist the client into a nearby wheelchair or other chair, and help the client to lower the head between the knees.
 - Stay with the client. **Rationale:** *A client who faints while in this position could fall head first out of the chair.*
 - When the weakness subsides, assist the client back to bed.
 - If a chair is not close by, assist the client to a horizontal position on the floor before fainting occurs.
 - Assume a broad stance with one foot in front of the other. **Rationale:** *A broad stance widens your base of support. Placing one foot behind the other allows you to rock backward and use the femoral muscles when supporting the client's weight and lowering the center of gravity (see the next step), thus preventing back strain.*
 - Bring the client backward so that your body supports the person. **Rationale:** *Clients who faint or start to fall usually pitch slightly forward because of the momentum of ambulating. Bringing the client's weight backward against your body allows gradual movement to the floor without injury to the client.*
 - Allow the client to slide down your leg, and lower the person gently to the floor, making sure the client's head does not hit any objects.

Variation: Two Nurses

- Place a gait/transfer belt around the client's waist. Each nurse grasps the side handle with the near hand and the lower aspect of the client's upper arm with the other hand.
 - Walk in unison with the client, using a smooth, even gait, at the same speed and with steps the same size as the client's. **Rationale:** *This gives the client a greater feeling of security.*
7. Document distance and duration of ambulation and assistive devices, if used, in the client record using forms or checklists supplemented by narrative notes when appropriate. Include description of the client's gait (including body alignment) when walking; pace; activity tolerance when walking (e.g., pulse rate, facial color, any shortness of breath, feelings of dizziness, or weakness); degree of support required; and respiratory rate and blood pressure after initial ambulation to compare with baseline data.

① Using a gait/transfer belt to support the client.

EVALUATION

- Establish a plan for continued ambulation based on expected or normal ability for the client.

LIFESPAN CONSIDERATIONS Assisting a Client to Ambulate**CHILDREN**

Children and adolescents who have suffered a sports injury (e.g., sprained ankle) may want to be more active than they should be. A cast, splint, or boot may be put in place to limit activity and assist in healing. Teach the child the importance of appropriate activity, and the use of assistive devices (e.g., crutches) if necessary. Help them focus on what they *can* do rather than what they cannot do (e.g., “You can stand at the free-throw line and shoot baskets”).

OLDER ADULTS

- Inquire how the client has ambulated previously and/or check any available chart notes regarding the client’s abilities and modify assistance accordingly.
- Take into account a decrease in speed, strength, resistance to fatigue, reaction time, and coordination due to a decrease in nerve conduction.
- Be cautious when using a gait belt with a client with osteoporosis. Too much pressure from the belt can increase the risk of vertebral compression fractures. If a client has had abdominal surgery, it may be necessary to use a gait vest instead of a gait belt.
- If assistive devices such as a walker or cane are used, make sure clients are supervised in the beginning to learn the proper method of using them. Crutches may be much more difficult for older adults to use due to decreased upper body strength.
- Be alert to signs of activity intolerance, especially in older adults with cardiac and lung problems.
- Set small goals and increase slowly to build endurance, strength, and flexibility.
- Be aware of any fall risks the older adult may have, such as the following:
 - Effects of medications
 - Neurologic disorders
 - Orthopedic problems
 - Presence of equipment that must accompany the client when ambulating
 - Environmental hazards
 - Orthostatic hypotension
- In older adults, the body’s responses return to normal more slowly. For instance, an increase in heart rate from exercise may stay elevated for hours before returning to normal.

Home Care Considerations Assisting a Client to Ambulate**SAFETY**

- When making a home visit, assess carefully for safety issues concerning ambulation. Counsel the client and family about inadequate lighting, unfastened rugs, slippery floors, and loose objects on the floors.
- Check the surroundings for adequate supports such as railings and grab bars.
- Recommend that nonskid strips be placed on outside steps and inside stairs that are not carpeted.
- Ask to see the shoes the client intends to wear while ambulating. They should be in good repair and should support the foot.

Some clients experience postural (orthostatic) hypotension on assuming a vertical position from a lying position and may need information about ways to control this problem (see Client Teaching). The client may exhibit some or all of the following symptoms: pallor, diaphoresis, nausea, tachycardia, and dizziness. If any of these are present, the client should be assisted to a supine position in bed and closely assessed.

Using Mechanical Aids for Walking

Mechanical aids for ambulation include canes, walkers, and crutches.

Canes

Three types of canes are commonly used: the standard straight-legged cane; the tripod cane, which has three feet; and the quad cane, which has four feet and provides the most support (Figure 44–62 ■). Cane tips should have rubber caps to improve traction and prevent slipping. The standard cane is 91 cm (36 in.) long; some aluminum canes can be adjusted from 56 to 97 cm (22 to 38 in.). The length should permit the elbow to be slightly flexed. Clients may use either one or two canes, depending on how much support they require.

Figure 44–62 ■ A quad cane.

CLIENT TEACHING

Using Canes

- Hold the cane with the hand on the stronger side of the body to provide maximum support and appropriate body alignment when walking.
- Position the tip of a standard cane (and the nearest tip of other canes) about 15 cm (6 in.) to the side and 15 cm (6 in.) in front of the near foot, so that the elbow is slightly flexed.

WHEN MAXIMUM SUPPORT IS REQUIRED

- Move the cane forward about 30 cm (1 ft), or a distance that is comfortable while the body weight is borne by both legs (Figure 44–63 A ■).
- Then move the affected (weak) leg forward to the cane while the weight is borne by the cane and stronger leg (Figure 44–63 B).

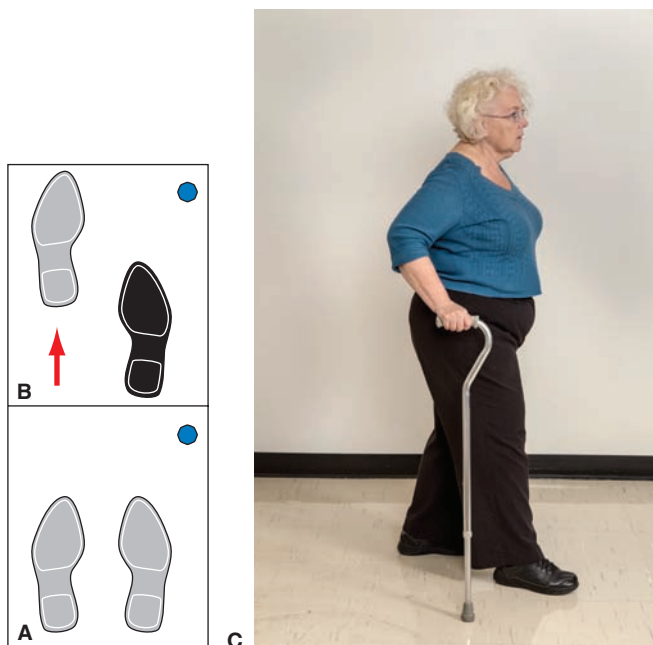

Figure 44–63 ■ Steps involved in using a cane to provide maximum support.

- Next, move the unaffected (stronger) leg forward ahead of the cane and weak leg while the weight is borne by the cane and weak leg (Figure 44–63 C).
- Repeat the steps. This pattern of moving provides at least two points of support on the floor at all times.

AS YOU BECOME STRONGER AND REQUIRE LESS SUPPORT

- Move the cane and weak leg forward at the same time, while the weight is borne by the stronger leg (Figure 44–64 A ■).
- Move the stronger leg forward, while the weight is borne by the cane and the weak leg (Figure 44–64 B).

Figure 44–64 ■ Steps involved in using a cane when less than maximum support is required.

Walkers

Walkers are mechanical devices for ambulatory clients who need more support than a cane provides and lack the strength and balance required for crutches. Walkers come in many different shapes and sizes, with devices suited to individual needs. The standard type is made of polished aluminum. It has four legs with rubber tips and plastic hand grips (Figure 44–65 A ■). Many walkers have adjustable legs.

The standard walker needs to be picked up to be used. The client therefore requires partial strength in both hands and wrists, strong elbow extensors, and strong shoulder depressors. The client also needs the ability to bear at least partial weight on both legs.

Four-wheeled and two-wheeled models of walkers (roller walkers) do not need to be picked up to be moved, but they are less stable than the standard walker is. They are used by clients who are too weak or unstable to pick up and move the walker with each step. Some roller walkers have a seat at the back so the client can sit down to rest when desired. An adaptation of the standard and four-wheeled walker is one that has two tips and two wheels (Figure 44–65 B). This type provides more stability than the four-wheeled model yet still permits the client to keep the walker in contact with the ground

all the time. The legs with wheels allow the client to easily push the walker forward, and the legs without wheels prevent the walker from rolling away as the client steps forward.

The nurse may need to adjust the height of a client's walker so that the hand bar is just below the client's waist and the client's elbows are slightly flexed. This position helps the client assume a more normal stance. A walker that is too low causes the client to stoop; one that is too high makes the client stretch and reach.

Crutches

Crutches may be a temporary need for some clients and a permanent one for others. Crutches should enable a client to ambulate independently; therefore, it is important to learn to use them properly. The most frequently used kinds of crutches are the underarm crutch, or axillary crutch with hand bars, and the Lofstrand crutch, which extends only to the forearm. On the Lofstrand crutch, the metal cuff around the forearm and the metal bar stabilize the wrists and thus make walking easier, especially on stairs. The platform, or elbow extensor crutch also has a cuff for the upper arm to permit forearm weight bearing. All crutches require suction tips, usually made of rubber, which help to prevent slipping on a floor surface.

A

B

Figure 44-65 ■ A, Standard walker; B, two-wheeled walker.

CLIENT TEACHING

Using Walkers

WHEN MAXIMUM SUPPORT IS REQUIRED

- Move the walker ahead about 15 cm (6 in.) while your body weight is borne by both legs.
- Then move the right foot up to the walker while your body weight is borne by the left leg and both arms.
- Next, move the left foot up to the right foot while your body weight is borne by the right leg and both arms.

IF ONE LEG IS WEAKER THAN THE OTHER

- Move the walker and the weak leg ahead together about 15 cm (6 in.) while your weight is borne by the stronger leg.
- Then move the stronger leg ahead while your weight is borne by the affected leg and both arms.

In crutch walking, the client's weight is borne by the muscles of the shoulder girdle and the upper extremities. Before beginning crutch walking, exercises that strengthen the upper arms and hands are recommended.

Measuring Clients for Crutches When nurses measure clients for axillary crutches, it is most important to obtain the correct length for the crutches and the correct placement of the handpiece. There are two methods of measuring crutch length:

1. The client lies in a supine position and the nurse measures from the anterior fold of the axilla to the heel of the foot and adds 2.5 cm (1 in.).
2. The client stands erect and positions the crutch as shown in Figure 44-66 ■. The nurse makes sure the shoulder rest of the crutch is at least three fingerwidths, that is, 2.5 to 5 cm (1 to 2 in.), below the axilla.

To determine the correct placement of the hand bar:

1. The client stands upright and supports the body weight by the hand grips of the crutches.

2. The nurse measures the angle of elbow flexion. It should be about 30 degrees. A goniometer (Figure 1 in Skill 30-16) may be used to verify the correct angle.

Crutch Gaits The crutch gait is the gait a person assumes on crutches by alternating body weight on one or both legs and the crutches. Five standard crutch gaits are the four-point gait, three-point gait, two-point gait, swing-to gait, and swing-through gait. The gait used depends on the following individual factors: (a) the ability to take steps, (b) the ability to bear weight and keep balance in a standing position on both legs or only one, and (c) the ability to hold the body erect.

Figure 44-66 ■ The standing position for measuring the correct length for crutches.

CLIENT TEACHING

Using Crutches

- Follow the plan of exercises developed for you to strengthen your arm muscles before beginning crutch walking.
- Have a health care professional establish the correct length for your crutches and the correct placement of the handpieces. Crutches that are too long force your shoulders upward and make it difficult for you to push your body off the ground. Crutches that are too short will make you hunch over and develop an improper body stance.
- The weight of your body should be borne by the arms rather than the axillae (armpits). Continual pressure on the axillae can injure the radial nerve and eventually cause crutch palsy, a weakness of the muscles of the forearm, wrist, and hand.
- Maintain an erect posture as much as possible to prevent strain on muscles and joints and to maintain balance.
- Each step taken with crutches should be a comfortable distance for you. It is wise to start with a small rather than large step.
- Inspect the crutch tips regularly, and replace them if worn.
- Keep the crutch tips dry and clean to maintain their surface friction. If the tips become wet, dry them well before use.
- Wear a shoe with a low heel that grips the floor. Rubber soles decrease the chances of slipping. Adjust shoelaces so they cannot come untied or reach the floor where they might catch on the crutches. Consider shoes with alternative forms of closure (e.g., Velcro), especially if you cannot easily bend to tie laces. Slip-on shoes are acceptable only if they are snug and the heel does not come loose when the foot is bent.

Clients also need instruction about how to get into and out of chairs and go up and down stairs safely. All of these crutch skills are best taught before the client is discharged and preferably before the client has surgery.

Crutch Stance (Tripod Position) Before crutch walking is attempted, the client needs to learn facts about posture and balance. The proper standing position with crutches is called the **tripod (triangle) position** (Figure 44–67 ■). The crutches are placed about 15 cm (6 in.) in front of the feet and out laterally about 15 cm (6 in.), creating a wide base of support. The feet are slightly apart. A tall client requires a wider base than does a short client. Hips and knees are extended, the back is straight, and the head is held straight and high. There should be no hunch to the shoulders and thus no weight borne by the axillae. The elbows are extended sufficiently to allow weight bearing on the hands. If the client is unsteady, the nurse places a gait/transfer belt around the client’s waist and grasps the belt from above, not from below. A fall can be prevented more effectively if the belt is held from above.

Four-Point Alternate Gait This is the most elementary and safest gait, providing at least three points of support at all times, but

Figure 44–67 ■ The tripod position.

it requires coordination. Clients can use it when walking in crowds because it does not require much space. To use this gait, the client needs to be able to bear weight on both legs (Figure 44–68 ■, reading from bottom to top). The nurse asks the client to:

1. Move the right crutch ahead a suitable distance, such as 10 to 15 cm (4 to 6 in.).
2. Move the left front foot forward, preferably to the level of the left crutch.

Figure 44–68 ■ The four-point alternate crutch gait.

Figure 44–69 ■ The three-point crutch gait.

3. Move the left crutch forward.
4. Move the right foot forward.

Three-Point Gait To use this gait, the client must be able to bear the entire body weight on the unaffected leg. The two crutches and the unaffected leg bear weight alternately (Figure 44–69 ■, reading from bottom to top). The nurse asks the client to:

1. Move both crutches and the weaker leg forward.
2. Move the stronger leg forward.

Two-Point Alternate Gait This gait is faster than the four-point gait. It requires more balance because only two points support the body at one time; it also requires at least partial weight bearing on each foot. In this gait, arm movements with the crutches are similar to the arm movements during normal walking (Figure 44–70 ■, reading from bottom to top). The nurse asks the client to:

1. Move the left crutch and the right foot forward together.
2. Move the right crutch and the left foot ahead together.

Swing-To Gait The swing gaits are used by clients with paralysis of the legs and hips. Prolonged use of these gaits results in atrophy of the unused muscles. The swing-to gait is the easier of these two gaits. The nurse asks the client to:

1. Move both crutches ahead together.
2. Lift body weight by the arms and swing to the crutches.

Swing-Through Gait This gait requires considerable skill, strength, and coordination. The nurse asks the client to:

1. Move both crutches forward together.

Figure 44–70 ■ The two-point alternate crutch gait.

2. Lift body weight by the arms and swing through and beyond the crutch.

Getting into a Chair Chairs that have armrests and are secure or braced against a wall are essential for clients using crutches. For this procedure, the nurse instructs the client to:

1. Stand with the back of the unaffected leg centered against the chair. The chair helps support the client during the next steps.
2. Transfer the crutches to the hand on the affected side and hold the crutches by the hand bars. The client grasps the arm of the chair with the hand on the unaffected side (Figure 44–71 ■). This allows the client to support the body weight on the arms and the unaffected leg.
3. Lean forward, flex the knees and hips, and lower into the chair.

Getting Out of a Chair For this procedure, the nurse instructs the client to:

1. Move forward to the edge of the chair and place the unaffected leg slightly under or at the edge of the chair. This position helps the client stand up from the chair and achieve balance, because the unaffected leg is supported against the edge of the chair.
2. Grasp the crutches by the hand bars in the hand on the affected side, and grasp the arm of the chair by the hand on the unaffected side. The body weight is placed on the crutches and the hand on the armrest to support the unaffected leg when the client rises to stand.
3. Push down on the crutches and the chair armrest while elevating the body out of the chair.
4. Assume the tripod position before moving.

Figure 44-71 ■ A client using crutches getting into a chair.

Going Up Stairs For this procedure, the nurse stands behind the client and slightly to the affected side if needed. The nurse instructs the client to:

1. Assume the tripod position at the bottom of the stairs.
2. Transfer the body weight to the crutches and move the unaffected leg onto the step (Figure 44-72 ■).
3. Transfer the body weight to the unaffected leg on the step and move the crutches and affected leg up to the step. The affected leg is always supported by the crutches.
4. Repeat steps 2 and 3 until the client reaches the top of the stairs.

Figure 44-72 ■ Climbing stairs: placing weight on the crutches while first moving the unaffected leg onto a step.

Figure 44-73 ■ Descending stairs: moving the crutches and affected leg to the next step.

Going Down Stairs For this procedure, the nurse stands one step below the client on the affected side if needed. The nurse instructs the client to:

1. Assume the tripod position at the top of the stairs.
2. Shift the body weight to the unaffected leg, and move the crutches and affected leg down onto the next step (Figure 44-73 ■).
3. Transfer the body weight to the crutches, and move the unaffected leg to that step. The affected leg is always supported by the crutches.
4. Repeat steps 2 and 3 until the client reaches the bottom of the stairs.

Evaluating

The goals established during the planning phase are evaluated according to specific desired outcomes, also established in that phase. Examples of these are shown in the accompanying Nursing Care Plan.

If outcomes are not achieved, the nurse, client, and support person if appropriate need to explore the reasons before modifying the care plan. For example, the following questions may be considered if an immobilized client fails to maintain muscle mass and tone and joint mobility:

- Has the client's physical or mental condition changed motivation to perform required exercise?
- Were appropriate range-of-motion exercises implemented?
- Was the client encouraged to participate in self-care activities as much as possible?
- Was the client encouraged to make as many decisions as possible when developing a daily activity plan and to express concerns?
- Did the nurse provide appropriate supervision and monitoring?
- Was the client's diet adequate to provide appropriate nourishment for energy requirements?

NURSING CARE PLAN Risk for Disuse Syndrome

Assessment Data

Nursing Assessment

Peter Chan, a 69-year-old, unmarried accountant being treated for congestive heart failure, states he has dyspnea with mild activity. ("I cannot climb a flight of stairs without stopping and resting and become breathless even when walking on level ground.") Prefers the orthopedic position. He works at home and sits at a table for most of the day.

Physical Examination

Height: 178 cm (5'10")
 Weight: 102 kg (225 lb)
 Temperature: 37.8°C (100.4°F)
 Pulse rate: 94 beats/min
 Respirations: 20/min
 Blood pressure: 174/92 mmHg
 Rales present in both lungs.
 Respirations slightly labored.
 Color pale.
 3+ (5 mm) edema both feet and ankles.

Diagnostic Data

CBC, and urinalysis within normal limits
 CXR reveals an enlarged heart

Nursing Diagnosis

Risk for Disuse Syndrome related to decreased activity resulting from inadequate balance between oxygen supply and demand associated with decreased cardiac output and obesity

Desired Outcomes*

Immobility Consequences:

Physiological [0204], as evidenced by

- No pressure ulcers
- Muscle strength not compromised

Immobility Consequences:

Psycho-cognitive [0205], as evidenced by no

- Apathy
- Sleep disturbances
- Negative body image

Mobility [0208], as evidenced by mildly compromised

- Walking
- Balance

Nursing Interventions*/Selected Activities

Positioning [0840]

Position to alleviate dyspnea, e.g., high Fowler's.

Rationale

Clients with increased pulmonary secretions are able to breathe better when upright because abdominal organs are lower and there is greater room for lung and diaphragmatic excursion.

Provide support to edematous areas, e.g., elevate feet on footstool when sitting.

Elevating the dependent area assists with decreasing tissue pressure and promoting fluid return to the venous system and the heart.

Encourage active range-of-motion exercises.

Active ROM helps maintain muscle strength and promote circulation. Mild activity also helps burn unneeded calories.

Exercise Therapy: Muscle Control [0226]

Collaborate with physical, occupational, and recreational therapists in developing and executing an individually tailored exercise program.

This client will need a multidisciplinary approach to his care. Each member contributes from his or her area of expertise. Research supports efficacy of individually tailored exercise plans. Factors such as having an exercise partner, using music, and type of activity can motivate client and enhance adherence to the plan over time.

Offer options, explain rationale for type of exercise and protocol to client, and allow him to make choices that appeal to him and that address his needs.

If the client understands what the reasons are for activity, he can make good choices.

Provide step-by-step cuing for each motor activity during exercise or ADLs.

As-needed reminders help the client recall what to do next.

Use visual aids to facilitate learning how to perform exercises.

Some people have better visual memory than auditory memory.

Evaluation

Outcomes met. Mr. Chan did not develop any skin breakdown or other evidence of the complications of immobility to date. However, since the risk factors remain, the care plan will be ongoing.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, indicators, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

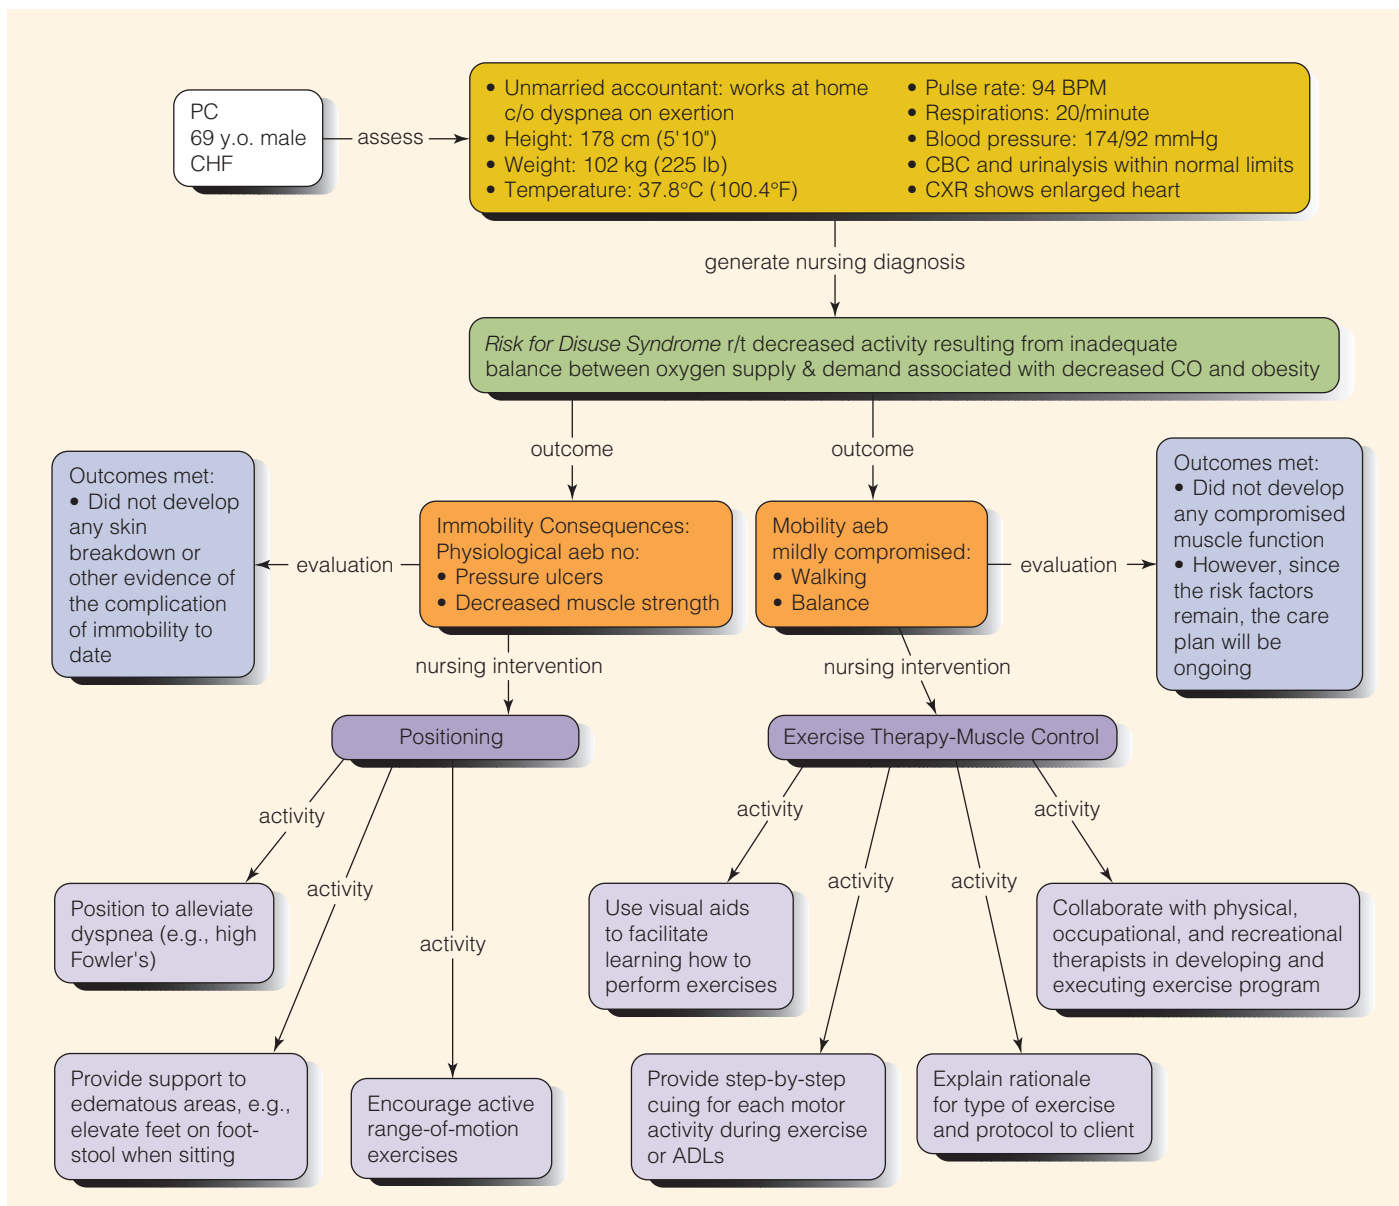

APPLYING CRITICAL THINKING

1. What assessment findings alert you that Mr. Chan is developing problems associated with his current state of decreased mobility?
2. Mr. Chan may benefit from using a walker to assist with ambulation at home. What teaching should be done in regard to use of a walker?
3. The care plan does not address one of Mr. Chan's risk factors—obesity. Would you add this to the plan?
4. What assumptions has the nurse made in assigning the desired outcome of "Immobility Consequences: Psycho-Cognitive"?
5. How are the choices of outcomes influenced by the cause of his nursing diagnosis (a chronic illness)?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Client at Risk for Disuse Syndrome

Chapter 44 Review

CHAPTER HIGHLIGHTS

- Exercise and activity are essential components for maintaining and regaining health and wellness.
- Research on exercise has demonstrated it to be an excellent strategy for preventing and treating some cardiovascular and pulmonary diseases, mood disorders, diseases of aging, diabetes, and immune diseases.
- The ability to move freely, easily, and purposefully in the environment is essential for people to meet their basic needs.
- Purposeful coordinated movement of the body relies on the integrated functioning of the musculoskeletal system, the nervous system, and the vestibular apparatus of the inner ear.
- Body movement involves four basic elements: body alignment, joint mobility, balance, and coordinated movement.
- People maintain alignment and balance when the line of gravity passes through the center of gravity and the base of support.
- Exercise is physical activity performed to improve health and maintain fitness. Activity tolerance is the type and amount of exercise or daily living activities an individual is able to perform without experiencing adverse effects. Functional strength is the ability to do work.
- Exercise is classified as either isotonic, isometric, or isokinetic and as either aerobic or anaerobic.
- Many factors influence body alignment and activity. These include growth and development, nutrition, personal values and attitudes, certain external factors, and prescribed limitations to movement.
- Immobility affects almost every body organ and system adversely. Problems include disuse osteoporosis and atrophy; contractures; diminished cardiac reserve; orthostatic hypotension; venous stasis, edema, and thrombus formation; decreased respiratory movement and pooling of secretions; decreased metabolic rate and negative nitrogen balance; urinary stasis, retention, infection, and calculi; constipation; and varying emotional reactions.
- Assessment relative to a client's activity and exercise includes a nursing history and physical examination of body alignment, gait, joint appearance and movement, capabilities and limitations for movement, muscle mass and strength, activity tolerance, and problems related to immobility.
- An activity and exercise history includes daily activity level, activity tolerance, type and frequency of exercise, and factors affecting mobility.
- NANDA nursing diagnoses that relate to activity and mobility problems include *Activity Intolerance*, *Risk for Activity Intolerance*, *Impaired Physical Mobility*, *Sedentary Lifestyle*, and *Risk for Disuse Syndrome*. Other relevant diagnoses are *Fear* (of falling), *Ineffective Coping*, *Situational Low Self-Esteem*, *Powerlessness*, *Risk for Falls*, and, if the client is immobilized, many other potential problems such as *Ineffective Airway Clearance* and *Risk for Infection*.
- Body mechanics is the efficient, coordinated, and safe use of the body to move objects and carry out the ADLs.
- Nurses must use good body mechanics in their daily work and especially when moving and turning clients in bed and assisting clients to make transfers. Proper body mechanics do not ensure protection from injury, however, and nurses and caregivers are encouraged to avoid solo manual lifting, repositioning, and transferring of clients.
- Positioning a client in good body alignment and changing the position regularly and systematically are essential aspects of nursing practice.
- Before positioning dependent clients, the nurse should plan a systematic 24-hour schedule for position changes, including positions that provide for full extension of the neck, hips, and knees. The nurse also uses appropriate supportive devices to maintain alignment and prevent strain on the client's muscles and joints.
- Before moving, turning, or transferring a client, the nurse must consider the client's health status and degree of exertion permitted, physical ability to assist, ability to comprehend instruction, degree of discomfort, client's weight, and whether to use assistive devices or another caregiver to assist.
- The nurse can assist clients to prepare for ambulation by helping them become as independent as possible while in bed. Ambulating techniques that facilitate normal walking gait yet provide needed supports are most effective.
- Preambulatory exercises that strengthen the muscles for walking are essential for clients who have been immobilized for a prolonged period.
- Clients need specific instructions about appropriate use of canes, walkers, and crutches.

TEST YOUR KNOWLEDGE

1. To increase stability during client transfer, the nurse increases the base of support by performing which action?
 1. Leaning slightly backward
 2. Spacing the feet farther apart
 3. Tensing the abdominal muscles
 4. Bending the knees
2. Isotonic exercises such as walking are intended to achieve which of the following? Select all that apply.
 1. Increase muscle tone and improve circulation.
 2. Increase blood pressure.
 3. Increase muscle mass and strength.
 4. Decrease heart rate and cardiac output.
 5. Maintain joint range of motion.
3. Five minutes after the client's first postoperative exercise, the client's vital signs have not yet returned to baseline. Which is an appropriate nursing diagnosis?
 1. *Activity Intolerance*
 2. *Risk for Activity Intolerance*
 3. *Impaired Physical Mobility*
 4. *Risk for Disuse Syndrome*
4. Which statement from a client with one weak leg regarding use of crutches when using stairs indicates a need for increased teaching?
 1. "Going up, the strong leg goes first, then the weaker leg with both crutches."
 2. "Going down, the weaker leg goes first with both crutches, then the strong leg."
 3. "The weaker leg always goes first with both crutches."
 4. "A cane or single crutch may be used instead of both crutches if held on the weaker side."

5. A nurse is teaching a client about active range-of-motion (ROM) exercises. The nurse then watches the client demonstrate these principles. The nurse would evaluate that teaching was successful when the client does which of the following?
 1. Exercises past the point of resistance.
 2. Performs each exercise one time.
 3. Performs each series of exercises once a day.
 4. Uses the same sequence during each exercise session.
6. When assessing a client's gait, which does the nurse look for and encourage?
 1. The spine rotates, initiating locomotion.
 2. Gaze is slightly downward.
 3. Toes strike the ground before the heel.
 4. Arm on the same side as the swing-through foot moves forward at the same time.
7. Performance of activities of daily living (ADLs) and active range-of-motion (ROM) exercises can be accomplished simultaneously as illustrated by which of the following? Select all that apply.
 1. Elbow flexion with eating and bathing
 2. Elbow extension with shaving and eating
 3. Wrist hyperextension with writing
 4. Thumb ROM with eating and writing
 5. Hip flexion with walking
8. A client weighs 250 pounds and needs to be transferred from the bed to a chair. Which instruction by the nurse to the unlicensed assistive personnel (UAP) is most appropriate?
 1. "Using proper body mechanics will prevent you from injuring yourself."
 2. "You are physically fit and at lesser risk for injury when transferring the client."
 3. "Use the mechanical lift and another person to transfer the client from the bed to the chair."
 4. "Use the back belt to avoid hurting your back."
9. The client is ambulating for the first time after surgery. The client tells the nurse, "I feel faint." Which is the best action by the nurse?
 1. Find another nurse for help.
 2. Return the client to her room as quickly as possible.
 3. Tell the client to take rapid, shallow breaths.
 4. Assist the client to a nearby chair.
10. The nurse is performing an assessment of an immobilized client. Which assessment causes the nurse to take action?
 1. Heart rate 86 beats/min
 2. Reddened area on sacrum
 3. Nonproductive cough
 4. Urine output of 50 mL/h

45 Sleep

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Explain the physiology and the functions of sleep.
2. Identify the characteristics of the NREM and REM sleep states.
3. Describe variations in sleep patterns throughout the life span.
4. Identify factors that affect sleep.
5. Describe common sleep disorders.
6. Identify the components of a sleep pattern assessment.
7. Develop nursing diagnoses, outcomes, and nursing interventions related to sleep problems.
8. Describe interventions that promote sleep.

KEY TERMS

INTRODUCTION

Sleep is a basic human need; it is a universal biologic process common to all people. Humans spend about one third of their lives asleep. We require sleep for many reasons: to cope with daily stresses, to prevent fatigue, to conserve energy, to restore the mind and body, and to enjoy life more fully. Sleep enhances daytime functioning, and is vital for cognitive, physiological, and psychosocial function (Gruber, 2013). Sleep is an important factor in a person's quality of life, yet sleep disorders and sleep deprivation are an unmet public health problem, as reported by the Centers for Disease Control and Prevention (CDC) (2014). It is estimated that 50 million to 70 million Americans suffer from a chronic disorder of sleep and wakefulness that hinders daily functioning and adversely affects health (McKnight-Eily et al., 2011).

Furthermore, many members of the general public and health professionals are unaware of the consequences of chronic sleep loss (e.g., increased risk of hypertension, diabetes, obesity, depression, heart attack, and stroke) (McKnight-Eily et al., 2011). A threat to the public's health is noted when clients fall asleep while driving. Falling asleep while driving was reported by 4.7% of respondents to the CDC study. It also leads to motor vehicle crashes with injuries or death.

PHYSIOLOGY OF SLEEP

Historically, sleep was considered a state of unconsciousness. More recently, **sleep** has come to be considered an altered state of consciousness in which the individual's perception of and reaction to the environment are decreased. Sleep is characterized by minimal physical activity, variable levels of consciousness, changes in the body's physiological processes, and decreased responsiveness to external stimuli. Some environmental stimuli, such as a smoke detector alarm, will usually awaken a sleeper, whereas many other noises will not. It appears that individuals respond to meaningful stimuli while sleeping and selectively disregard nonmeaningful stimuli. For example, a mother may respond to her baby's crying but not to the crying of another baby.

1066

The cyclic nature of sleep is thought to be controlled by centers located in the lower part of the brain. Neurons within the reticular formation, located in the brainstem, integrate sensory information from the peripheral nervous system and relay the information to the cerebral cortex (see Anatomy & Physiology Review). The upper part of the reticular formation consists of a network of ascending nerve fibers called the reticular activating system (RAS), which is involved with the sleep/wake cycle. An intact cerebral cortex and reticular formation are necessary for the regulation of sleep and waking states.

Neurotransmitters, located within neurons in the brain, affect the sleep/wake cycles. For example, serotonin is thought to lessen the response to sensory stimulation and gamma-aminobutyric acid (GABA) to shut off the activity in the neurons of the reticular activating system. Another key factor to sleep is exposure to darkness. Darkness and preparing for sleep (e.g., lying down, decreasing noise) cause a decrease in stimulation of the RAS. During this time, the pineal gland in the brain begins to actively secrete the natural hormone melatonin, and the person feels less alert. During sleep, the growth hormone is secreted and cortisol is inhibited.

With the beginning of daylight, melatonin is at its lowest level in the body and the stimulating hormone, cortisol, is at its highest. Wakefulness is also associated with high levels of acetylcholine, dopamine, and noradrenaline. Acetylcholine is released in the reticular formation, dopamine in the midbrain, and noradrenaline in the pons. These neurotransmitters are localized within the reticular formation and influence cerebral cortical arousal.

Circadian Rhythms

Biologic rhythms exist in plants, animals, and humans. In humans, these are controlled from within the body and synchronized with environmental factors, such as light and darkness. The most familiar biologic rhythm is the circadian rhythm. It is a sort of 24-hour internal biologic clock. The term *circadian* is from the Latin *circa dies*, meaning "about a day." Although sleep and waking cycles are the best

ANATOMY & PHYSIOLOGY REVIEW

Reticular Activating System

Nerve impulses from the senses reach the reticular activating system (RAS), which is in the reticular formation (located in the brainstem) with projections to the hypothalamus and cerebral cortex. The nerve

fibers in the RAS relay impulses to the cerebral cortex for perception by the person.

The reticular formation in the brainstem.

QUESTIONS

1. How would you describe activity of the RAS in preparation for and during sleep?
2. What happens physiologically when your alarm clock wakes you in the morning?

3. What areas of the brain are affected by head trauma or stroke and affect an individual's level of alertness?

See student resource website for answers.

known of the circadian rhythms, body temperature, blood pressure, and many other physiological functions also follow a circadian pattern (Tranah et al., 2010).

Sleep is a complex biologic rhythm. When a person's biologic clock coincides with the sleep/wake cycles, the person is said to be in circadian synchronization; that is, the person is awake when the body temperature is highest, and asleep when the body temperature is lowest. Circadian regularity begins to develop by the sixth week of life, and by 3 to 6 months most infants have a regular sleep/wake cycle.

Types of Sleep

Sleep architecture refers to the basic organization of normal sleep. The two types of sleep are **NREM** (non-rapid-eye-movement) **sleep** and **REM** (rapid-eye-movement) **sleep**. During sleep, NREM and REM sleep alternate in cycles. Changes in the architecture of one's sleep can be linked to physiological or psychosocial changes. For example, Williams syndrome is a genetic disorder of neurodevelopment that results in cognitive changes. Clients diagnosed with Williams syndrome have alterations in sleep patterns resulting in decreased sleep efficacy (Gombos, Bodizs, & Kovacs, 2011).

NREM SLEEP

NREM sleep occurs when activity in the RAS is inhibited. About 75% to 80% of sleep during a night is NREM sleep. NREM sleep was previously divided into four stages. It is now divided into three stages. Each of the stages is associated with distinct brain activity and physiology. Stage 1 is the stage of very light sleep and lasts only a few minutes. During this stage, the person feels drowsy and relaxed, the eyes roll from side to side, and the heart and respiratory rates drop slightly. The sleeper can be readily awakened and may deny that he or she was sleeping. Low-voltage brain waves are noted in stage 1 (Redeker & McEnany, 2011).

Stage 2 is the stage of sleep during which body processes continue to slow down. The eyes are generally still, the heart and respiratory rates decrease slightly, and body temperature falls. An individual in stage 2 requires more intense stimuli than in stage 1 to awaken such as touching or shaking.

Stage 3 is the deepest stage of sleep, differing only in the percentage of delta waves recorded during a 30-second period. During *deep sleep* or *delta sleep*, the sleeper's heart and respiratory rates drop 20% to 30% below those exhibited during waking hours. The sleeper is

BOX 45-1 Physiological Changes During NREM Sleep

- Arterial blood pressure falls.
- Pulse rate decreases.
- Peripheral blood vessels dilate.
- Cardiac output decreases.
- Skeletal muscles relax.
- Basal metabolic rate decreases 10% to 30%.
- Growth hormone levels peak.
- Intracranial pressure decreases.

difficult to arouse. The person is not disturbed by sensory stimuli, the skeletal muscles are very relaxed, reflexes are diminished, and snoring is most likely to occur. This stage is essential for restoring energy and releasing important growth hormones (Box 45-1).

CLINICAL ALERT!

Sleep deprivation in hospitalized clients contributes to their anxiety and fear. It also causes immunosuppression, inflammation, alterations of sympathetic and parasympathetic equilibrium, and increases in insulin resistance (Pilkington, 2013).

REM SLEEP

REM sleep usually recurs about every 90 minutes and lasts 5 to 30 minutes. Most dreams take place during REM sleep but usually will not be remembered unless the person arouses briefly at the end of the REM period.

During REM sleep, the brain is highly active, and brain metabolism may increase as much as 20%. For example, during REM sleep, levels of acetylcholine and dopamine increase, with the highest levels of acetylcholine release occurring during REM sleep. Because both of these neurotransmitters are associated with cortical activation, it makes sense that their levels would be high during dreaming sleep. This type of sleep is also called paradoxical sleep because electroencephalogram (EEG) activity resembles that of wakefulness. Distinctive eye movements occur, voluntary muscle tone is dramatically decreased, and deep tendon reflexes are absent. In this phase, the sleeper may be difficult to arouse or may wake spontaneously, gastric secretions increase, and heart and respiratory rates often are irregular. It is thought that the regions of the brain that are used in learning, thinking, and organizing information are stimulated during REM sleep.

CLINICAL ALERT!

Clients who experience sleep deprivation will more commonly experience a negative temperament during periods of minor stress. They are more likely to have an outburst of emotion and express feelings of being overwhelmed (Minkel et al., 2012).

Sleep Cycles

During a sleep cycle, people typically pass through NREM and REM sleep, the complete cycle usually lasting about 90 to 110 minutes in adults. In the first sleep cycle, a sleeper usually passes through the first two stages of NREM sleep in a total of about 20 to 30 minutes. Stage 3 lasts about 50 to 60 minutes. After stage 3 NREM, the sleep passes back through stages 2 and 1 over about 20 minutes. Thereafter, the

Figure 45-1 ■ Time spent in REM and NREM stages of sleep in an adult.

first REM stage occurs, lasting about 10 minutes, completing the first sleep cycle. It is not unusual for the first REM period to be very brief or even skipped entirely. The healthy adult sleeper usually experiences four to six cycles of sleep during 7 to 8 hours (Figure 45-1 ■). The sleeper who is awakened during any stage must begin anew at stage 1 NREM sleep and proceed through all stages to REM sleep.

The duration of NREM stages and REM sleep varies throughout the sleep period. During the early part of the night, the deep sleep periods are longer. As the night progresses, the sleeper spends less time in stage 3 of NREM sleep. REM sleep increases and dreams tend to lengthen. Before sleep ends, periods of near wakefulness occur, and stages 1 and 2 NREM and REM sleep dominate.

FUNCTIONS OF SLEEP

The effects of sleep on the body are not completely understood. Sleep exerts physiological effects on both the nervous system and other body structures. Sleep in some way restores normal levels of activity and normal balance among parts of the nervous system. Sleep is also necessary for protein synthesis, which allows repair processes to occur.

The role of sleep in psychological well-being is best noticed by the deterioration in mental functioning related to sleep loss. Individuals with inadequate amounts of sleep tend to become emotionally irritable, have poor concentration, and experience difficulty making decisions.

NORMAL SLEEP PATTERNS AND REQUIREMENTS

Although it used to be believed that maintaining a regular sleep/wake rhythm is more important than the number of hours actually slept, recent research has shown that sleep deprivation is associated with significant cognitive and health problems. Although reestablishing the sleep/wake rhythm (e.g., after the disruption of surgery) is important, it is appropriate to allow and encourage daytime napping in hospitalized clients.

Newborns

Newborns sleep 12 to 18 hours a day, on an irregular schedule with periods of 1 to 3 hours spent awake. Unlike older children and adults, newborns enter REM sleep (called active sleep during the newborn period) immediately. Rapid eye movements are observable through closed lids, and the body movements and irregular respirations may be observed. NREM sleep (also called quiet sleep during the newborn period) is characterized by regular respirations, closed eyes,

and the absence of body and eye movements. Newborns spend nearly 50% of their time in each of these states, and the sleep cycle is about 50 minutes.

It is best to put newborns to bed when they are sleepy but not asleep. Newborns can be encouraged to sleep less during the day by exposing them to light and by playing more with them during the day hours. As evening approaches, the environment can be less bright and quieter with less activity (National Sleep Foundation, n.d.c).

Infants

At first, infants awaken every 3 or 4 hours, eat, and then go back to sleep. Periods of wakefulness gradually increase during the first months. By 6 months, most infants sleep through the night (from midnight to 5 AM) and begin to establish a pattern of daytime naps. At the end of the first year, an infant usually takes two naps per day and should get about 9 to 12 hours of sleep in 24 hours.

About half of the infant's sleep time is spent in light sleep. During light sleep, the infant exhibits a great deal of activity, such as movement, gurgles, and coughing. Parents need to make sure that infants are truly awake before picking them up for feeding and changing. Putting infants to bed when they are drowsy but not asleep helps them to become "self-soothers." This means that they fall asleep independently and if they do awake at night, they can put themselves back to sleep. Infants who become used to parental assistance at bedtime may become "signalers" and cry for their parents to help them return to sleep at night (National Sleep Foundation, n.d.c).

Toddlers

Between 12 and 14 hours of sleep are recommended for children 1 to 3 years of age. Most still need an afternoon nap, but the need for mid-morning naps gradually decreases. The toddler may exhibit a great deal of resistance to going to bed and may awaken during the night. Nighttime fears and nightmares are also common. A security object such as a blanket or stuffed animal may help. Parents need assurance that if the child has had adequate attention from them during the day, maintaining a daily sleep schedule and consistent bedtime routine will promote good sleep habits for the entire family (National Sleep Foundation, n.d.c).

Preschoolers

The preschool-age child (3 to 5 years of age) requires 11 to 13 hours of sleep per night, particularly if the child is in preschool. Sleep needs fluctuate in relation to activity and growth spurts. Many children of this

age dislike bedtime and resist by requesting another story, game, or television program. The 4- to 5-year-old may become restless and irritable if sleep requirements are not met (National Sleep Foundation, n.d.c).

Parents can help children who resist bedtime by maintaining a regular and consistent sleep schedule. It also helps to have a relaxing bedtime routine that ends in the child's room. Preschool children wake up frequently at night, and they may be afraid of the dark or experience night terrors or nightmares. Often limiting or eliminating TV will reduce the number of nightmares (National Sleep Foundation, n.d.c).

School-Age Children

The school-age child (5 to 12 years of age) needs 10 to 11 hours of sleep per night, but most receive less because of increasing demands (e.g., homework, sports, social activities). They may also be spending more time at the computer and watching TV. Some may be drinking caffeinated beverages. All of these activities can lead to difficulty falling asleep and fewer hours of sleep. Nurses can teach parents and school-age children about healthy sleep habits. A regular and consistent sleep schedule and bedtime routine need to be continued.

CLINICAL ALERT!

Children who have a TV and/or computer in their bedroom are more likely to get less sleep.

Adolescents

Adolescents (12 to 18 years of age) require 9 to 10 hours of sleep each night; however, few actually get that much sleep (Law, Dufton, & Palermo, 2011). Teens are sleepy at times and places where they should be fully awake—at school, at home, and on the road. This can result in lower grades, negative moods (e.g., unhappy, sad, tense), and increased potential for car crashes (Amos & D'Andrea, 2012). Interestingly, the National Sleep Foundation (n.d.c) found that although more than half of adolescents knew they were not getting enough sleep, 90% of the parents believed their adolescent was getting enough sleep. Nurses can teach parents to recognize signs and symptoms that indicate their teen is not getting enough sleep (see Clinical Manifestations).

As children reach adolescence, their circadian rhythms tend to shift. Research in the 1990s found that later sleep and wake patterns among adolescents are biologically determined; the natural tendency for teenagers is to stay up late at night and wake up later in the

Evidence-Based Practice Why Is Poor Sleep Challenging the Health of a Nation?

EVIDENCE-BASED PRACTICE

Wells, Eeg, and Vaughn (2012) sought to investigate the effect poor sleep patterns have on society. The authors reviewed news reports, journal articles, and literature to identify themes related to poor sleep and the impact of sleep deprivation. Individuals experiencing sleep deprivation have a decreased ability to perform well, thus diminishing productivity. Many disasters are related to fatigue. For example, the *Challenger* space shuttle explosion was related to O-ring failure. The individuals responsible for making the decision on the O-ring's effect at the time of launch were sleep deprived. The study found that sleep deprivation impairs an individual's judgment and increases the risk for workplace injury or critical errors leading to negative outcomes. Another example of a disaster that occurred

due to sleep deprivation was the *Exxon Valdez* grounding on Bligh Reef in Alaska. The National Transportation Safety Board reported that the crew member who was responsible had had only 4 hours of sleep. The medical community has recognized that when residents worked in excess of 80 hours per week, the rate of medical errors increased. Currently, residents are required to work under 80 hours and have mandatory rest periods.

IMPLICATIONS

The nursing profession is not immune to errors related to client care. Nurses may be required to work different shifts throughout the week. Changes in work schedules can impair nurses' sleep patterns and contribute to inattention, resulting in health care delivery errors.

CLINICAL MANIFESTATIONS

Sleep Deprivation and Sleep Problems in Teens

The teen:

- Has difficulty waking in the morning for school.
- Falls asleep in class or during quiet times of the day.
- Increases the use of caffeinated beverages like coffee, soda, or energy drinks.
- Feels tired, making it difficult to initiate or persist in projects such as a school assignment.
- Is irritable, anxious, and angers easily on days when he or she gets less sleep.
- Is involved in many extracurricular activities, has a job, and stays up late doing homework every night, cutting into sleep time.
- Sleeps extra long periods of time on the weekend.

morning. A psychosocial factor affecting later bedtime in the adolescent population is the desire for greater independence. The use of the Internet, watching television, and cell phone usage disrupts the ability to fall asleep due to blue-spectrum light exposure (Carskadon, 2011).

Carskadon (2011) also describes sleep behaviors of adolescents resulting in unhealthy outcomes. The start time in many middle and high schools has been before 8 AM. This start time conflicts with the adolescent's sleep patterns and thus contributes to their sleep deprivation (Figure 45–2 ■). School districts in Minnesota and Kentucky have delayed school times by 1 hour for middle school and high school students. The schools district in Kentucky reported that motor vehicle crashes involving teenage drivers ages 17 to 18 decreased by 16.5% following the change in start times (Amos & D'Andrea, 2012).

During adolescence, boys begin to experience **nocturnal emissions** (orgasm and emission of semen during sleep), known as “wet dreams,” several times each month. Boys need to be informed about this normal development to prevent embarrassment and fear.

Adults

Most healthy adults get 7 to 8 hours of sleep per night (National Sleep Foundation, n.d.d). However, individual needs do vary—some adults may be able to function well (e.g., without sleepiness or drowsiness) with 6 hours of sleep, and others may need 10 hours to function optimally. Signs that may indicate that a person is not getting enough

sleep include falling asleep or becoming drowsy during a task that is not fatiguing (e.g., listening to a presentation), not being able to concentrate or remember information, and being unreasonably irritable with others. Lack of sleep also contributes to short-term memory loss and inadequate performance on newly learned tasks (National Sleep Foundation, n.d.d).

The National Sleep Foundation (n.d.a, n.d.d) reports that certain adults are particularly vulnerable to not getting enough sleep: students, shift workers, travelers, and individuals suffering from acute stress, depression, or chronic pain. Adults working long hours or multiple jobs may find their sleep less refreshing. Also, the sleep habits of children have an impact on the adults caring for them. A woman's sleep pattern is more commonly affected by the birth of a child. However, both parents of infants and young children experience fatigue related to interrupted sleep or sleep deprivation. This lack of sleep is associated with lower parental competence and greater stress (Cooklin, Giallo, & Rose, 2012). Biologic conditions such as pregnancy, menses, and the perimenopausal period can also affect a woman's sleep patterns.

Nurses need to teach adults the importance of obtaining sufficient sleep and provide tips on how to promote sleep that results in the client waking up feeling restored or refreshed. See Client Teaching later in this chapter.

Older Adults

A hallmark change with age is a tendency toward earlier bedtime and wake times. Older adults (65 to 75 years) usually awaken 1.3 hours earlier and go to bed approximately 1 hour earlier than younger adults (ages 20 to 30). Older adults may show an increase in disturbed sleep that can create a negative impact on their quality of life, mood, and alertness. They may awaken an average of six times during the night. Although the ability to sleep becomes more difficult, the need to sleep does not decrease with age. During sleep, an older adult has a flattened-circadian rhythm. This is noted by the earlier bedtime and morning arousal. Redeker and McEnany (2011) describe this rhythm as advanced sleep phase syndrome. Older adults have difficulty falling back to sleep after awakening and have a diminished amount of REM sleep. Many older adults report daytime napping, which may contribute to reduced nocturnal sleep.

Medical conditions and pain are factors that interrupt sleep. Older adults who have several medical conditions and complain of having sleeping problems should discuss this with their primary care provider. The older individual may have a major sleep disorder that is complicating treatment of other conditions. It is important for the nurse to teach about the connection between sleep, health, and aging. See Client Teaching about sleep promotion later in this chapter.

Some older clients with dementia may experience *sundown syndrome*. Although not a sleep disorder directly, it refers to a pattern of symptoms (e.g., agitation, anxiety, aggression, and sometimes delusions) that occur in the late afternoon (thus the name). These symptoms can last through the night, further disrupting sleep (National Sleep Foundation, n.d.b).

FACTORS AFFECTING SLEEP

Both the quality and the quantity of sleep are affected by a number of factors. *Sleep quality* is a subjective characteristic and is often determined by whether a person wakes up feeling energetic or not. *Quantity of sleep* is the total time the individual sleeps.

Figure 45–2 ■ Many adolescents do not get enough sleep.

Illness

Illness that causes pain or physical distress (e.g., arthritis, back pain) can result in sleep problems. People who are ill require more sleep than normal, and the normal rhythm of sleep and wakefulness is often disturbed. People deprived of REM sleep subsequently spend more sleep time than normal in this stage.

Respiratory conditions can disturb an individual's sleep. Shortness of breath often makes sleep difficult, and people who have nasal congestion or sinus drainage may have trouble breathing and hence may find it difficult to sleep.

People who have gastric or duodenal ulcers may find their sleep disturbed because of pain, often a result of the increased gastric secretions that occur during REM sleep.

Certain endocrine disturbances can also affect sleep. Hyperthyroidism lengthens presleep time, making it difficult for a client to fall asleep. Hypothyroidism, conversely, decreases stage 3 sleep. Women with low levels of estrogen often report excessive fatigue. In addition, they may experience sleep disruptions due, in part, to the discomfort associated with hot flashes or night sweats that can occur with reduced estrogen levels.

Elevated body temperatures can cause some reduction in delta sleep and REM sleep. The need to urinate during the night also

disrupts sleep, and people who awaken at night to urinate sometimes have difficulty getting back to sleep.

Environment

Environment can promote or hinder sleep. The person must be able to achieve a state of relaxation prior to entering a period of sleep. Any change—for example, noise in the environment—can inhibit sleep. The absence of usual stimuli or the presence of unfamiliar stimuli can prevent people from sleeping. Hospital environments can be quite noisy, and special care needs to be taken to reduce noise in the hallways and nursing care units. In fact, some hospitals have instituted “quiet times” in the afternoon on nursing units where the lights are lowered and activity and noise are purposefully decreased so clients can rest or nap.

Discomfort from environmental temperature (e.g., too hot or cold) and lack of ventilation can affect sleep. Light levels can be another factor. A person accustomed to darkness while sleeping may find it difficult to sleep in the light. Another influence includes the comfort and size of the bed. A person's partner who has different sleep habits, snores, or has other sleep difficulties may become a problem for the person also.

LIFESPAN CONSIDERATIONS Sleep Disturbances

CHILDREN

Learning to sleep alone without the parent's help is a skill that all children need to master. Regular bedtime routines and rituals such as reading a book help children learn this skill and can prevent sleep disturbance. Some sleep disturbances seen in children include the following:

- *Trained night feeder.* Infants who are fed during the night, are fed until they fall asleep and then put into bed, or who have a bottle left with them in their bed learn to expect and demand middle-of-the-night feedings. Infants who are growing well do not need night feeding after about 4 months of age. Infants should never be put to bed with a bottle. This practice increases the risk of otitis media. Infants who are diagnosed with failure to thrive may need to be fed at night.
- *Sleep refusal.* Many toddlers and young children are resistant to settling down to sleep. This sleep refusal may be due to not being tired, anxiety about separation from the parent, stress (e.g., a recent move), lack of a regular sleep routine, the child's temperament, or changes in sleep arrangements (e.g., move from a crib to a “big” bed).
- *Night terrors.* Night terrors are partial awakenings from NREM stage 3 sleep. They are usually seen in children 3 to 6 years of age. The child may sleepwalk, or may sit up in bed screaming and thrashing about. They usually cannot be wakened, but should be protected from injury, helped back to bed, and soothed back to sleep. Babysitters should be alerted to the possibility of a night terror occurring. Children do not remember the incident the next day, and there is no indication of a neurologic or emotional problem. Excessive fatigue and a full bladder may contribute to the problem. Having the child take an afternoon nap and empty the bladder before going to sleep at night may be helpful.

ADULTS

- New jobs, pregnancy, and babies are common examples that often disrupt the sleep of a young adult.

- The sleep patterns of middle-aged adults can be disrupted by the need to take care of older parents and/or chronically ill partners in the home.
- See Client Teaching on page 1077 for tips on promoting sleep.

OLDER ADULTS

The quality of sleep is often diminished in older adults. Some of the leading factors that often are influential in sleep disturbances include the following:

- Side effects of medications
- Gastric reflux disease
- Respiratory and circulatory disorders, which may cause breathing problems or discomfort
- Pain from arthritis, increased stiffness, or impaired immobility
- Nocturia
- Depression
- Loss of life partner and/or close friends
- Confusion related to delirium or dementia.

Interventions to promote sleep and rest can help enhance the rejuvenation and renewal that sleep provides. The following interventions can help promote sleep:

- Reduce or eliminate the consumption of caffeine and nicotine.
- Be sure their environment is warm and safe, especially if they get out of bed during the night.
- Provide comfort measures, such as analgesics if indicated, and proper positioning.
- Enhance the sense of safety and security by checking on clients frequently and making sure that the call light is within reach. Answer the call light promptly.
- If lack of sleep is caused by medications or certain health conditions, interventions should focus on resolving the underlying problem.
- Evaluate the situation and find out what the rest and sleep disturbances mean to the client. They may not perceive sleeplessness to be a serious problem, but will just do other activities and sleep when tired.

Lifestyle

Following an irregular morning and nighttime schedule can affect sleep. Moderate exercise in the morning or early afternoon usually is conducive to sleep, but exercise late in the day can delay sleep. The person's ability to relax before retiring is an important factor affecting the ability to fall asleep. It is best, therefore, to avoid doing homework or office work before or after getting into bed.

Night shift workers frequently obtain less sleep than other workers and have difficulty falling asleep after getting off work. Wearing dark wrap-around sunglasses during the drive home and light-blocking shades can minimize the alerting effects of exposure to daylight, thus making it easier to fall asleep when body temperature is rising.

Emotional Stress

Stress is considered by most sleep experts to be the one of the greatest causes of difficulties in falling asleep or staying asleep. Hellhammer and Schubert (2013) have identified that a constant exposure to stress will increase the activation of the hypothalamic–pituitary–adrenal (HPA) axis leading to sleep disorders. A person who becomes preoccupied with personal problems (e.g., school- or job-related pressures, family or marriage problems) may be unable to relax sufficiently to get to sleep. Anxiety increases the norepinephrine blood levels through stimulation of the sympathetic nervous system. This chemical change results in less deep and REM sleep and more stage changes and awakenings.

Stimulants and Alcohol

Caffeine-containing beverages act as stimulants of the central nervous system (CNS). Drinking beverages containing caffeine in the afternoon or evening may interfere with sleep. People who drink an excessive amount of alcohol often find their sleep disturbed. Alcohol disrupts REM sleep, although it may hasten the onset of sleep. While making up for lost REM sleep after some of the effects of the alcohol have worn off, people often experience nightmares. The alcohol-tolerant person may be unable to sleep well and become irritable as a result.

Diet

Weight gain has been associated with reduced total sleep time as well as broken sleep and earlier awakening. Weight loss, on the other hand, seems to be associated with an increase in total sleep time and less broken sleep. Dietary L-tryptophan—found, for example, in cheese and milk—may induce sleep, a fact that might explain why warm milk helps some people get to sleep.

Smoking

Nicotine has a stimulating effect on the body, and smokers often have more difficulty falling asleep than nonsmokers. Smokers are usually easily aroused and often describe themselves as light sleepers. By refraining from smoking after the evening meal, the person usually sleeps better; moreover, many former smokers report that their sleeping patterns improved once they stopped smoking.

Motivation

Motivation can increase alertness in some situations (e.g., a tired person can probably stay alert while attending an interesting concert or surfing the web late at night). Motivation alone, however, is usually not sufficient to overcome the normal circadian drive to sleep during

the night. Nor is motivation sufficient to overcome sleepiness due to insufficient sleep. A combination of boredom and lack of sleep can contribute to feeling tired.

Medications

Some medications affect the quality of sleep. Most hypnotics can interfere with deep sleep and suppress REM sleep. Beta-blockers have been known to cause insomnia and nightmares. Narcotics, such as morphine, are known to suppress REM sleep and to cause frequent awakenings and drowsiness. Tranquilizers interfere with REM sleep. Although antidepressants suppress REM sleep, this effect is considered a therapeutic action. In fact, selectively depriving a depressed client of REM sleep will result in an immediate but transient improvement in mood. Clients accustomed to taking hypnotic medications and antidepressants may experience a REM rebound (increased REM sleep) when these medications are discontinued. Warning clients to expect a period of more intense dreams when these medications are discontinued may reduce their anxiety about this symptom. Boxes 45–2 and 45–3, respectively, list drugs that can disrupt sleep or cause excessive daytime sleepiness.

COMMON SLEEP DISORDERS

A knowledge of common sleep disorders can help nurses assess the sleep complaints of their clients and, when appropriate, make a referral to a specialist in sleep disorders medicine. Although sleep disorders are typically categorized for the purpose of research as dyssomnias, parasomnias, and disorders associated with medical or psychiatric illness, it is usually more appropriate for clinicians to focus on the client's symptoms (e.g., insomnia, excessive sleepiness, and abnormal events) that occur during sleep (parasomnias).

Insomnia

Insomnia is described as the inability to fall asleep or remain asleep. Individuals with insomnia do not awaken feeling rested. Insomnia

BOX 45–2 Drugs That Disrupt Sleep

These drugs may disrupt REM sleep, delay onset of sleep, or decrease sleep time:

- Alcohol
- Amphetamines
- Antidepressants
- Beta-blockers
- Bronchodilators
- Caffeine
- Decongestants
- Narcotics
- Steroids

BOX 45–3 Drugs That May Cause Excessive Daytime Sleepiness

These drugs may be associated with excessive daytime sleepiness:

- Antidepressants
- Antihistamines
- Beta-blockers
- Narcotics

Evidence-Based Practice How Do Sleep and Fatigue Affect Decision Regret Among Critical Care Nurses?

EVIDENCE-BASED PRACTICE

Research has proven that nurses who work long hours have a greater chance of making errors when caring for clients. Scott, Arslanian-Engoren, and Engoren (2014) conducted a nonexperimental, descriptive study of full-time critical care nurses. The objective of this study was to examine the association between fatigue and clinical decision making in the critical care unit.

The study included 605 nurses who responded to questionnaires. The first questionnaire was the Pittsburgh Sleep Quality Index. This index gathers subjective data on the nurse's sleep quality, sleep latency, sleep duration, habitual sleep efficiency, use of sleep medication, disturbances of sleep, and activity dysfunction during the daytime hours. The Epworth Sleepiness Scale measured the likelihood that the nurse might doze while performing different activities. The study also assessed the nurses' sleep quality and occupational fatigue. The last questionnaire was the Clinical Decision Self-Efficacy questionnaire. The nurses were asked to answer open-ended questions and rate their confidence

in making clinical decisions when they were alert or when they were sleepy.

Of the nurses who responded, 29% reported decision regret. Nurses who worked nights or 12-hour shifts reported higher rates of decision regret. All nurses reporting decision regret had a greater amount of acute fatigue and daytime sleepiness than those without decision regret.

IMPLICATIONS

All nurses must recognize the impact of sleep deprivation and fatigue on their ability to deliver safe and effective care. Nurses should avoid substances such as alcohol or caffeine prior to sleeping because they can cause altered sleep patterns, which cause fatigue during work hours. It is important that both nurses and employers recognize that 12-hour shifts contribute to errors in the delivery of care. The nurse should avoid working 12-hour shifts on two consecutive days to minimize the risk for fatigue.

is the most common sleep complaint in America. Acute insomnia lasts one to several nights and is often caused by personal stressors or worry. If the insomnia persists for longer than a month, it is considered chronic insomnia. More often, people experience chronic-intermittent insomnia, which means difficulty sleeping for a few nights, followed by a few nights of adequate sleep before the problem returns (National Sleep Foundation, n.d.e). See Clinical Manifestations for symptoms of insomnia. The two main risk factors for insomnia are older age and female gender (National Sleep Foundation, n.d.d). Women suffer sleep loss in connection with hormonal changes (e.g., menstruation, pregnancy, and menopause). The incidence of insomnia increases with age, but it is thought that this is caused by some other medical condition.

Treatment for insomnia frequently requires the client to develop new behavior patterns that induce sleep and maintain it. Examples of behavioral treatments include the following:

- **Stimulus control:** creating a sleep environment that promotes sleep
- **Cognitive therapy:** learning to develop positive thoughts and beliefs about sleep
- **Sleep restriction:** following a program that limits time in bed in order to get to sleep and stay asleep throughout the night (National Sleep Foundation, n.d.e).

The long-term efficacy of hypnotic medications is questionable. Such medications do not deal with the cause of the problem, and

CLINICAL MANIFESTATIONS

Insomnia

- Difficulty falling asleep
- Waking up frequently during the night
- Difficulty returning to sleep
- Waking up too early in the morning
- Unrefreshing sleep
- Daytime sleepiness
- Difficulty concentrating
- Irritability

From "Insomnia and Sleep," National Sleep Foundation, n.d.e. Retrieved from <http://sleepfoundation.org/sleep-disorders-problems/insomnia-and-sleep>.

their prolonged use can create drug dependencies. Although antihistamines such as diphenhydramine (Benadryl) are thought to be safer for older clients than hypnotics, their side effects (i.e., atropine-like effects, dizziness, sedation, and hypotension) make them extremely hazardous. In fact, antihistamines should not be recommended for any client with a history of asthma, increased intraocular pressure, hyperthyroidism, cardiovascular disease, or hypertension.

Excessive Daytime Sleepiness

Clients may experience excessive daytime sleepiness as a result of hypersomnia, narcolepsy, sleep apnea, and insufficient sleep.

HYPERSOMNIA

Hypersomnia refers to conditions where the affected individual obtains sufficient sleep at night but still cannot stay awake during the day. Hypersomnia can be caused by medical conditions, for example, CNS damage and certain kidney, liver, or metabolic disorders, such as diabetic acidosis and hypothyroidism. Rarely does hypersomnia have a psychological origin.

NARCOLEPSY

Narcolepsy is a disorder of excessive daytime sleepiness caused by the lack of the chemical hypocretin in the area of the CNS that regulates sleep. Clients with narcolepsy have sleep attacks or excessive daytime sleepiness, and their sleep at night usually begins with a sleep-onset REM period (dreaming sleep occurs within the first 15 minutes of falling asleep). The majority of clients also have cataplexy or the sudden onset of muscle weakness or paralysis in association with strong emotion, sleep paralysis (transient paralysis when falling asleep or waking up), hypnagogic hallucinations (visual, auditory, or tactile hallucinations at sleep onset or when waking up), and/or fragmented nighttime sleep. Their fragmented nocturnal sleep is not the cause of their excessive daytime sleepiness; many clients, particularly younger clients, have sound restorative nocturnal sleep but still cannot stay awake during the daytime. Onset of symptoms tends to occur between ages 15 and 30, and symptom severity usually stabilizes within the first 5 years of onset.

CNS stimulants such as methylphenidate (Ritalin) or amphetamines have been used to reduce excessive daytime sleepiness.

Xanthines, such as caffeine, stimulate the cerebral cortex to increase alertness. Antidepressants, both older monoamine oxidase inhibitors (MAOIs) and the newer serotonergic antidepressants, are usually quite effective for controlling cataplexy. Modafinil (Provigil) has psychoactive effects to alter mood, perception, and thinking to control excessive daytime sleepiness in narcoleptic clients. Although its exact mechanism of action is unknown, it has fewer side effects and a lower potential for abuse than other drugs. Modafinil is also used for sleep apnea/hypopnea syndrome (Frandsen & Pennington, 2014). Sodium oxybate (Xyrem) is approved for the treatment of cataplexy. It has been shown to reduce excessive daytime sleepiness in clients with narcolepsy, although the exact mechanism of action is unknown. Because Xyrem is difficult to administer (it is only available as a liquid and taken at bedtime and then again 2.5 to 4 hours after sleep onset) and its use is tightly controlled by the FDA, only those clients whose symptoms are not controlled by other medications are usually offered Xyrem. Only one pharmacy in the United States is allowed to dispense Xyrem. As a result, clients need to allow adequate time for obtaining their medications from the central pharmacy. The herbal supplement guarana can also be administered to increase mental alertness during the daytime.

CLINICAL ALERT!

Sodium oxybate is also known as gamma hydroxybutyrate or GHB—one of the drugs frequently associated with “date rapes.”

SLEEP APNEA

Sleep apnea is characterized by frequent short breathing pauses during sleep. Although all individuals have occasional periods of apnea during sleep, more than five apneic episodes or five breathing pauses longer than 10 seconds per hour is considered abnormal and should be evaluated by a sleep medicine specialist. Symptoms suggestive of sleep apnea include loud snoring, frequent nocturnal awakenings, excessive daytime sleepiness, difficulties falling asleep at night, morning headaches, memory and cognitive problems, and irritability. Although sleep apnea is most frequently diagnosed in men and postmenopausal women, it may occur during childhood.

The periods of apnea, which last from 10 seconds to 2 minutes, occur during REM or NREM sleep. Frequency of episodes ranges from 50 to 600 per night. Because these apneic pauses are usually associated with an arousal, clients frequently report that their sleep is nonrestorative and that they regularly fall asleep when engaging in sedentary activities during the day.

Three common types of sleep apnea are obstructive apnea, central apnea, and mixed apnea. Obstructive apnea occurs when the structures of the pharynx or oral cavity block the flow of air. The person continues to try to breathe; that is, the chest and abdominal muscles move. The movements of the diaphragm become stronger and stronger until the obstruction is removed. Enlarged tonsils and adenoids, a deviated nasal septum, nasal polyps, and obesity predispose the client to obstructive apnea. An episode of obstructive sleep apnea usually begins with snoring; thereafter, breathing ceases, followed by marked snorting as breathing resumes. Toward the end of each apneic episode, increased carbon dioxide levels in the blood cause the client to wake.

Central apnea is thought to involve a defect in the respiratory center of the brain. All actions involved in breathing, such as chest movement and airflow, cease. Clients who have brainstem injuries and muscular dystrophy, for example, often have central sleep apnea. At this time, there is no available treatment. Mixed apnea is a combination of central apnea and obstructive apnea.

Treatment for sleep apnea is directed at the cause of the apnea. For example, enlarged tonsils may be removed. Other surgical procedures, including laser removal of excess tissue in the pharynx, reduce or eliminate snoring and may be effective in relieving the apnea. In other cases, the use of a nasal continuous positive airway pressure (CPAP) device at night is effective in maintaining an open airway. Weight loss may also help decrease the severity of symptoms.

Sleep apnea profoundly affects a person's work or school performance. In addition, prolonged sleep apnea can cause a sharp rise in blood pressure and may lead to cardiac arrest. Over time, apneic episodes can cause cardiac arrhythmias, pulmonary hypertension, and subsequent left-sided heart failure.

CLINICAL ALERT!

Partners of clients with sleep apnea may become aware of the problem because they hear snoring that stops during the apneic period and then restarts. Surgical removal of tonsils or other tissue in the pharynx, if not the cause of the sleep apnea, can actually worsen the situation by removing the snoring and, thus, the warning that apnea is occurring.

INSUFFICIENT SLEEP

Healthy individuals who obtain less sleep than they need will experience sleepiness and fatigue during the daytime hours. Depending on the severity and chronicity of this voluntary, albeit unintentional sleep deprivation, individuals may develop attention and concentration deficits, reduced vigilance, distractibility, reduced motivation, fatigue, malaise, and occasionally diplopia and dry mouth. The cause of these symptoms may or may not be attributed to insufficient sleep, because many Americans believe that 6.8 hours of sleep is sufficient to maintain optimal daytime performance. In fact, the sleep times of Americans have decreased dramatically during the past decade, with adults averaging only 6.8 hours of sleep on weekdays and 7.4 hours on weekends. All age groups, not just adults and adolescents, are getting less than the recommended amounts of sleep. Even 4- to 5-year-old children now average less than 9.5 hours of sleep, approximately 1.5 to 2.5 hours less than recommended.

Although the effects of obtaining less than optimal amounts of sleep are generally considered benign, there is growing evidence that insufficient sleep can have significant deleterious effects. Staying awake 19 consecutive hours produces the same impairments in reaction times and cognitive function as a blood alcohol level of 0.05, and staying awake for 24 consecutive hours has the same effects on reaction times and cognitive function as being legally drunk (with a blood alcohol level of 0.1). Nurses who report reduced hours of sleep are more likely to make an error, to have difficulty staying awake on duty, and to have difficulty staying awake while driving home from work than those who obtained more sleep.

When clients report obtaining more sleep on weekends or days off, it usually indicates that they are not obtaining sufficient sleep. Convincing clients to obtain more sleep may be difficult, but it can result in the resolution of their daytime symptoms.

Parasomnias

A **parasomnia** is behavior that may interfere with sleep and may even occur during sleep. It is characterized by physical events such as movements or experiences that are displayed as emotions, perceptions, or dreams. The *International Classification of Sleep Disorders* subdivides parasomnias into three classes: non-rapid eye movement, rapid eye movement, and miscellaneous with no specific stage of sleep (Judd & Sateia, 2014). Parasomnias with non-rapid eye movement are associated with confusion upon arousal, sleep tremors, and sleep walking. Parasomnias with rapid eye movement are associated with arousal disorders such as sleep paralysis. This may be a nightmare disorder with exaggerated features of REM sleep. Miscellaneous parasomnias are not associated with any stage of sleep and may produce nocturnal enuresis or hallucinations. The miscellaneous parasomnias are often related to a medication, substance abuse, or a medical disorder. Box 45–4 describes examples of parasomnias.

●○○ NURSING MANAGEMENT

Assessing

A complete assessment of a client's sleep difficulty includes a sleep history, health history, physical exam, and, if warranted, a sleep diary and diagnostic studies. All nurses, however, can take a brief sleep history and educate their clients about normal sleep.

BOX 45–4 Parasomnias

- *Bruxism*. Usually occurring during stage 2 NREM sleep, this clenching and grinding of the teeth can eventually erode dental crowns, cause teeth to come loose, and lead to deterioration of the temporomandibular (TMJ) joint, called TMJ syndrome.
- *Enuresis*. Bed-wetting during sleep can occur in children over 3 years old. More males than females are affected. It often occurs 1 to 2 hours after falling asleep, when rousing from NREM stage 3.
- *Periodic limb movement disorder (PLMD)*. In this condition, the legs jerk twice or three times per minute during sleep. It is most common among older adults. This kicking motion can wake the client and result in poor sleep. PLMD differs from restless leg syndrome (RLS), which occurs whenever the person is at rest, not just at night when sleeping. RLS may occur during pregnancy or be due to other medical problems that can be treated. Many clients with PLMD or RLS respond well to medications such as levodopa, pramipexole, ropinirole, and gabapentin (Frandsen & Pennington, 2014).
- *Sleeptalking*. Talking during sleep occurs during NREM sleep before REM sleep. It rarely presents a problem to the person unless it becomes troublesome to others.
- *Sleepwalking*. Sleepwalking (somnambulism) occurs during stage 3 of NREM sleep. It is episodic and usually occurs 1 to 2 hours after falling asleep. Sleepwalkers tend not to notice dangers (e.g., stairs) and often need to be protected from injury.

Sleep History

A brief sleep history, which is usually part of the comprehensive nursing history, should be obtained for all clients entering a health care facility. It should, however, be deferred or omitted if the client is critically ill. Key questions to ask include the following:

- When do you usually go to sleep? And when do you wake up? Do you nap? If so, when? If the client is a child, it is also important to ask about bedtime rituals. This information provides the nurse with information about the client's usual sleep duration and preferred sleep times, and allows for the incorporation of the client's preferences in the plan of care.
- Do you have any problems with your sleep? Has anyone ever told you that you snore loudly or thrash around a lot at night? Are you able to stay awake at work, when driving, or engaging in your usual activities?

These questions elicit information about sleep complaints including the possibility of excessive daytime sleepiness. Loud snoring suggests the possibility of obstructive sleep apnea, and any client replying yes to this question should be referred to a specialist in sleep disorders medicine. Referrals should also be made if clients indicate they have difficulty staying awake during the day or that their movements disturb the sleep of their bed partners.

- Do you take any prescribed medications, over-the-counter (OTC) medications, or herbal remedies to help you sleep? Or to stay awake?

This information alerts the nurse to the use of prescription hypnotics and stimulants as well as the use of OTC sleep aids and herbal remedies.

- Is there anything else I need to know about your sleep?

This allows the client to voice any concerns or bring up topics that the nurse may not have asked about.

If the client is being admitted to a long-term care facility, it is also appropriate to ask about preferred room temperature, lighting (complete darkness versus using a night-light), and preferred bedtime routine.

A more detailed assessment is required if the client indicates any difficulty sleeping, difficulty remaining awake during the day, and/or recent changes in sleep pattern. This detailed history should explore the exact nature of the problem and its cause, when it first began and its frequency, how it affects daily living, what the client is doing to cope with the problem, and whether these methods have been effective. Questions the nurse might ask the client with a sleeping disturbance are shown in the accompanying Assessment Interview.

Health History

A health history is obtained to rule out medical or psychiatric causes of the client's difficulty sleeping. It is important to note that the presence of a medical or psychiatric illness (e.g., depression, Parkinson's disease, Alzheimer's disease, or arthritis) does not preclude the possibility that a second problem (e.g., obstructive sleep apnea) may be contributing to the difficulty sleeping. Because medications can frequently cause or exacerbate sleep disturbances, information should be obtained about all of the prescribed and nonprescription medications, including herbal remedies, that a client consumes.

ASSESSMENT INTERVIEW Sleep Disturbances

- How would you describe your sleeping problem? What changes have occurred in your sleeping pattern? How often does this happen?
- How many cups of coffee, tea, or caffeinated beverages do you drink per day? Do you drink alcohol? If so, how much?
- Do you have difficulty falling asleep?
- Do you wake up often during the night? If so, how often?
- Do you wake up earlier in the morning than you would like and have difficulty falling back to sleep?
- How do you feel when you wake up in the morning?
- Are you sleeping more than usual? If so, how often do you sleep?
- Do you have periods of overwhelming sleepiness? If so, when does this happen?
- Have you ever suddenly fallen asleep in the middle of a daytime activity? Does anything unusual happen when you laugh or get angry?
- Has anyone ever told you that you snore, walk in your sleep, or stop breathing for a while when sleeping?
- What have you been doing to deal with this sleeping problem? Does it help?
- What do you think might be causing this problem? Do you have any medical condition that might be causing you to sleep more (or less)? Are you receiving medications for an illness that might alter your sleeping pattern? Are you experiencing any stressful or upsetting events or conflicts that may be affecting your sleep?
- How is your sleeping problem affecting you?

Physical Examination

Rarely are sleep abnormalities noted during the physical examination unless the client has obstructive sleep apnea or some other health problem. Common findings among clients with sleep apnea include an enlarged and reddened uvula and soft palate, enlarged tonsils and adenoids (in children), obesity (in adults), and in male clients a neck size greater than 17.5 inches. Occasionally a deviated septum may be noted, but it is rarely the cause of obstructive sleep apnea.

Sleep Diary

A sleep specialist may ask clients to keep a sleep diary or log for 1 to 2 weeks in order to get a more complete picture of their sleep complaints. A sleep diary may include all or selected aspects of the following information that pertain to the client's specific problem:

- Time of (a) going to bed, (b) trying to fall asleep, (c) falling asleep (approximate time), (d) any instances of waking up and duration of these periods, (e) waking up in the morning, and (f) any naps and their duration
- Activities performed 2 to 3 hours before bedtime (type, duration, and time)
- Consumption of caffeinated beverages and alcohol and amounts of those beverages
- Any prescribed medications, OTC medications, and herbal remedies taken during the day
- Bedtime rituals before sleep
- Any difficulties remaining awake during the day and times when difficulties occurred
- Any worries that the client believes may affect sleep
- Factors that the client believes have a positive or negative effect on sleep.

If the client is a child, the sleep diary or log may be completed by a parent.

Diagnostic Studies

Sleep is measured objectively in a sleep disorder laboratory by **polysomnography** in which an **electroencephalogram (EEG)**, **electromyogram (EMG)**, and **electro-oculogram (EOG)** are recorded simultaneously. Electrodes are placed on the scalp to record brain waves (EEG), on the outer canthus of each eye to record eye movement (EOG), and on the chin muscles to record the structural electromyogram (EMG). The electrodes transmit electric energy from the cerebral cortex and muscles of the face to pens that record the brain waves and muscle activity on graph paper. Respiratory effort and airflow, ECG, leg movements, and oxygen saturation are also monitored. Oxygen saturation is determined by monitoring with a pulse oximeter, a light-sensitive electric cell that attaches to the ear or a finger. Oxygen saturation and ECG assessments are of particular importance if sleep apnea is suspected. Through polysomnography, the client's activity (movements, struggling, noisy respirations) during sleep can be assessed. Such activity of which the client is unaware may be the cause of arousal during sleep.

Diagnosing

Insomnia, the NANDA International (Herdman & Kamitsuru, 2014) diagnosis given to clients with sleep problems, is usually made more explicit with descriptions such as "difficulty falling asleep" or "difficulty staying asleep"; for example, *Insomnia* (delayed onset of sleep) related to overstimulation prior to bedtime.

Various factors or etiologies may be involved and must be specified for the individual. These include physical discomfort or pain;

Home Care Considerations Sleep

PATIENT-CENTERED CARE

- Assess client and caregiver's knowledge about sleep and wellness. Develop appropriate teaching interventions to augment any detected lack of knowledge areas.
- Complete an initial and periodic assessment of the client's sleep area. Look for the presence of environmental factors (e.g., mattress firmness, room temperature, noise and light levels, and distractions such as TV, radio, or computer) that may affect sleep.
- When in the home care setting, remember to assess for the possibility of sleep disruption and deprivation in the caregiver. A sleep-deprived family member may be caring for a well-rested client. Respite care, where someone relieves the caregiver and cares for the client for a period of time, may be needed.

anxiety about actual or anticipated loss of a loved one, loss of a job, loss of life due to serious disease process, or worry about a family member's behavior or illness; frequent changes in sleep time due to shift work or overtime; and changes in sleep environment or bedtime rituals (e.g., noisy environment, alcohol or other drug dependency, drug withdrawal, misuse of sedatives prescribed for insomnia, and effects of medications such as steroids or stimulants).

Sleep pattern disturbances may also be stated as the etiology of another diagnosis, in which case the nursing interventions are directed toward the sleep disturbance itself. Examples include the following:

- *Risk for Injury* related to somnambulism
- *Ineffective Coping* related to insufficient quality and quantity of sleep
- *Fatigue* related to insufficient sleep
- *Impaired Gas Exchange* related to sleep apnea
- *Deficient Knowledge* (nonprescription remedies for sleep) related to misinformation
- *Anxiety* related to sleep apnea and/or the diagnosis of a sleep disorder
- *Activity Intolerance* related to sleep deprivation or excessive daytime sleepiness.

Planning

The major goal for clients with sleep disturbances is to maintain (or develop) a sleeping pattern that provides sufficient energy for daily activities. Other goals may relate to enhancing the client's feeling of well-being or improving the quality and quantity of the client's sleep. The nurse plans specific nursing interventions to reach the goal based on the etiology of each nursing diagnosis. These interventions may include reducing environmental distractions, promoting bedtime

rituals, providing comfort measures, scheduling nursing care to provide for uninterrupted sleep periods, and teaching stress reduction, relaxation techniques, or good sleep hygiene. Specific nursing activities associated with each of these interventions can be selected to meet the individual needs of the client. See the Nursing Care Plan and the Concept Map at the end of the chapter.

Implementing

The term **sleep hygiene** refers to interventions used to promote sleep. Nursing interventions to enhance the quantity and quality of clients' sleep involve largely nonpharmacologic measures. These involve health teaching about sleep habits, support of bedtime rituals, the provision of a restful environment, specific measures to promote comfort and relaxation, and appropriate use of hypnotic medications.

For hospitalized clients, sleep problems are often related to the hospital environment or their illness. Assisting the client to sleep in such instances can be challenging to a nurse, often involving scheduling activities, administering analgesics, and providing a supportive environment. Explanations and a supportive relationship are essential for the fearful or anxious client. Different types of hypnotics may be prescribed depending on the type of sleep problem (e.g., difficulties falling asleep or difficulties maintaining sleep). Drugs with longer half-lives are often prescribed for difficulties maintaining sleep, but must be used with caution in older adults.

Client Teaching

Healthy individuals need to learn the importance of sleep in maintaining active and productive lifestyles. They need to learn (a) the conditions that promote sleep and those that interfere with sleep, (b) safe use of sleep medications, (c) effects of other prescribed medications

CLIENT TEACHING

Promoting Sleep

SLEEP PATTERN

- If you have difficulty falling asleep or staying asleep, it is important to establish a regular bedtime and wake-up time for all days of the week to enhance your biologic rhythm. A short daytime nap (e.g., 15 to 30 minutes), particularly among older adults, can be restorative and not interfere with nighttime sleep. A younger person with insomnia should not nap.
- Establish a regular, relaxing bedtime routine before sleep such as reading, listening to soft music, taking a warm bath, or doing some other quiet activity you enjoy.
- Avoid dealing with office work or family problems before bedtime.
- Get adequate exercise during the day to reduce stress, but avoid excessive physical exertion at least 3 hours before bedtime.
- Use the bed for sleep or sexual activity, so that you associate it with sleep. Take work material, computers, and TVs out of the bedroom. Lying awake, tossing and turning, will strengthen the association between wakefulness and lying in bed (many people with insomnia report falling asleep in a chair or in front of the TV but having trouble falling asleep in bed).
- When you are unable to sleep, get out of bed, go into another room, and pursue some relaxing activity until you feel drowsy.

ENVIRONMENT

- Create a sleep-conducive environment that is dark, quiet, comfortable, and cool.
- Keep noise to a minimum; block out extraneous noise as necessary with white noise from a fan, air conditioner, or white noise machine. Music is not recommended because studies have shown that music will promote wakefulness (it is interesting and people will pay attention to it).
- Sleep on a comfortable mattress and pillows.

DIET

- Avoid heavy meals 2 to 3 hours before bedtime.
- Avoid alcohol and caffeine-containing foods and beverages (e.g., coffee, tea, chocolate) at least 4 hours before bedtime. Caffeine can interfere with sleep. Both caffeine and alcohol act as diuretics, creating the need to void during sleep time.
- If a bedtime snack is necessary, consume only light carbohydrates or a milk drink. Heavy or spicy foods can cause gastrointestinal upsets that disturb sleep.

MEDICATIONS

- Use sleeping medications only as a last resort. Use OTC medications sparingly because many contain antihistamines that cause daytime drowsiness.
- Take analgesics before bedtime to relieve aches and pains.
- Consult with your health care provider about adjusting other medications that may cause insomnia.

on sleep, (d) effects of their disease states on sleep, and (e) importance of long periods of uninterrupted sleep. Tips for promoting sleep are listed in Client Teaching.

Supporting Bedtime Rituals

Most people are accustomed to bedtime rituals or presleep routines that are conducive to comfort and relaxation. Altering or eliminating such routines can affect a client's sleep. Common prebedtime activities of adults include listening to music, reading, taking a soothing bath, and praying. Children need to be socialized into a presleep routine such as a bedtime story, holding onto a favorite toy or blanket, and kissing everyone goodnight. Sleep is also usually preceded by hygienic routines, such as washing the face and hands (or bathing), brushing the teeth, and voiding.

In institutional settings, nurses can provide similar bedtime rituals—assisting with a hand and face wash, providing a massage or hot drink, plumping pillows, and providing extra blankets as needed. Conversing about accomplishments of the day or enjoyable events such as visits from friends can also help to relax clients and bring peace of mind.

Creating a Restful Environment

All people need a sleeping environment with minimal noise, a comfortable room temperature, appropriate ventilation, and appropriate lighting. Although most people prefer a darkened environment, a lowlight source may provide comfort for children or those in a strange environment. Infants and children need a quiet room usually separate from the parents' room, a light or warm blanket as appropriate, and a location away from open windows or drafts.

Environmental distractions such as environmental noises and staff communication noise are particularly troublesome for hospitalized clients. Environmental noises include the sound of paging systems, telephones, and call lights; monitors beeping; doors closing; elevator chimes; furniture squeaking; and linen carts being wheeled through corridors. Staff communication is a major factor creating noise, particularly at staff change of shift.

To create a restful environment, the nurse needs to reduce environmental distractions, reduce sleep interruptions, ensure a safe environment, and provide a room temperature that is satisfactory to the client. Some interventions to reduce environmental distractions, especially noise, are listed in Box 45–5.

The environment must also be safe so that the client can relax. People who are unaccustomed to narrow hospital beds may feel more secure with side rails.

Additional safety measures include:

- Placing beds in low positions.
- Using night-lights.
- Placing call bells within easy reach.

Promoting Comfort and Relaxation

Comfort measures are essential to help the client fall asleep and stay asleep, especially if the effects of the person's illness interfere with sleep. A concerned, caring attitude, along with the following interventions, can significantly promote client comfort and sleep:

- Provide loose-fitting nightwear.
- Assist clients with hygienic routines.

BOX 45–5 Reducing Environmental Distractions in Hospitals

- Close window curtains if street lights shine through.
- Close curtains between clients in semiprivate and larger rooms.
- Reduce or eliminate overhead lighting; provide a night-light at the bedside or in the bathroom.
- Use a flashlight to check drainage bags, etc., without turning on the overhead lights.
- Ensure a clear pathway around the bed to avoid bumping the bed and jarring the client during sleeping hours.
- Close the door of the client's room.
- Adhere to agency policy about times to turn off communal televisions or radios.
- Lower the ring tone of nearby telephones.
- Discontinue use of the paging system after a certain hour (e.g., 2100 hours) or reduce its volume.
- Keep required staff conversations at low levels; conduct nursing reports or other discussions in a separate area away from client rooms.
- Wear rubber-soled shoes.
- Ensure that all cart wheels are well oiled.
- Perform only essential noisy activities during sleeping hours.

- Make sure the bed linen is smooth, clean, and dry.
- Assist or encourage the client to void before bedtime.
- Offer to provide a back massage before sleep.
- Position dependent clients appropriately to aid muscle relaxation, and provide supportive devices to protect pressure areas.
- Schedule medications, especially diuretics, to prevent nocturnal awakenings.
- For clients who have pain, administer analgesics 30 minutes before sleep.
- Listen to the client's concerns and deal with problems as they arise.

People of any age, but especially older adults, are unable to sleep well if they feel cold. Changes in circulation, metabolism, and body tissue density reduce the older person's ability to generate and conserve heat. To compound this problem, hospital gowns have short sleeves and are made of thin polyester. Bed sheets also are often made of polyester rather than a warm fabric, such as cotton flannel. The following interventions can be used to keep older adults warm during sleep:

- Before the client goes to bed, warm the bed with prewarmed bath blankets.
- Use 100% cotton flannel sheets or apply thermal blankets between the sheet and bedspread.
- Encourage the client to wear own clothing, such as flannel nightgown or pajamas, socks, leg warmers, long underwear, sleeping cap (if scalp hair is sparse), or sweater, or use extra blankets.

Emotional stress obviously interferes with a person's ability to relax, rest, and sleep, and inability to sleep further aggravates feelings of tension. Sleep rarely occurs until a person is relaxed. Relaxation techniques can be encouraged as part of the nightly routine. Slow, deep breathing for a few minutes followed by slow, rhythmic contraction and relaxation of muscles can alleviate tension and induce calm. Imagery, meditation, and yoga can also be taught. These techniques are discussed in Chapter 19 .

Enhancing Sleep with Medications

Sleep medications often prescribed on a prn (as-needed) basis for clients include the sedative-hypnotics, which induce sleep, and anti-anxiety drugs or tranquilizers, which decrease anxiety and tension. When prn sleep medications are ordered in institutional settings, the nurse is responsible for making decisions with the client about when to administer them. These medications should be administered only with complete knowledge of their actions and effects and only when indicated.

Both nurses and clients need to be aware of the actions, effects, and risks of the specific medication prescribed. Although medications vary in their activity and effects, considerations include the following:

- Sedative-hypnotic medications produce a general CNS depression and an unnatural sleep; REM or NREM sleep is altered to some extent and daytime drowsiness and a morning hangover effect may occur. Some of the new hypnotics, such as zolpidem (Ambien), do not alter REM sleep or produce rebound insomnia when discontinued.
- Antianxiety medications decrease levels of arousal by facilitating the action of neurons in the CNS that suppress responsiveness to stimulation. These medications are contraindicated in pregnant women because of their associated risk of congenital anomalies, and in breast-feeding mothers because the medication is excreted in breast milk.
- Sleep medications vary in their onset and duration of action and will impair waking function as long as they are chemically active. Some medication effects can last many hours beyond the time that the client's perception of daytime drowsiness and impaired psychomotor skills have disappeared. Clients need to be cautioned about such effects and about driving or handling machinery while the drug is in their system.
- Sleep medications affect REM sleep more than NREM sleep. Clients need to be informed that one or two nights of increased dreaming (REM rebound) are usual after the drug is discontinued after long-term use.
- Initial doses of medications should be low and increases added gradually, depending on the client's response. Older adults, in particular, are susceptible to side effects because of their metabolic changes; they need to be closely monitored for changes in mental alertness and coordination. Clients need to be instructed to take the smallest effective dose and then only for a few nights or intermittently as required.
- Regular use of any sleep medication can lead to tolerance over time (e.g., 4 to 6 weeks) and rebound insomnia. In some instances, this may lead clients to increase the dosage. Clients must be cautioned about developing a pattern of drug dependency.
- Abrupt cessation of barbiturate sedative-hypnotics can create withdrawal symptoms such as restlessness, tremors, weakness, insomnia, increased heart rate, seizures, convulsions, and even death. Long-term users need to taper their medications under the supervision of a specialist.

TABLE 45-1 Selected Sedative-Hypnotic Medications Used for Insomnia

Medication	Half-Life (hours)
Chloral hydrate (Noctec)	8–11
Eszopiclone (Lunesta)	5–6
Flurazepam (Dalmane)	47–100
Lorazepam (Ativan)	10–20
Melatonin	1
Temazepam (Restoril)	8–24
Triazolam (Halcion)	2–3
Zaleplon (Sonata)	1
Zolpidem (Ambien)	2.5

About half of the clients who seek medical intervention for sleep problems are treated with sedative-hypnotics. Sometimes the prescription of hypnotics can be appropriate. For example, women with chronic difficulties maintaining sleep or nonrestorative sleep associated with menopausal symptoms often benefit by the prescription of 10 mg of zolpidem, a low dose that was documented to be both safe and efficacious in this population. Hypnotics are not appropriate if clients have any symptoms suggestive of sleep-related breathing disorders or decreased renal and/or hepatic function.

Table 45-1 presents some of the common medications used for enhancing sleep and the half-life of these medications. The half-life represents how long it takes for half of the medication to be metabolized and eliminated by the body; hence, those with shorter half-lives are less likely to cause residual drowsiness after administration, but may be less effective for the treatment of sleep maintenance insomnia.

Evaluating

Using data collected during care and the desired outcomes developed during the planning stage as a guide, the nurse judges whether client goals and outcomes have been achieved. Data collection may include (a) observations of the duration of the client's sleep, (b) questions about how the client feels on awakening, or (c) observations of the client's level of alertness during the day.

If the desired outcomes are not achieved, the nurse and client should explore the reasons, which may include answers to the following questions:

- Were etiologic factors correctly identified?
- Has the client's physical condition or medication therapy changed?
- Did the client comply with instructions about establishing a regular sleep/wake pattern?
- Did the client avoid ingesting caffeine?
- Did the client participate in stimulating daytime activities to avoid excessive daytime naps?
- Were all possible measures taken to provide a restful environment for the client?
- Were the comfort and relaxation measures effective?

DRUG CAPSULE

Non-Benzodiazepine Sedative-Hypnotics zolpidem (Ambien)

THE CLIENT WITH MEDICATIONS THAT AFFECT SLEEP OR ALERTNESS

Zolpidem is used for the short-term (7- to 10-day) management of insomnia. The medication is used to reduce sleep latency and awakenings, and to lengthen sleep durations. Unlike traditional benzodiazepine sedative-hypnotics, zolpidem does not reduce REM sleep durations or cause rebound insomnia when the drug is discontinued. At therapeutic doses, it causes little or no respiratory depression, and it has a low potential for abuse. Clients using it for short periods have not demonstrated tolerance, physical dependence, or withdrawal symptoms. It has a rapid onset of action and a half-life of 2.5 hours.

NURSING RESPONSIBILITIES

- The drug has a rapid onset of action, so it should not be given until just prior to bedtime in order to minimize sedation while awake.

- Clients should be monitored for side effects (e.g., daytime drowsiness and dizziness). Older clients and those with hepatic insufficiency should start with a lower dose (e.g., 5 mg).

CLIENT AND FAMILY TEACHING

- Clients should be cautioned that zolpidem can intensify the actions of other CNS depressants and warned against combining zolpidem with alcohol and all other drugs that depress CNS function.
- Clients should be cautioned not to take this medication until they are ready to go to bed because of its rapid onset of action. Some clients may engage in activities such as driving and eating with no memory of having participated in those activities.

Central Nervous System Stimulant modafinil (Provigil)

Modafinil has been approved by the FDA for the treatment of narcolepsy, excessive daytime sleepiness associated with obstructive sleep apnea, and shift work sleep disorder. Because the drug does not alter the function of the dopamine neurotransmitter system, modafinil lacks the addictive potential of traditional stimulants. The drug alters mood, perception, and thinking. The onset of action is rapid and reaches peak plasma levels in 2 to 4 hours. It has a long half-life (approximately 15 hours) and thus can usually be administered only once a day (in the morning). It does not interfere with sleep at night.

NURSING RESPONSIBILITIES

- Monitor the client for side effects, particularly if the client is older or has hepatic dysfunction. Side effects are rare and usually consist of headache, nausea, and nervousness.
- If the client has obstructive sleep apnea, ensure that the client continues to use nasal CPAP.

CLIENT AND FAMILY TEACHING

- Explain that modafinil is not a substitute for obtaining adequate amounts of sleep. Any client with the diagnosis of narcolepsy, obstructive sleep apnea, or shift work sleep disorder needs to obtain adequate amounts of sleep in addition to taking prescribed medications.
- Caution clients with obstructive sleep apnea that it is very important to continue using nasal CPAP and that modafinil is being prescribed only to reduce excessive daytime sleepiness and will not reduce the number of apneic episodes during sleep.
- Modafinil may accelerate the metabolism of oral contraceptives, leading to lower plasma levels. Women using low-dose birth control pills may want to consider switching birth control methods or adding a second type of birth control.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

NURSING CARE PLAN Sleep

Assessment Data

Nursing Assessment

Jack Harrison is a 36-year-old police officer assigned to a high-crime police precinct. One week ago he received a surface bullet wound to his arm. Today he arrives at the outpatient clinic to have the wound redressed. While speaking with the nurse, Mr. Harrison mentions that he has recently been promoted to the rank of detective and has assumed new responsibilities. He states that since his promotion, he has experienced increasing difficulty falling asleep and sometimes staying asleep. He expresses concern over the danger of his occupation and his desire to do well in his new position. He complains of waking up feeling tired and irritable.

Physical Examination

Height: 185.4 cm (6'2")
 Weight: 85.7 kg (189 lb)
 Temperature: 37.0°C (98.6°F)
 Pulse: 80 beats/min
 Respirations: 18/min
 Blood pressure: 144/88 mmHg

Diagnostic Data

CBC within normal range,
 x-ray left arm: evidence of superficial soft tissue injury

Nursing Diagnosis

Insomnia related to anxiety (as evidenced by difficulty falling and remaining asleep, fatigue, and irritability)

Desired Outcomes*

- Sleep** [0004] as evidenced by:
- No compromise in sleeping through the night consistently
 - No compromise in feeling rejuvenated after sleep
 - No dependence on sleep aids

NURSING CARE PLAN Sleep—continued

Nursing Interventions*/Selected Activities

Rationale

Sleep Enhancement [1850]

Determine the client's sleep and activity pattern.

The amount of sleep an individual needs varies with lifestyle, health, and age.

Encourage Mr. Harrison to establish a bedtime routine to facilitate transition from wakefulness to sleep.

Rituals and routines induce comfort, relaxation, and sleep.

Encourage him to eliminate stressful situations before bedtime.

Stress interferes with a person's ability to relax, rest, and sleep.

Instruct Mr. Harrison and significant others about factors (e.g., physiological, psychological, lifestyle, frequent work shift changes, excessively long work hours, and other environmental factors) that contribute to sleep pattern disturbances.

Knowledge of causative factors can enable the client to begin to control factors that inhibit sleep.

Discuss with Mr. Harrison and his family comfort measures, sleep-promoting techniques, and lifestyle changes that can contribute to optimal sleep.

Knowledge of factors that affect sleep enables the client to implement changes in lifestyle and prebedtime activities.

Monitor bedtime food and beverage intake for items that facilitate or interfere with sleep.

Milk and protein foods contain tryptophan, a precursor of serotonin, which is thought to induce and maintain sleep. Stimulants should be avoided because they inhibit sleep.

Security Enhancement [5380]

Discuss specific situations or individuals that threaten Mr. Harrison or his family.

Fear is reduced when the reality of a situation is confronted in a safe environment. Awareness of factors that cause intensification of fears enhances control.

Assist him to use coping responses that have been successful in the past.

Feelings of safety and security increase when an individual identifies previously successful ways of dealing with anxiety-provoking or fearful situations.

Anxiety Reduction [5820]

Create an atmosphere to facilitate trust.

Trust is an essential first step in the therapeutic relationship.

Seek to understand Mr. Harrison's perspective of a stressful situation.

Anxiety is a feeling aroused by a vague, nonspecific threat. Identifying the client's perspective will facilitate planning for the best approach to anxiety reduction.

Encourage verbalization of feelings, perceptions, and fears.

Open expression of feelings facilitates identification of specific emotions such as anger or helplessness, distorted perceptions, and unrealistic fears.

Determine the client's decision-making ability.

Maladaptive coping mechanisms are characterized by an inability to make decisions and choices.

Evaluation

Outcome met. Mr. Harrison acknowledges his insomnia is a somatic expression of his anxiety regarding job promotion and fear of failing. He states that talking with the police department counselor has been helpful. He is practicing relaxation techniques each night and sleeps an average of 7 hours a night. Mr. Harrison expresses a feeling of being rested on awakening.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

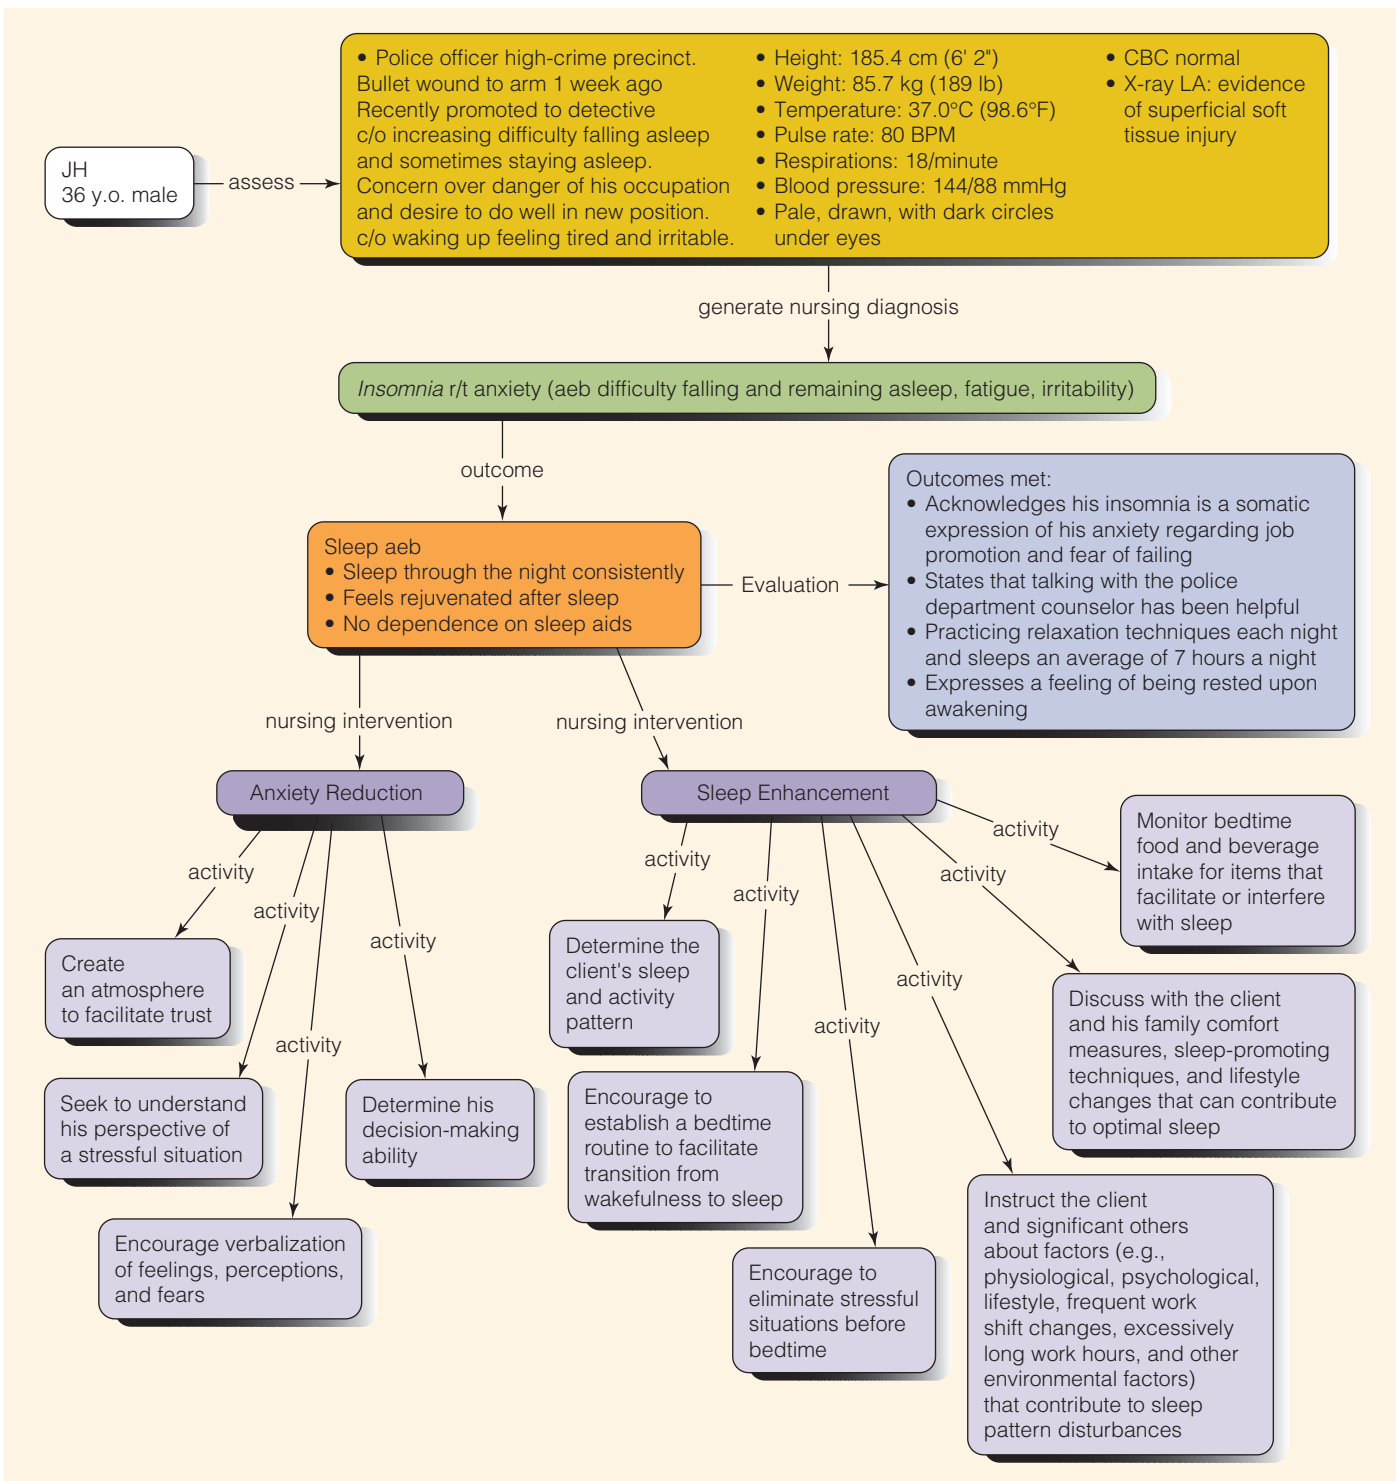

APPLYING CRITICAL THINKING

1. What further information would be helpful to obtain from Mr. Harrison about his sleep problem?
2. What suggestions can you make that may help him develop better sleep habits?
3. What are the most common problems that interfere with clients' ability to sleep?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Sleep

Chapter 45 Review

CHAPTER HIGHLIGHTS

- Sleep is needed for optimal psychological and physiological functioning.
- Insufficient sleep is widespread among all age groups in this country. Approximately 50 million to 70 million Americans suffer from a chronic disorder of sleep and wakefulness that hinders daily functioning and adversely affects health. Reports from government agencies have stated that sleep disorders and sleep deprivation are an unmet public health problem.
- Sleep is a naturally occurring altered state of consciousness in which a person's perception and reaction to the environment are decreased.
- The sleep cycle is controlled by specialized areas in the brainstem and is affected by the individual's circadian rhythm.
- NREM sleep consists of three stages, progressing from stage 1, very light sleep, to stage 3 deep sleep. NREM sleep dominates during naps and nocturnal sleep periods. NREM sleep is essential for physiological well-being.
- REM sleep recurs about every 90 minutes and is often associated with dreaming. REM sleep is essential for psychosocial and mental equilibrium.
- During a normal night's sleep, an adult has four to six sleep cycles, each with NREM (quiet sleep) and REM (rapid-eye-movement) sleep.
- The ratio of NREM to REM sleep varies with age.
- Many factors can affect sleep, including illness, environment, lifestyle, emotional stress, stimulants and alcohol, diet, smoking, motivation, and medications.
- Common sleep disorders include insomnia, hypersomnia, narcolepsy, parasomnias (such as somnambulism, sleepwalking, and bruxism), and sleep apnea.
- Assessment of a client's sleep includes a sleep history, a health history, and a physical examination to detect signs that may indicate the presence of sleep apnea.
- Nursing responsibilities to help clients sleep include (a) teaching clients ways to enhance sleep, (b) supporting bedtime rituals, (c) creating a restful environment, (d) promoting comfort and relaxation, and (e) enhancing sleep with medications.

TEST YOUR KNOWLEDGE

1. A client is admitted for a sleep disorder. The nurse knows that the reticular activating system (RAS) is involved in the sleep/wake cycle. In the accompanying illustration, which letter indicates the location of the RAS?

1. A
 2. B
 3. C
 4. D
2. A client has a history of sleep apnea. Which is the most appropriate question for the nurse to ask?
1. Do you have a history of cardiac irregularities?
 2. Do you have a history of any kind of nasal obstruction?
 3. Have you had chest pain with or without activity?
 4. Do you have difficulty with daytime sleepiness?
3. Because of significant concerns about financial problems, a middle-aged client complains of difficulty sleeping. Which outcome would be the most appropriate for the nursing care plan? "By day 5, the client will:
1. Sleep 8 to 10 hours per day."
 2. Report falling asleep within 20 to 30 minutes."
 3. Have a plan to pay all the bills."
 4. Decrease worrying about financial problems and will keep busy until bedtime."
4. A client reports to the nurse that she has been taking barbiturate sleeping pills every night for several months and now wishes to stop taking them. Which statement is the most appropriate advice for the nurse to provide the client?
1. Take the last pill on a Friday night so disrupted sleep can be compensated on the weekend.
 2. Continue to take the pills since sleeping without them after such a long time will be difficult and perhaps impossible.
 3. Discontinue taking the pills.
 4. Continue taking the pills and discuss tapering the dose with the primary care provider.
5. During a well-child visit, a mother tells the nurse that her 4-year-old daughter typically goes to bed at 10:30 PM and awakens each morning at 7 AM. She does not take a nap in the afternoon. Which is the best response by the nurse?
1. Encourage the mother to consider putting her daughter to bed between 8 and 9 PM.
 2. Reassure the mother that it is normal for 4-year-olds to resist napping, but encourage her to insist that she rest quietly each afternoon.
 3. Recommend that her daughter be allowed to sleep later in the morning.
 4. Reassure her that her daughter's sleep pattern is normal and that she has outgrown her need for an afternoon nap.

6. A college student was referred to the campus health service because of difficulty staying awake in class. What should be included in the nurse's assessment? Select all that apply.
 1. Amount of sleep he usually obtains during the week and on weekends
 2. How much alcohol he usually consumes
 3. Onset and duration of symptoms
 4. Whether or not his classes are boring
 5. What medications, including herbal remedies, he is taking
7. During a yearly physical, a 52-year-old male client mentions that his wife frequently complains about his snoring. During the physical exam, the nurse notes that his neck size is 18 inches, his soft palate and uvula are reddened and swollen, and he is overweight. What is the most appropriate nursing intervention for the nurse to recommend to this client?
 1. Recommend that he and his wife sleep in separate bedrooms so that his snoring does not disturb his wife.
 2. Refer him to a dietitian for a weight loss program.
 3. Caution him not to drink or take sleeping pills since they may make his snoring worse.
 4. Refer him to a sleep disorders center for evaluation and treatment of his symptoms.
8. A new nursing graduate's first job requires 12-hour night shifts. Which strategy will make it easier for the graduate to sleep during the day and remain awake at night?
 1. Wear dark wrap-around sunglasses when driving home in the morning, and sleep in a darkened bedroom.
 2. Exercise on the way home to avoid having to stand around waiting for equipment at the gym.
 3. Drink several cups of strong coffee or 16 oz of caffeinated soda when beginning the shift.
 4. Try to stay in a brightly lit area when working at night.
9. The nurse is answering questions after a presentation on sleep at a local senior citizens center. A woman in her late 70s asks for an opinion about the advisability of allowing her husband to nap for 15 to 20 minutes each afternoon. Which is the nurse's best response?
 1. "Taking an afternoon nap will interfere with his being able to sleep at night. If he's tired in the afternoon, see if you can interest him in some type of stimulating activity to keep him awake."
 2. "He shouldn't need to take an afternoon nap if he's getting enough sleep at night."
 3. "Unless your husband has trouble falling asleep at night, a brief afternoon nap is fine."
 4. "Encourage him to consume coffee or some other caffeinated beverage at lunch to prevent drowsiness in the afternoon."
10. During admission to a hospital unit, the client tells the nurse that her sleep tends to be very light and that it is difficult for her to get back to sleep if she's awakened at night. Which interventions should the nurse implement? Select all that apply.
 1. Remind colleagues to keep their conversation to a minimum at night.
 2. Encourage the client's family members to bring in a radio to play soft music at night.
 3. Deliver necessary medications and procedures at 1.5- or 3-hour intervals between 11 PM and 6 AM.
 4. Encourage the client to ask family members to bring in a fan to provide white noise.
 5. Increase the temperature in the room.

46 Pain Management

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Discriminate between nociceptive and neuropathic pain categories.
2. Describe the four processes involved in nociception and how pain interventions can work during each process.
3. Describe the gate control theory and its application to nursing care.
4. Describe factors that can affect a person's perception of and reaction to pain.
5. Identify subjective and objective data to collect and analyze when assessing pain.
6. Identify examples of nursing diagnoses for clients with pain.
7. Individualize a pain treatment plan based on clinical and personal goals, while setting objective outcome criteria by which to evaluate a client's response to interventions for pain.
8. Compare and contrast barriers to effective pain management affecting nurses and clients.
9. Differentiate tolerance, physical dependence, pseudoaddiction, and addiction.
10. Describe pharmacologic interventions for pain.
11. Describe the World Health Organization's three-step analgesic ladder approach developed for cancer pain control.
12. Identify risks and benefits of various analgesic delivery routes and analgesic delivery technologies.
13. Describe nonpharmacologic pain control interventions.
14. Verbalize the steps used in performing a back massage.
15. Recognize when it is appropriate to delegate aspects of back massage to unlicensed assistive personnel.
16. Demonstrate appropriate documentation and reporting of back massage.
17. List three nonpharmacologic interventions directed at each of the following: the body, the mind, the spirit, and social interactions.

INTRODUCTION

Pain is an unpleasant and highly personal experience that may be imperceptible to others, while consuming all parts of an individual's life. The best definition of pain comes from Margo McCaffery, an internationally known nurse expert on pain. Her often-quoted definition of pain says "pain is whatever the person says it is, and exists whenever he says it does" (Pasero & McCaffery, 2011, p. 21). This definition certainly portrays how subjective pain is. Another widely agreed-on definition of **pain** is "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain [IASP], 2012). Three aspects of these definitions have important implications for nurses. First, pain is a physical *and* emotional experience, not all in the body or all in the mind. Second, it is

in response to actual *or* potential tissue damage, so laboratory or radiographic reports may not be abnormal despite the real pain. Finally, pain is described in terms of such damage (e.g., neuropathic pain). Given that some clients are reluctant to disclose the presence of pain unless asked, nurses will be unaware of a client's pain until they assess for it. Additionally, it is clear that even clients who are nonverbal (e.g., preverbal children, intubated clients, people with cognitive impairments or those who are unconscious) experience pain that demands nursing assessment and treatment even though the clients are unable to describe their discomfort. Pain interferes with functional abilities and quality of life. Severe or persistent pain affects all body systems, causing potentially serious health problems while increasing the risk of complications, delays in healing, and an accelerated progression of fatal illnesses (Arnstein, 2010).

Pain management is the alleviation of pain or a reduction in pain to a level of comfort that is acceptable to the client. Even if the original cause of the pain heals, the changes in the nervous system resulting from suboptimal pain management can result in the development of chronic pain. Persistent pain also contributes to insomnia, weight gain or loss, constipation, hypertension, deconditioning, chronic stress, and depression. These effects can interfere with work, recreation, domestic activities, and personal care activities to the point at which many sufferers question whether life is worth living. Effective pain management is an important aspect of nursing care to promote healing, prevent complications, reduce suffering, and prevent the development of incurable pain states. To be a true client advocate, nurses must realize their role as advocates for pain relief.

Pain is more than a symptom of a problem; it is a high-priority problem in itself. Pain presents both physiological and psychological dangers to health and recovery. Severe pain is viewed as an emergency situation deserving attention and prompt professional treatment.

THE NATURE OF PAIN

Although pain is a universal experience, the nature of the experience is unique to the individual based, in part, on the type of pain experienced, the psychosocial context or meaning, and the response. Adding to the complexity, pain may be a physiological warning system alerting the nurse to a problem or unmet need demanding attention; or it may be a diseased, malfunctioning segment of the nervous system. Advances in the understanding of physiological mechanisms may someday replace the currently used categories of acute pain or chronic (persistent) pain. In addition to the underlying mechanisms, nurses attuned to a holistic view of care need to consider how these

physiological signals affect the mind, body, spirit, and social interactions. In this section, a review is included of the scientific, theoretical, and clinical concepts that form the foundation of knowledge needed by nurses to assess and treat clients with pain in a holistic, comprehensive fashion.

Types of Pain

Pain may be described in terms of location, duration, intensity, and etiology.

LOCATION

Classifications of pain based on location (e.g., head, back, chest) may be problematic. The International Headache Society (n.d.) recognizes approximately 80 different types of headaches. Many have similar clinical presentations but different clinical needs. Nevertheless, location of pain is an important consideration. For example, if after knee surgery, a client reports moderately severe chest pain, the nurse must act immediately to further evaluate and treat this discomfort. The ability to discriminate between cardiac and noncardiac chest pain challenges even expert clinicians, but the fact that chest pain is evaluated and treated differently than knee pain in this client is understandable. Complicating the categorization of pain by location is the fact that some pains radiate (spread or extend) to other areas (e.g., low back to legs). Pain may also be **referred** (appear to arise in different areas) to other parts of the body. For example, cardiac pain may be felt in the shoulder or left arm, with or without chest pain (Figure 46–1 ■). **Visceral pain** (pain arising from organs or hollow viscera) is often perceived in an area remote from the organ causing the pain.

Figure 46–1 ■ Common sites of referred pain from various body organs.

DURATION

When pain lasts only through the expected recovery period, it is described as **acute pain**, whether it has a sudden or slow onset, regardless of its intensity. **Chronic pain**, also known as persistent pain, is prolonged, usually recurring or lasting 3 months or longer, and interferes with functioning. Acute and chronic pain produce different physiological and behavioral responses, as shown in Table 46–1. Although experts may disagree on whether the cutoff point for chronic pain should be 3 or 6 months after onset, or expected healing time, NANDA International (Herdman & Kamitsuru, 2014) specifies the accepted nursing diagnosis of *Chronic Pain* to be mild to severe, constant or recurring, without an anticipated or predictable end and with a duration of greater than 3 months (p. 442).

Cancer pain may result from the direct effects of the disease and its treatment, or it may be unrelated. Over time, other diagnoses have been included in the “malignant pain” category, such as HIV/AIDS or burn pain, which tend to be treated more aggressively than “noncancer pain.”

INTENSITY

Most practitioners classify intensity of pain by using a standard scale: 0 (no pain) to 10 (worst possible pain) scale. Linking the rating to health and functioning scores, pain in the 1 to 3 range is deemed **mild pain**, a rating of 4 to 6 is **moderate pain**, and pain reaching 7 to 10 is deemed **severe pain** and is associated with the worst outcomes.

ETIOLOGY

Designating types of pain by etiology can be done under the broad categories of nociceptive pain and neuropathic pain. **Nociceptive pain** is experienced when an intact, properly functioning nervous system sends signals that tissues are damaged, requiring attention and proper care. For example, the pain experienced following a cut or broken bone alerts the person to avoid further damage until it is properly healed. Once stabilized or healed, the pain goes away; thus this pain is transient. There may also be persistent forms of nociceptive pain. An example is a person who has lost the protective cartilage in joints. Pain will occur when the joints are stressed because the

bone-to-bone contact damages tissues. This common form of osteoarthritis produces pain in millions of people, some of whom have intermittent pain whereas others have constant pain for years.

Subcategories of nociceptive pain include somatic and visceral. **Somatic pain** originates in the skin, muscles, bone, or connective tissue. The sharp sensation of a paper cut or aching of a sprained ankle are common examples of somatic pain. Visceral pain results from activation of pain receptors in the organs and/or hollow viscera. Visceral pain tends to be characterized by cramping, throbbing, pressing, or aching qualities. Often visceral pain is associated with feeling sick (e.g., sweating, nausea, or vomiting) as in the examples of labor pain, angina pectoris, or irritable bowel.

Neuropathic pain is associated with damaged or malfunctioning nerves due to illness (e.g., post-herpetic neuralgia, diabetic peripheral neuropathy), injury (e.g., phantom limb pain, spinal cord injury pain), or undetermined reasons. Neuropathic pain is typically chronic; it is described as burning, “electric-shock,” and/or tingling, dull, and aching. Episodes of sharp, shooting pain can also be experienced. Neuropathic pain tends to be difficult to treat.

The two subtypes of neuropathic pain are based on the part of the nervous system believed to be damaged. **Peripheral neuropathic pain** (e.g., phantom limb pain, post-herpetic neuralgia, carpal tunnel syndrome) follows damage or sensitization of peripheral nerves. **Central neuropathic pain** (e.g., spinal cord injury pain, poststroke pain, multiple sclerosis pain) results from malfunctioning nerves in the central nervous system (CNS). **Sympathetically maintained pain** occurs occasionally when abnormal connections between pain fibers and the sympathetic nervous system perpetuate problems with both the pain and sympathetically controlled functions (e.g., edema, temperature and blood flow regulation).

Common chronic pain syndromes are briefly described in Clinical Manifestations.

Concepts Associated with Pain

It is useful for nurses to differentiate pain threshold from pain tolerance. **Pain threshold** is the least amount of stimuli that is needed for a person to label a sensation as pain. Threshold studies are typically conducted in a laboratory with many controls and measured amounts of stimuli (typically electrically generated). Pain threshold may vary slightly from person to person, and may be related to age, gender, or race, but it changes little in the same individual over time. **Pain tolerance** is the maximum amount of painful stimuli that a person is willing to withstand without seeking avoidance of the pain or relief. Pain tolerance varies considerably from person to person, even within the same person at different times and in different circumstances. For example, a woman may tolerate a considerable amount of labor pain because she does not want to alter her level of alertness or the vitality of her baby. She likely would not tolerate a fraction of that pain during a routine dental procedure before requesting appropriate pain relief medicine.

Hyperalgesia, allodynia, hyperpathia, and dysesthesia are conditions of abnormal pain processing that may signal the development of neuropathic processes. If recognized early these may be reversed; if ignored, they may lead to the development of incurable pain syndromes. The terms **hyperalgesia** and **hyperpathia** may be used interchangeably to mean heightened responses to a painful stimuli (e.g., severe pain response to a paper cut). **Allodynia** includes non-painful stimuli (e.g., light touch, contact with linen, water, or wind)

TABLE 46–1 Comparison of Acute and Chronic Pain

Acute Pain	Chronic Pain
Mild to severe	Mild to severe
Sympathetic nervous system responses:	Parasympathetic nervous system responses:
<ul style="list-style-type: none"> • Increased pulse rate • Increased respiratory rate • Elevated blood pressure • Diaphoresis • Dilated pupils 	<ul style="list-style-type: none"> • Vital signs normal • Dry, warm skin • Pupils normal or dilated
Related to tissue injury; resolves with healing	Continues beyond healing
Client may be restless and anxious	Client is usually depressed and withdrawn
Client reports pain	Client often does not mention pain unless asked
Client may exhibit behavior indicative of pain: crying, rubbing area, holding area	Pain behavior often absent

CLINICAL MANIFESTATIONS

Common Chronic Pain Syndromes

- *Post-herpetic neuralgia.* This condition, which currently affects 2 million Americans, occurs when a case of herpes zoster (shingles) typically erupts decades after a primary infection (chickenpox) during a period of stress or compromised immune functioning. After the painful unilateral vesicular rash fades, burning or electric-shock pain in the area may persist for months or years. Advancing age is a risk factor for persistent post-herpetic neuralgia. A vaccine has been approved and is recommended for all people over the age of 60 to prevent shingles and the possibility of post-herpetic neuralgia.
- *Phantom pain.* Phantom sensations, the feeling that a lost body part is present, occur in most people after amputation. For many, this sensation is painful and it may occur spontaneously, or is evoked (e.g., by a poor-fitting prosthesis). When the amputation involves a limb, it is termed *phantom limb pain*, whereas following breast surgery, it is called *postmastectomy pain*. If the limb was painful or mangled before the amputation, that is commonly the sensation that is experienced (unless the discomfort is completely relieved prior to surgery). It is important for the nurse to remember to explain the reasons for phantom limb pain, as clients may have difficulty understanding why they have pain when the limb is gone. They may start to question their sanity.
- *Trigeminal neuralgia.* This is an intense stablike pain that is distributed by one or more branches of the trigeminal nerve (fifth cranial). The pain is usually experienced on parts of the face and head. It is so severe that it produces facial muscle spasms.
- *Headache.* An estimated 40% of the worldwide population suffers at least one severe, disabling headache per year. This commonly occurring painful condition can be caused by either intracranial or extracranial problems, serious or benign conditions. To establish a plan to prevent or treat headache, the nurse needs to assess the quality, location, onset, duration, and frequency of the pain, as well as any signs and symptoms that precede the headache. There are many types of headaches, but the three most common include migraine, tension type, and cluster. Migraine and tension-type headaches are three times more common in women than in men, while cluster headaches occur primarily in men.
- *Low back pain.* Nearly everyone suffers from low back pain at some time during their lives. Most occurrences of low back pain go away within a few days. Chronic back pain persists for more than 3 months. It is often progressive and the cause can be difficult to determine.
- *Fibromyalgia.* An estimated 5 million Americans suffer from a condition known as fibromyalgia, a chronic disorder characterized by widespread musculoskeletal pain, fatigue, and multiple tender points. This disease is poorly understood and primarily occurs in women. “Tender points” refers to tenderness that occurs in precise, localized areas, particularly in the neck, spine, shoulders, and hips. People with this syndrome may also experience sleep disturbances, morning stiffness, irritable bowel syndrome, anxiety, and other symptoms. Although the symptoms present as muscle pain, stiffness, and weakness, it is considered by many to be a problem of abnormal CNS functioning, particularly as it relates to the way nerves process pain.

that produces pain. **Dysesthesia** is an unpleasant abnormal sensation. Dysesthesia mimics or imitates the pathology of a central neuropathic pain disorder, such as the pain that follows a stroke or spinal cord injury. See Box 46–1 for a review of concepts associated with pain.

PHYSIOLOGY OF PAIN

The transmission and perception of pain are complex processes. The central nervous system's structure constantly changes, and the constituency and function of its chemical mediators are not well understood. The extent to which pain is perceived depends on the

interaction between the body's analgesia system, the nervous system's transmission, and the mind's interpretation of stimuli and its meaning.

Nociception

The peripheral nervous system includes specialized primary sensory neurons that detect mechanical, thermal, or chemical conditions associated with potential tissue damage. When these nociceptors are activated, signals are transduced and transmitted to the spine and brain where the signals are modified before they are ultimately

BOX 46–1 Concepts Associated with Pain

Acute pain: Pain that is directly related to tissue injury and resolves when tissue heals.

Cancer pain: Pain associated with the disease, treatment, or some other factor in individuals with cancer.

Chronic or persistent pain: Pain that persists beyond 3 to 6 months secondary to chronic disorders or nerve malfunctions that produce ongoing pain after healing is complete.

Intractable pain: A pain state (generally severe) for which no cure is possible even after accepted medical evaluation and treatments have been implemented. The focus of treatment turns from cure to pain reduction, functional improvement, and the enhancement of quality of life.

Neuropathic pain: Pain that is related to damaged or malfunctioning nervous tissue in the peripheral and/or CNS.

Nociceptive pain: Pain that is directly related to tissue damage. May be somatic (e.g., damage to skin, muscle, bone) or visceral (e.g., damage to organs).

Pain threshold: The least amount of stimuli necessary for a person to label a sensation as pain.

Pain tolerance: The most pain an individual is willing or able to tolerate before taking evasive actions.

The following states indicate abnormal nerve functioning, and the associated cause needs to be identified/treated (as soon as possible) before irreversible damage occurs:

Allodynia: Sensation of pain from a stimulus that normally does not produce pain (e.g., light touch).

Dysesthesia: An unpleasant abnormal sensation that can be either spontaneous or evoked.

Hyperalgesia: Increased sensation of pain in response to a normally painful stimulus.

The following concepts are important reasons to prevent pain or treat it as soon as possible to prevent the amplification, spread, and persistence of pain:

Sensitization: An increased sensitivity of a receptor after repeated activation by noxious stimuli.

Windup: Progressive increase in excitability and sensitivity of spinal cord neurons, leading to persistent, increased pain.

TABLE 46–2 Types of Pain Stimuli

Stimulus Type	Physiological Basis of Pain
MECHANICAL	
1. Trauma to body tissues (e.g., surgery)	Tissue damage; direct irritation of the pain receptors; inflammation
2. Alterations in body tissues (e.g., edema)	Pressure on pain receptors
3. Blockage of a body duct	Distention of the lumen of the duct
4. Tumor	Pressure on pain receptors; irritation of nerve endings
5. Muscle spasm	Stimulation of pain receptors (also see chemical stimuli)
THERMAL	
Extreme heat or cold (e.g., burns)	Tissue destruction; stimulation of thermosensitive pain receptors
CHEMICAL	
1. Tissue ischemia (e.g., blocked coronary artery)	Stimulation of pain receptors because of accumulated lactic acid (and other chemicals, such as bradykinin and enzymes) in tissues
2. Muscle spasm	Tissue ischemia secondary to mechanical stimulation (see above)

understood and then “felt.” The physiological processes related to pain perception are described as **nociception**. Four physiological processes are involved in nociception: transduction, transmission, perception, and modulation.

TRANSDUCTION

Specialized pain receptors or **nociceptors** can be excited by mechanical, thermal, or chemical stimuli (Table 46–2). During the transduction phase, harmful stimuli trigger the release of biochemical mediators, such as prostaglandins, bradykinin, serotonin, histamine, and substance P, which sensitize nociceptors. Painful stimulation also causes movement of ions across cell membranes, which excites nociceptors. Pain medications can work during this phase by blocking the production of prostaglandin (e.g., ibuprofen or aspirin) or by decreasing the movement of ions across the cell membrane (e.g., local anesthetic). Another example is the topical analgesic capsaicin (Zostrix), which depletes the accumulation of substance P and blocks transduction.

TRANSMISSION

The second process of nociception, transmission of pain, includes three segments. During the first segment of transmission, the pain impulses travel from the peripheral nerve fibers to the spinal cord. Substance P serves as a neurotransmitter, enhancing the movement of impulses across the nerve synapse from the primary afferent neuron to the second-order neuron in the dorsal horn of the spinal cord (Figure 46–2 ■). Two types of nociceptor fibers cause this transmission to the dorsal horn of the spinal cord: unmyelinated C fibers, which transmit dull, aching pain, and thin A-delta fibers, which transmit sharp, localized pain. The second segment is transmission of the pain signal through an ascending pathway in the spinal cord to the brain (Figure 46–3 ■). The third segment involves transmission of information to the brain where pain perception occurs.

Pain control can take place during this second process of transmission. For example, opioids (narcotic analgesics) block the release of neurotransmitters, particularly substance P, which stops the pain at the spinal level. Capsaicin may also deplete substance P, which could inhibit the transmission of pain signals.

Figure 46–2 ■ Substance P assists the transmission of impulses across the synapse from the primary afferent neuron to a second-order neuron in the spinothalamic tract.

PERCEPTION

The third process, perception, is when the client becomes conscious of the pain. Pain perception is the sum of complex activities in the CNS that may shape the character and intensity of pain perceived and give meaning to the pain. The psychosocial context of the situation and the meaning of the pain based on past experiences and future hopes and dreams help to shape the behavioral response that follows. Cognitive-behavioral therapy and approaches such as distraction and imagery have been developed based on evidence that brain processes can influence pain perception (Pasero & McCaffery, 2011, p. 6).

MODULATION

Often described as the “descending system,” this final process occurs when neurons in the brain send signals back down to the dorsal horn of the spinal cord. These descending fibers release substances such as endogenous opioids, serotonin, and norepinephrine, which can inhibit or reduce the ascending painful impulses in the dorsal horn. In contrast, excitatory amino acids (e.g., glutamate, N-methyl-D-aspartate [NMDA]), can increase these pain signals. The effects of excitatory amino acids tend to persist, while the effects of the inhibitory neurotransmitters (endogenous opioids, serotonin, and norepinephrine) tend to be short lived because they are reabsorbed into the nerves. Tricyclic antidepressants can relieve pain by blocking the reuptake (resorption) of norepinephrine and serotonin, making them

Figure 46-3 ■ Physiology of pain perception. Pain processing involves the ascending (in red) and descending (in blue) pathways.

more available to fight pain; or NMDA antagonists (e.g., ketamine, dextromethorphan) may be used to help diminish the pain signals.

Gate Control Theory

According to Melzack and Wall's gate control theory (1965), small-diameter (A-delta or C) peripheral nerve fibers carry signals of noxious (painful) stimuli to the dorsal horn, where these signals are modified when they are exposed to the substantia gelatinosa (the milieu in the CNS), which may be imbalanced in an excitatory or inhibitory direction. Ion channels on the pre- and postsynaptic membranes serve as gates that, when open, permit positively charged ions to rush into the second-order neuron, sparking an electrical impulse and sending pain signals to the thalamus.

Peripherally, large-diameter (A-beta) nerve fibers, which typically send messages of touch or warm or cold temperatures, have an inhibitory effect on the substantia gelatinosa, and may activate descending mechanisms that can lessen the intensity of pain perceived or inhibit the transmission of those pain impulses—closing the (ion) gates (Figure 46-4 ■).

Higher centers in the brain, especially those associated with affect and motivation, are capable of modifying the substantia gelatinosa, which influences the opening or closing of the gates. For

Figure 46-4 ■ A schematic illustration of the gate control theory.

example, if a little girl is playing with a ball that rolls under the couch, and in the process of retrieving it her hand gets stuck and pinched (the A-delta fibers are activated), the anxiety of not knowing what to do, combined with the negative impact on motivation (not being able to play with the ball), excites the substantia gelatinosa and facilitates opening the gates transmitting messages of pinching pain. When her mother comes and frees her and “kisses her boo-boo,” the A-delta fibers are activated by the light touch, moisture, and warmth of the kiss. The girl feels love and is motivated to please her mother, all of which combine to calm the substantia gelatinosa and close the gates, inhibiting the transmission of further pain. Clinically, nurses can use this model to stop nociceptor firing (treat the underlying cause), apply topical therapies (e.g., heat, ice, electrical stimulation, or massage), and address the client’s mood (e.g., reduce fear, anxiety, and anger) and goals (e.g., client education, anticipatory guidance).

Responses to Pain

The body’s response to pain is a complex process rather than a specific action. It has both physiological and psychosocial aspects. Initially the sympathetic nervous system responds, resulting in the fight-or-flight response, with a noticeable increase in pulse and blood pressure. The person may hold his or her breath, or have short, shallow breathing. There may also be some reflexive movements as the person withdraws from the painful stimuli (Figure 46–5 ■). Over a matter of minutes, or hours, the pulse and blood pressure return to baseline despite the persistence of pain. Contrary to the adaptation noted in vital signs, the pain fibers themselves adapt very little and become sensitized in a way that intensifies, prolongs, and/or spreads the pain.

Unrelieved pain has been noted to have a potentially harmful effect on a person’s well-being. Pain interferes with sleep, affects

appetite, and lowers the quality of life for clients and their family members. A natural response to pain is to stop activity, tense muscles, and withdraw from the pain-provoking activities. This reduced mobility may produce muscle atrophy and painful spasm, putting the client at risk of complications related to immobility or cardiopulmonary deconditioning. Uncontrolled pain impairs immune function, which slows healing and increases susceptibility to infections and dermal ulcers. The short, shallow breathing that accompanies pain produces atelectasis, lowers circulating oxygen levels, and increases cardiac workload. The physical stress and emotional distress of severe or prolonged pain can contribute to the development of a wide variety of physical and emotional disorders.

Persistent, severe pain changes the nervous system in a way that intensifies, spreads, and prolongs the pain, risking the development of incurable chronic pain syndromes. Beginning at 24 hours, persistent unrelieved severe pain changes the structure and function of the nervous system in a way that prolongs and intensifies the pain experience. A windup phenomenon occurs. This phenomenon is the result of repeated pain signals that cause stronger and longer responses in the CNS (Arnstein, 2010). The windup causes even normal tissue to become extremely sensitive to pressure in areas that are not identified as painful. Thus to prevent the development of persistent pain and promote overall health and well-being, the nurse must act to promote optimal and expedient pain control.

FACTORS AFFECTING THE PAIN EXPERIENCE

Numerous factors can affect a person’s perception of and reaction to pain. These include the person’s ethnic and cultural values, developmental stage, environment and support people, previous pain experiences, and the meaning of the current pain.

Ethnic and Cultural Values

Ethnic background and cultural heritage have long been recognized as factors that influence both a person’s reaction to pain and the expression of that pain. Behavior related to pain is a part of the socialization process. Individuals in one culture may learn to be expressive about pain, whereas individuals from another culture may have learned to keep those feelings to themselves.

Although there appears to be little variation in pain threshold, cultural background can affect the level of pain that an individual is willing to tolerate. In some Middle Eastern and African cultures, self-infliction of pain is a sign of mourning or grief. In other groups, pain may be anticipated as part of the ritualistic practices, and therefore tolerance of pain signifies strength and endurance. Additionally, there are significant variations in the expression of pain. Studies have shown that individuals of northern European descent tend to be more stoic and less expressive of their pain than individuals from southern European backgrounds.

Nurses must realize their own attitudes and expectations about pain. For example, Pasero and McCaffery (2011) reported that in a large study of clients ($n = 374,891$) admitted to the emergency department with similar pain reports, Caucasian clients were more likely to receive opioids than African American, Hispanic, Asians, and other clients (p. 160). This may be because of a hidden bias that nurses are not aware of at a conscious level. Nurses who deny, refute, or downplay the pain they observe in others may be culturally incompetent

Figure 46–5 ■ Proprioceptive reflex to a pain stimulus.

Culturally Responsive Care

PATIENT-CENTERED CARE

Transcultural Differences in Responses to Pain

Expressions of pain vary from culture to culture and may vary from person to person within a culture. Treat each client as an individual and provide the type of pain relief that is the best fit for the client.

AFRICAN AMERICANS

- Some believe pain and suffering is a part of life and is to be endured.
- Some may deny or avoid dealing with pain until it becomes unbearable.
- Some believe that prayer and laying on of hands will free a person from suffering and pain.

HISPANIC/LATINO

- Mexican Americans may tend to view pain as a part of life and as an indicator of the seriousness of an illness.
- Some believe that enduring pain is a sign of strength.
- Puerto Ricans may tend to be loud and outspoken in their expressions of pain. This is a socially learned way to cope and it is important for the nurse to not judge or disapprove.

ASIANS AMERICANS

- Chinese culture values silence. As a result, some clients may be quiet when in pain because they do not want to cause dishonor to themselves and their family. Therefore, offer pain medications frequently because they generally agree to the use of pain medications, but may be afraid to ask for them.
- Japanese may have a stoic (minimal verbal and nonverbal expressions) response to pain. They may even refuse pain

medication. Bearing pain is considered a virtue and a matter of family honor.

- Filipino clients may believe that pain is “God’s will” and therefore to be endured, not expressed. Some older Filipino clients may refuse pain medication.
- If the client is a Buddhist, remaining calm when in pain is viewed as bringing oneself to a higher state of being.

NATIVE AMERICANS

- In general, Native Americans are quiet, less expressive verbally and nonverbally, and may tolerate a high level of pain. They tend to not request pain medication and may tolerate pain until they are physically disabled.

ARAB AMERICANS

- Pain is regarded as unpleasant and they anticipate immediate relief from their symptoms. Expressive emotional and vocal responses to pain are reserved for immediate family, not for health professionals. As a result, this may lead to conflicting perceptions among the family members and the nurse regarding the effectiveness of the client’s pain relief. For example, the nurse may believe the client has adequate pain management, whereas the family is requesting additional pain medication for their family member.

From *Transcultural Health Care: A Culturally Competent Approach*, 4th ed. (pp. 109, 173, 193, 246, 387, 423), by L. D. Purnell, 2013, Philadelphia, PA: F.A. Davis; and *Pocket Guide to Culturally Sensitive Health Care*, (pp. 12, 27, 123, 136, 157) by B. Stuart, C. Cherry, & J. Stuart, 2011, Philadelphia, PA: F.A. Davis.

(unaware and emotionally apathetic toward others’ viewpoints). To become culturally competent, nurses must become knowledgeable about differences in the meaning of and appropriate responses to pain. They must be sympathetic to concerns and develop the skills needed to address pain in a culturally sensitive way.

Developmental Stage

The age and developmental stage of a client is an important variable that will influence both the reaction to and the expression of pain. Age variations and related nursing interventions are presented in Table 46–3.

The field of pain management for infants and children has grown significantly. It is now accepted that anatomic, physiological, and biochemical elements necessary for pain transmission are present in newborns, regardless of their gestational age. For many years, the myth of infants and children not “feeling” pain has prevailed. Now, it is universally accepted that environmental, nonpharmacologic, and pharmacologic interventions are to be used to prevent, reduce, or eliminate pain in neonates. Physiological indicators may vary in infants, so behavioral observation is recommended for pain assessment. Children may be less able than an adult to articulate their experience or needs related to pain, which may result in their pain being undertreated. However, children as young as 3 years, if evaluated properly, can accurately report the location and intensity of their pain.

With puberty comes the emergence of some pain syndromes, particularly in young women. Unfortunately, women are overrepresented in a large number of painful disorders, including headaches, fibromyalgia, lupus, and menstrual-related disorders. Men are more vulnerable to pain related to their occupational or

risk-taking patterns, including burn pain, post-trauma pain, and pain related to HIV/AIDS. A needless disparity continues that the very young, the very old, women, and ethnic minorities are undertreated for their pain more frequently than their adult male counterparts. Studies report that racial disparities in pain and health exist (Narayan, 2010).

Studies have shown that 57% of older adults living in the United States often experience pain, with 35% to 48% of community-dwelling older adults experiencing daily pain (Tabloski & Connell, 2014, p. 211). With the number of older individuals in our society increasing dramatically, by 2030, nurses will be caring for older adults in all settings of care in greater numbers.

Older adults constitute the largest group of individuals seeking health care services. The prevalence of pain in the older population is generally higher due to both acute and chronic disease conditions. Pain threshold does not appear to change with aging, although the effect of analgesics may increase due to physiological changes related to drug metabolism and excretion (Arnstein, 2010).

Environment and Support People

A strange environment such as a hospital, with its noises, lights, and activity, can compound pain. In addition, the lonely person who is without a support network may perceive pain as severe, whereas the person who has supportive people around may perceive less pain. Some people prefer to withdraw when they are in pain, whereas others prefer the distraction of people and activity around them. Family caregivers can provide significant support to a person in pain. With the increase in outpatient and home care, families are assuming an increased responsibility for the management of pain. Education related to the assessment and management of pain can

TABLE 46–3 Age Variations in the Pain Experience

Age Group	Pain Perception and Behavior	Selected Nursing Interventions
Infant	Perceives pain. Responds to pain with increased sensitivity. Older infant tries to avoid pain; for example, turns away and physically resists.	Give a glucose pacifier. Use tactile stimulation. Play music or tapes of a heartbeat.
Toddler and preschooler	Develops the ability to describe pain and its intensity and location. Often responds with crying and anger because child perceives pain as a threat to security. Reasoning with child at this stage is not always successful. May consider pain a punishment. Feels sad. May learn there are gender differences in pain expression. Tends to hold someone accountable for the pain.	Distract the child with toys, books, pictures. Involve the child in blowing bubbles as a way of “blowing away the pain.” Appeal to the child’s belief in magic by using a “magic” blanket or glove to take away pain. Hold the child to provide comfort. Explore misconceptions about pain.
School-age child	Tries to be brave when facing pain. Rationalizes in an attempt to explain the pain. Responsive to explanations. Can usually identify the location and describe the pain. With persistent pain, may regress to an earlier stage of development.	Use imagery to turn off “pain switches.” Provide a behavioral rehearsal of what to expect and how it will look and feel. Provide support and nurturing.
Adolescent	May be slow to acknowledge pain. Recognizing pain or “giving in” may be considered weakness. Wants to appear brave in front of peers and not report pain.	Provide opportunities to discuss pain. Provide privacy. Present choices for dealing with pain. Encourage music or TV for distraction.
Adult	Behaviors exhibited when experiencing pain may be gender-based behaviors learned as a child. May ignore pain because to admit it is perceived as a sign of weakness or failure. Fear of what pain means may prevent some adults from taking action.	Deal with any misconceptions about pain. Focus on the client’s control in dealing with the pain. Allay fears and anxiety when possible.
Older Adult	May have multiple conditions presenting with vague symptoms. May perceive pain as part of the aging process. May have decreased sensations or perceptions of the pain. Lethargy, anorexia, and fatigue may be indicators of pain. May withhold statements of pain because of fear of the treatment, of any lifestyle changes that may be involved, or of becoming dependent. May describe pain differently, that is, as “ache,” “hurt,” or “discomfort.” May consider it unacceptable to admit or show pain.	Take a thorough history and assessment. Spend time with the client and listen carefully. Clarify misconceptions. Encourage independence whenever possible.

positively affect the perceived quality of life for both clients and their caregivers.

Expectations of significant others can affect a person’s perceptions of and responses to pain. In some situations girls may be permitted to express pain more openly than boys. Family role can also affect how a person perceives or responds to pain. For instance, a single mother supporting three children may ignore pain because of her need to stay on the job. The presence of support people often modifies a client’s reaction to pain. For example, toddlers often tolerate pain more readily when supportive parents or nurses are nearby.

Previous Pain Experiences

Previous pain experiences alter a client’s sensitivity to pain. People who have personally experienced pain or who have been exposed to the suffering of someone close to them are often more threatened by anticipated pain than people without a pain experience. In addition, the success or lack of success of pain relief measures influences a person’s expectations for relief and future response to interventions. For example, a person who has tried several nondrug pain relief measures without success may have little hope about the helpfulness of nursing interventions and may demand medication as the only thing that helps the pain.

LIFESPAN CONSIDERATIONS Pain

CHILDREN

Children continue to receive inadequate medication to treat their pain. This may be due to nurses' lack of knowledge about how to evaluate pain in children. The pain of infants and young children who cannot verbalize well is particularly difficult to assess. Nurses will benefit from learning how to use pain assessment tools and by being alert to the possibility that children may be experiencing significant levels of pain, even if they do not appear to be in pain.

OLDER ADULTS

The presentation of pain may vary in older adults for a variety of reasons. Changes in nerve structure and functioning or vascular changes with aging may cause a variation in the pain sensation. Sometimes the pain is heightened in those whose nervous systems have been sensitized from previous unresolved pain, whereas at other times significant tissue damage (e.g., silent heart attack) may occur without pain being experienced. In some situations, pain presents itself with atypical symptoms, such as confusion, restlessness, or irritability. This is especially true in clients with dementia who have a difficult time understanding and verbalizing what they are feeling.

Maintaining optimal function is especially crucial for a high quality of life in older clients. If pain is not effectively controlled, the following areas are often affected in their daily lives:

- Activity tolerance
- Mobility
- Ability to socialize

- Sleep disturbance
- Ability to perform ADLs
- Ability to remain as independent as possible.

All efforts, pharmacologic and nonpharmacologic, should be used to help provide pain reduction, while maintaining or enhancing functional ability. Involvement of the client and family is important when working with the primary care provider, pharmacist, and nurse to plan which treatment is most appropriate and most acceptable to the client.

The principle “start low and go slow” is especially important when ordering dosages and pain medications for older adults. Typically, the starting dose of medicines for older adults is reduced by 25% to 50%, and then titrated for effect. Decreased renal and liver function may prolong the duration of action, but it also increases the risk of toxicity from pain medications in older clients. In particular, risk of silent gastrointestinal bleeding and renal damage from nonsteroidal anti-inflammatory drugs (NSAIDs) increases, so dosages and lab work need to be carefully monitored related to hematocrit and renal function (liver function is monitored with acetaminophen). Comorbid conditions may also affect medication selection in older adults; for example, clients with gastric ulcers, hypertension, or the combination of asthma and nasal polyps should not receive NSAIDs. Older adults with chronic obstructive pulmonary disease (COPD) must have their respiratory rate carefully monitored when placed on an opioid pain reliever, especially at night when respirations slow and the risk of oxygen desaturation is high.

Meaning of Pain

Some clients may accept pain more readily than others, depending on the circumstances and the client's interpretation of its significance. A client who associates the pain with a positive outcome may withstand the pain amazingly well. For example, a woman giving birth to a child or an athlete undergoing knee surgery to prolong his career may tolerate pain better because of the benefit associated with it. These clients may view the pain as a temporary inconvenience rather than a potential threat or disruption to daily life.

By contrast, clients with unrelenting chronic, persistent pain may suffer more intensely. Persistent pain affects the body, mind, spirit, and social relationships in an undesirable way. Physically, the pain limits functioning and contributes to the disuse or deconditioning alluded to previously. For many, the change in activities of daily living (ADLs), such as eating, sleeping, toileting, also takes a toll. The side effects of the many medications used to try to control the pain also place a heavy burden on the body.

Mentally, individuals with chronic pain change their outlook, becoming more pessimistic, often to the point of helplessness and hopelessness. Mood often becomes impaired when pain persists, because the sadness of being unable to do important or enjoyable activities combines with self-doubts and learned helplessness to produce depression. Anxiety, worry, and uncertainty about coping with the pain may escalate emotionally, to the point of panic. Spiritually, pain may be viewed in a variety of ways. It may be perceived as a punishment for wrongdoing, a betrayal by the higher power, a test of fortitude, or a threat to the essence of who the person is. Pain may be a source of spiritual distress, or it may be a source of strength and enlightenment. Socially, pain often strains valued relationships, in part because of the impaired ability to fulfill role expectations.

●○○ NURSING MANAGEMENT**Assessing**

Accurate pain assessment is essential for effective pain management. Many health facilities make pain assessment the **fifth vital sign**. This strategy of linking pain assessment to routine vital sign assessment and documentation represents a push to make pain assessment a routine aspect of care for all clients. Given the highly subjective and individually unique nature of pain, a comprehensive assessment of the pain experience (physiological, psychological, behavioral, emotional, and sociocultural) provides the necessary foundation for optimal pain control.

The extent and frequency of the pain assessment varies according to the situation and the organizational policy. For clients experiencing acute, severe pain, the nurse may focus only on location, quality, and severity, and provide interventions to control the pain before conducting a more detailed evaluation. Clients with less severe or chronic pain can usually provide a more detailed description of the experience. As the fifth vital sign, pain should be screened for every time vital signs are evaluated. A simple screening question such as “Are you experiencing any discomfort right now?” will usually suffice. For example, in the initial postoperative period, vital signs are taken as frequently as every 15 minutes. Screening for pain this frequently is justifiable because there is a high incidence of pain in the perioperative period. Local, regional, or general anesthesia may be wearing off, or if severe pain is reported, the medication administered postoperatively is frequently administered via the intravenous (IV) route and has a peak effect noted within 15 minutes.

Major barriers to better pain control for both nurses and clients relate to failure to assess pain, underestimation of pain, failure

BOX 46-2

Why Clients May Be Reluctant to Report Pain

- Unwillingness to trouble staff who are perceived as busy
- Do not want to be labeled as a “complainer” or “bad”
- Fear of the injectable route of analgesic administration—especially children
- Belief that unrelieved pain is an expected, normal part of recovery or aging
- Belief that others will think they are weak if they express pain
- Difficulty or inability to communicate their discomfort
- Concern about risks associated with opioid drugs (e.g., addiction)
- Concern about unwanted side effects, especially of opioid drugs
- Concern that use of drugs now will render the drug inefficient later in life
- Fear that reporting pain will lead to further tests and expenses
- Belief that nothing can be done to control pain
- Belief that enduring pain and suffering may lead to spiritual enlightenment
- Culture affects behavioral responses to pain and treatment preferences (e.g., some cultures are comfortable expressing pain while others are stoic and are not comfortable expressing or reporting pain)

to accept the client's report of pain, failure to act on the client's report of pain, and concerns about addiction (Pasero & McCaffery, 2011). Given that many clients will not voice their pain unless asked about it, pain assessments *must* be initiated by the nurse. Some of the many reasons clients may be reluctant to report pain are listed in Box 46-2. Because the words *pain* or *complain* may have emotional or sociocultural meaning attached, it is better to ask “Do you have any discomfort to report?” rather than “Do you have any complaints of pain?” It is also essential that nurses listen to and believe the client's statements of pain. Believing the client's statement is crucial in establishing the sense of trust needed to develop a therapeutic relationship.

Pain assessments consist of two major components: (a) a pain history to obtain facts from the client and (b) direct observation of behaviors, physical signs of tissue damage, and secondary physiological responses of the client. The goal of assessment is to gain an objective understanding of a subjective experience.

Pain History

While taking a pain history, the nurse must provide an opportunity for clients to express in their own words how they view the pain and the situation. This will help the nurse understand what the pain means to the client and how the client is coping with it. Remember that each person's pain experience is unique and that the client is the best interpreter of the pain experience. This history should be geared to the specific client. For example, questions asked of a car crash victim would be different from those asked of a postoperative client or someone suffering from chronic pain. The initial pain assessment for someone in severe acute pain may consist of only a few questions before intervention occurs. In addition, the nurse should focus on the following:

- Previous pain treatment and effectiveness
- When and what analgesics were last taken
- Other medications being taken
- Allergies to medications.

For the person with chronic pain, the nurse may focus on the client's coping mechanisms, effectiveness of current pain management, and ways in which the pain has affected the client's body, thoughts and feelings, activities, and relationships.

Data that should be obtained in a comprehensive pain history include pain location, intensity, quality, patterns, precipitating factors, alleviating factors, associated symptoms, effect on ADLs, coping resources, and affective responses. Other data include past pain experiences and the meaning of pain to the client, as previously discussed. Questions to elicit these data are shown in the Assessment Interview.

ASSESSMENT INTERVIEW Pain History

- *Location:* Where is your discomfort?
- *Quality:* Tell me what your discomfort feels like.
- *Intensity:* On a scale of 0 to 10, with “0” representing no pain (substitute the term client uses, e.g., “no burning”) and “10” representing the worst possible pain (e.g., “burning sensation”), how would you rate the degree of discomfort you are having right now?
- *Pattern*
 - a. *Time of onset:* When did or does the pain start?
 - b. *Duration:* How long have you had it, or how long does it usually last?
 - c. *Constancy:* Do you have pain-free periods? When? And for how long?
- *Precipitating factors:* What triggers the pain or makes it worse?
- *Alleviating factors:* What measures or methods have you found helpful in reducing or relieving the pain? What pain medications do you use?
- *Associated symptoms:* Do you have any other symptoms (e.g., nausea, dizziness, blurred vision, shortness of breath) before, during, or after your pain?
- *Effects on ADLs:* How does the pain affect your daily life (e.g., eating, working, sleeping, and social and recreational activities)?
- *Past pain experiences:* Tell me about past pain experiences you have had and what was done to relieve the pain.
- *Meaning of pain:* What does having this pain mean to you? Does it signal something about the future or past? What worries or scares you the most about your pain?
- *Coping resources:* What do you usually do to help you deal with pain?
- *Affective response:* How does the pain make you feel? Anxious? Depressed? Frightened? Tired? Burdensome?

Location

To ascertain the specific location of the pain, ask the client to point to the site of the discomfort. A chart consisting of drawings of the body can assist in identifying pain locations. The client marks the location of pain on the chart. This tool can be especially effective with clients who have more than one source of pain. A client who has multiple pain sites of different character can use symbols to draw the distribution of different pain types (e.g., circle aching areas, mark areas where shock-like pain is felt with an X).

When assessing the location of a child's pain, the nurse needs to understand the child's vocabulary. For example, "tummy" might refer either to the abdomen or to part of the chest. Asking the child to point to the pain helps clarify the child's word usage to identify location. The use of figure drawings can assist in identifying pain locations. Parents can also be helpful in interpreting the meaning of a child's words.

When documenting pain location the nurse may use various body landmarks. Further clarification is possible with the use of terms such as *proximal*, *distal*, *medial*, *lateral*, and *diffuse*.

Pain Intensity or Rating Scales

The single most important indicator of the existence and intensity of pain is the client's report of pain. In practice, nurses tend to use less reliable measures for pain assessment such as changes in vital signs and observation of client behaviors that they interpret as drug seeking (D'Arcy, 2011). Pain assessment that is not done accurately or completely leads to undertreatment of pain. The use of pain intensity scales is an easy and reliable method of determining the client's pain intensity. Such scales provide consistency for nurses to communicate with the client (adults and children over the age of 7) and other health care providers. To avoid confusion, numerical rating scales (NRS) should use a 0-to-10 range with 0 indicating "no pain" and 10 indicating the "worst pain possible" for that individual. An 11-point (0–10) rating scale is shown in Figure 46–6 ■. The inclusion of word modifiers on the scale can assist some clients who find it difficult to apply a number level to their pain. For example, after ruling out "0" and "10" (neither no pain nor the worst possible pain), a nurse can ask the client if it is mild (ratings in the 1–3 range), moderate (ratings in the 4–6 range), or severe (ratings in the 7–9 range).

Another way to evaluate the intensity of pain for clients who are unable to use the numeric rating scales is to determine the extent of pain awareness and degree of interference with functioning. For example, 0 = no pain; 2 = awareness of pain only when paying attention to it; 4 = can ignore pain and do things; 6 = cannot ignore pain, interferes with functioning; 8 = impairs ability to function or concentrate; and 10 = intense incapacitating pain. It is believed that the degree to which pain interferes with functioning is a good marker for the severity of pain, especially for those with chronic pain.

CLINICAL ALERT!

Perception is reality. The client's self-report of pain is what must be used to determine pain intensity. The nurse is obligated to record the pain intensity as reported by the client. By challenging the believability of the client's report, the nurse is undermining the therapeutic relationship and preventing the fulfillment of advocacy and helping people with pain, which is called for in the ANA's Standards of Professional Performance for Pain Management Nursing.

Figure 46–6 ■ An 11-point pain intensity scale with word modifiers.

When noting pain intensity it is important to determine any related factors that may be affecting the pain. When the intensity changes, the nurse needs to consider the possible cause. For example, the abrupt cessation of acute abdominal pain may indicate a ruptured appendix. Several factors affect the perception of intensity: (a) the amount of distraction, or the client's concentration on another event; (b) the client's state of consciousness; (c) the level of activity; and (d) the client's expectations.

Not all clients understand or relate to numerical pain intensity scales. These include preverbal children, older adults with impairments in cognition or communication, and people who do not speak English. For these clients the Wong-Baker FACES Rating Scale (Figure 46–7 ■) may be easier to use. The FACES scale includes a number scale along with an illustrated facial expression so that the pain intensity can be documented. When using the FACES rating scale, it is important to remember that the client's facial expression does not need to match the picture. The client points to the picture that represents how much pain the client is experiencing.

Pain scales have been developed for use when assessing clients with chronic pain. These scales include a numeric intensity rating and other aspects of chronic pain, such as verbal descriptors, pictures for the clients to draw the pain they are experiencing, and indicators of mood (D'Arcy, 2011). Two commonly used pain scales are the Brief Pain Inventory (BPI) and the Short Form McGill Pain Questionnaire (SF-MPQ).

When clients are unable to verbalize their pain for reasons of age, mental capacity, medical interventions, or other reasons, nurses need to accurately assess the intensity of each client's pain and the effectiveness of the pain management interventions. For these clients, the nurse must rely on observation of behavior.

Several validated behavioral pain rating scales are useful in specific populations. The FLACC scale has been validated in children 2 months to 7 years old and rates pain behaviors as manifested by Facial expressions, Leg movement, Activity, Cry, and Consolability measures that yield a score of 0 to 10. A scale specifically designed for older adults with advanced dementia is PAINAD. This scale looks at five specific indicators: breathing, vocalization, facial expression, body language, and consolability (D'Arcy, 2011; Pasero & McCaffery, 2011). Given the diversity of pain and behaviors among clients spanning a broad range of age and physical and mental capabilities, it is unrealistic to believe a single pain assessment tool can be applied across all populations. The pain scale needs to fit the client being assessed.

For effective use of pain rating scales, clients need not only to understand the use of the scale but also to be educated about how the information will be used to determine changes in their condition and the effectiveness of pain management interventions. Clients should also be asked to indicate what level of comfort is acceptable

Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain. Face 0 is very happy because he doesn't hurt at all. Face 1 hurts just a little bit. Face 2 hurts a little more. Face 3 hurts even more. Face 4 hurts a whole lot. Face 5 hurts as much as you can imagine, although you don't have to be crying to feel this bad. Ask the person to choose the face that best describes how he is feeling.

Rating scale is recommended for persons age 3 years and older.

Brief word instructions: Point to each face using the words to describe the pain intensity. Ask the child to choose the face that best describes own pain and record the appropriate number.

so that they can perform specific activities. To align the client's goals and expectations with reality, it is important to note that acute pain can typically be decreased by 50% and chronic pain can be decreased by 25%. To ensure that optimal pain management is achieved, the client works together with professionals toward established goals of pain reduction and functional improvement.

The use of a pain numerical rating scale together with a faces pain flow sheet has been shown to be effective in improving pain management (McCaffery & Pasero, 2011). Documentation can be

completed by the nurse, the client, or a caregiver. A rating scale can be used in acute, outpatient, and home care settings. See Figure 46-8 ■ for an example of a pain documentation form in an electronic health record (EHR).

Pain Quality

Descriptive adjectives help people communicate the quality of pain. A headache may be described as "unbearable" or an abdominal pain as "piercing like a knife." The astute clinician can collect subtle

TABLE 46-4 Commonly Used Pain Descriptors

Term	Sensory Words	Affective Words
Pain	Searing	Unbearable
	Scalding	Killing
	Sharp	Intense
	Piercing	Torturing
	Drilling	Agonizing
	Wrenching	Terrifying
	Shooting	Exhausting
	Burning	Suffocating
	Crushing	Frightful
	Penetrating	Punishing Miserable
Hurt	Hurting	Heavy
	Pricking	
	Pressing	Throbbing
	Tender	
Ache	Numb	Annoying
	Cold	Nagging
	Flickering	Tiring
	Radiating	Troublesome
	Dull	Gnawing
	Sore	Uncomfortable
	Aching	Sickening
	Cramping	Tender

clinical clues from the quality of the pain described; thus it is important to record the description verbatim. Some of the commonly used pain descriptors are listed in Table 46-4. Note that the term “unbearable” is listed as an affective term and “piercing” is a sensory term. Both pains are real physical conditions signaling an underlying condition, but the affective description “unbearable” suggests that there is a coexisting emotional distress that needs to be addressed as well. Pain described as burning or shock-like tends to be neuropathic in origin and may be responsive to anticonvulsants (e.g., gabapentin or pregabalin), with or without an opioid (e.g., morphine, fentanyl, hydromorphone).

Pattern

The pattern of pain includes time of onset, duration, and recurrence or intervals without pain. The nurse therefore determines when the pain began; how long the pain lasts; whether it recurs and, if so, the length of the interval without pain; and when the pain last occurred. Attention to the pattern of pain helps the nurse anticipate and meet the needs of the client, as well as recognize patterns of grave concern (e.g., chest pain only on exertion).

Precipitating Factors

Certain activities sometimes precede pain. For example, physical exertion may precede chest pain, or abdominal pain may occur after eating. These observations can help prevent pain and determine its cause. Environmental factors such as extreme cold or heat and extremes of humidity can affect some types of pain. For example, people with rheumatic conditions have worse pain on cold, damp days or just before a large storm. Physical and emotional stressors can also precipitate pain. Strong emotions can trigger a migraine headache or an episode of chest pain. Extreme physical exertion can trigger muscle spasms in the neck, shoulders, or back.

Alleviating Factors

Nurses must ask clients to describe anything that they have done to alleviate the pain (e.g., home remedies such as herbal teas, medications, rest, applications of heat or cold, prayer, or distractions like TV). It is important to explore the effect any of these measures had on the pain, whether or not relief was obtained, or whether the pain became worse. It is helpful to recommend a diary be kept to gather this information.

Associated Symptoms

Also included in the clinical appraisal of pain are associated symptoms such as nausea, vomiting, dizziness, and diarrhea. These symptoms may relate to the onset of the pain or they may result from the presence of the pain.

Effect on Activities of Daily Living

Knowing how ADLs are affected by pain helps the nurse understand the client's perspective on the pain's severity. The nurse should ask the client to describe how the pain has affected the following aspects of life:

- Sleep
- Appetite
- Concentration
- Work/school
- Interpersonal relationships
- Marital relations/sex
- Home activities
- Driving/walking
- Leisure activities
- Emotional status (mood, irritability, depression, anxiety).

A rating scale of none, a little, or a great deal, or another range can be used to determine the degree of alteration in ADLs.

Coping Resources

Each individual will exhibit personal ways of coping with pain. Strategies may relate to earlier pain experiences or the specific meaning of the pain; some may reflect religious or cultural influences. Nurses can encourage and support the client's use of methods known to have helped in modifying pain, unless they are specifically contraindicated. Strategies may include seeking quiet and solitude, learning about their condition, pursuing interesting or exciting activities (for distraction), saying prayers (or engaging in other meaningful rituals), or socializing (with family, friends, support groups, etc.).

Affective Responses

Affective responses vary according to the situation, the degree and duration of pain, the interpretation of it, and many other factors. The nurse needs to explore the client's feelings of anxiety, fear, exhaustion, level of function, depression, or a sense of failure. Because many people with chronic pain become depressed and potentially suicidal, it may also be necessary to assess the client's suicide risk. In such situations, the nurse needs to ask the client, “Do you ever feel so bad that you want to die? Have you considered harming yourself or others recently?” The vast majority of chronic pain sufferers, however, are not actively suicidal and do not have a specific, lethal plan. For those who express suicidal intent, nurses need to be familiar with state regulations, organizational policies, and resources available to guide practice in this area.

Evidence-Based Practice Is There a Relationship Between Nurses' Demographic Information and Nurses' Knowledge Regarding Pain Assessment and Management?

EVIDENCE-BASED PRACTICE

Repeated evidence has shown the importance of nurses needing current knowledge and appropriate attitudes regarding pain assessment and management, regardless of client age and clinical practice area. Despite all of this research, inadequate pain assessment and management remain significant problems in health care. The purposes of this study by Al-Shaer, Hill, and Anderson (2011) were to determine nurses' knowledge regarding pain assessment and management, and to identify relationships that exist between selected demographic information and nurses' knowledge. The study used a nonexperimental, descriptive design with a convenience sample of 129 RNs from 10 separate nursing units in a midwestern metropolitan 502-bed hospital. Data were collected using a modified version of the Nurses' Knowledge and Attitude Survey Regarding Pain (NKAS) and a demographic tool. The modified NKAS consisted of 32 items: original items concerning cancer were omitted and each item had a definite correct/incorrect answer. The 32 items included 13 pharmacologic, 3 nonpharmacologic, and 16 assessment questions. Thus, there were three subscores and one overall score. Two vignettes were used to evaluate nurses' assessment of pain level and subsequent pharmacologic interventions as part of the survey. The vignettes described two clients complaining of the same level of pain who had been medicated with the same amount of morphine. The only difference between the two scenarios is that one client was grimacing while the other was smiling.

Out of a possible 32 points on the NKAS, the majority received a letter grade of B (80% to 89%) or higher. No statistical differences

existed in knowledge scores with respect to shift worked, work status, age, and total years of nursing practice. However, knowledge scores did vary with some of the variables. For example, nurses who had worked 16 or more years on their nursing unit scored significantly higher than nurses who had worked 1 to 5 years on their unit. Total knowledge scores did not differ significantly by degree preparation of the nurse. Baccalaureate-prepared nurses, however, scored significantly higher on the 16 assessment items. The RNs who worked on the oncology unit scored significantly higher on the total knowledge survey. A question regarding meperidine (Demerol) and aspirin equianalgesic dosing was the most frequently missed question.

IMPLICATIONS

The authors state that nurses in this study were above average in their knowledge of pain assessment and management. However, the lack of knowledge regarding pharmacologic interventions reinforces findings in the existing body of pain research. Unlike previous studies, nursing experience was important and the nursing unit appeared to be important with oncology nurses being significantly more knowledgeable. A major limitation of the study was the convenience sample, which does not allow for generalizability of study results. The authors suggest further research using the modified tool be conducted so findings from future research can be compared to those in this study. They also suggest analysis of nursing curricula to help identify educational shortcomings.

Observation of Behavioral and Physiological Responses

A client's self-report is the gold standard for pain assessment. Not all clients, however, are able to self-report. This group, referred to as "nonverbal" clients, includes the very young, individuals who are cognitively impaired, critically ill, or comatose, and some individuals at end of life. These clients are definitely a challenge as the nurse provides effective pain management.

There are wide variations in nonverbal responses to pain. Facial expression is often the first indication of pain, and it may be the only one. Clenched teeth, tightly shut eyes, open somber eyes, biting of the lower lip, and other facial grimaces may be indicative of pain. Vocalizations such as moaning and groaning or crying and screaming are sometimes associated with pain.

Immobilization of the body or a part of the body may also indicate pain. The client with chest pain often holds the left arm across the chest. A person with abdominal pain may assume the position of greatest comfort, often with the knees and hips flexed, and move reluctantly.

Purposeless body movements can also indicate pain—for example, tossing and turning in bed or flinging the arms about. Involuntary movements such as a reflexive jerking away from a needle inserted through the skin indicate pain. An adult may be able to control this reflex; however, a child may be unable or unwilling to do so.

Behavioral changes such as confusion and restlessness may be indicators of pain in both cognitively intact and cognitively impaired (Chapman, 2010; D'Arcy, 2011). Older adults with chronic pain may become agitated or aggressive.

Rhythmic body movements or rubbing may indicate pain. An adult or child may assume a fetal position and rock back and forth when experiencing abdominal pain. During labor a woman may massage her abdomen rhythmically with her hands.

It is important to note that because behavioral responses are controllable, they may not be very revealing. When pain is chronic, behavioral responses are rarely overt because the individual develops personal coping styles for dealing with pain, discomfort, or suffering.

Physiological responses vary with the origin and duration of the pain. Early in the onset of acute pain, the sympathetic nervous system is stimulated, resulting in increased blood pressure, pulse rate, respiratory rate, pallor, diaphoresis, and pupil dilation. The body does not sustain the increased sympathetic function over a prolonged period and, therefore, the sympathetic nervous system adapts, causing the responses to be less evident or even absent. Physiological responses are most likely to be absent in clients with chronic pain because of autonomic nervous system adaptation. Thus, measures of physiological responses (e.g., pulse, blood pressure) are poor indicators of the presence, absence, or severity of pain.

When clients are unable to self-report pain, an alternative approach based on the Hierarchy of Importance of Pain Measures, shown in Box 46–3, is recommended as a framework for pain assessment (Pasero & McCaffery, 2011).

Daily Pain Diary

For clients who experience chronic pain, a daily diary may help the client and health care provider identify pain patterns in addition to factors that exacerbate or mediate the pain experience. In home care, the family or other caregiver can be taught to complete the diary with

BOX 46–3 Hierarchy of Importance of Pain Measures**A FRAMEWORK FOR DETERMINING THE PRESENCE OF PAIN IN “NONVERBAL” CLIENTS AND DEVELOPING A TREATMENT PLAN**

1. Attempt to obtain a self-report.
 - Do not assume a client is unable to self-report until you have attempted to do so using a reliable and valid self-report tool. If unable to provide a self-report, proceed with the following steps.
2. Consider potential causes of pain (e.g., acute pain, chronic pain, procedures known to cause pain).
 - When pain is assumed to be present, provide appropriate treatment.
 - Some institutions use the abbreviation “APP” (assume pain present).
3. Observe client behaviors.
 - For example, facial expressions, restlessness, crying, changes in activity.
 - Behavioral pain assessment tools may be helpful. It is important to remember that a behavioral pain score is not considered equivalent to a self-report of pain intensity (e.g., a behavior pain score of 4/10 does not equal a self-report of pain intensity of 4/10).

4. Obtain information from family members and caregivers who know the client well.
 - These proxy assessments should be combined with other evidence when possible.
5. Attempt an analgesic trial and observe changes in the client’s behavior.
 - Provide a low dose of an analgesic if pain is suspected.
 - Observe for behavioral changes.
 - A low dose of analgesic may not be high enough. If that dose was tolerated and if there is no change in behavior, the dose should be increased or another analgesic added. Then observe for change in behavior.
 - If behaviors improve, assume pain was the cause, continue the analgesic, and add appropriate nonpharmacologic interventions.

From “Pain Assessment in the Patient Unable to Self-Report: Position Statement with Clinical Practice Recommendations,” by K. Herr, P. J. Coyne, M. McCaffery, R. Manworren, & S. Merkel, 2011, *Pain Management Nursing*, 12(4), pp. 230–250; “Pain Assessment in Nonverbal Older Adults with Advanced Dementia,” by S. M. Miller, 2011, *Journal for Nurse Practitioners*, 7(9), pp. 781–782; and *Pain Assessment and Pharmacologic Management*, by C. Pasero and M. McCaffery, 2011, p. 123, St. Louis, MO: Mosby Elsevier.

the family member who is unable to do so alone. The record could include the following:

- Time of onset of pain
- Activity or situation
- Physical pain character (quality) and intensity level (0–10)
- Emotions experienced and intensity level (0–10)
- Use of analgesics or other relief measures (intervention)
- Pain rating after intervention taken
- Comments.

Pain diaries have been shown to improve pain management. They avoid “recall bias” and allow clients to understand and express their pain experience and possibly determine patterns that can help providers suggest better interventions. The diary may also increase clients’ sense of control by helping them use medication more effectively. For example, a pain diary may show the client that waiting too long to take an analgesic means that it takes longer to control the pain.

The recorded data in the diary provides the basis for developing or modifying the plan for care. For this tool to be effective, it is important for the nurse to educate the client and family about the value and use of the diary in achieving effective pain control. Review the diary each visit, asking questions, sharing observations, and providing hints. Determining the client’s ability to use the diary is essential.

Diagnosing

NANDA International (Herdman & Kamitsuru, 2014) includes the following diagnostic labels for clients experiencing pain or discomfort:

- *Acute Pain*
- *Chronic Pain*.

When writing the diagnostic statement, the nurse should specify the location (e.g., right ankle pain or left frontal headache). Related factors, when known, should also be part of the diagnostic statement. These may include both physiological and psychological factors. For

example, in addition to the injurious agent, related factors may include deficient knowledge of pain management techniques or fear of drug tolerance or addiction.

Because the presence of pain can affect so many aspects of a client’s functioning, pain may be the etiology of other nursing diagnoses. Examples of such nursing diagnoses follow:

- *Ineffective Airway Clearance* related to weak cough secondary to postoperative incisional abdominal pain
- *Hopelessness* related to feelings of continual pain
- *Anxiety* related to past experiences of poor control of pain and anticipation of pain
- *Ineffective Coping* related to prolonged continuous back pain, ineffective pain management, and inadequate support systems
- *Ineffective Health Maintenance* related to chronic pain and fatigue
- *Deficient Knowledge* (pain control measures) related to lack of exposure to information resources
- *Impaired Physical Mobility* related to pain and inflammation secondary to arthritic pain in knee and ankle joints
- *Insomnia* related to increased pain perception at night.

Planning

The established goals for the client will vary according to the diagnosis and its defining characteristics. Specific nursing interventions can be selected to meet the individual needs of the client.

Planning Independent of Setting

When planning, nurses need to choose pain relief measures appropriate for the client, based on the assessment data and input from the client or support people. Nursing interventions may include a variety of pharmacologic and nonpharmacologic strategies. Developing a plan that incorporates a wide range of approaches is usually most effective. Whether in acute care, home care, or long-term care settings, it is important for everyone involved in pain management to

understand the plan of care. The plan should be documented in the client's record; in home care, a copy needs to be made available to the client, support people, and caregivers.

When the client's pattern and level of pain can be anticipated or is already known, regular or scheduled administration of analgesics can provide a steady serum level. With acute pain, this may be possible in the first 24 to 48 hours following surgery when the client is likely to have pain requiring opioid analgesics. Frequency of administration can be adjusted to prevent pain from recurring. When persistent, continuous pain exists, analgesics should be given around the clock (ATC), with additional as-needed (prn) doses available (Pasero & McCaffery, 2011). Nonpharmacologic interventions should also be regularly scheduled. An additional advantage of scheduling is that the client spends less time in pain and therefore does not experience as much anxiety or fear of the recurrence of pain or the helplessness of not knowing what to do when it flares.

Planning for Home Care

In preparation for discharge, the nurse should determine the client's and family's needs, strengths, and resources. The accompanying Home Care Assessment describes the specific assessment data required when establishing a discharge plan. Using the assessment data, the nurse tailors a teaching plan for the client and family.

Implementing

Nursing management of pain consists of both independent and collaborative nursing actions. In general, noninvasive measures may be performed as an independent nursing function, whereas administration of analgesic medication generally requires a medical order from a primary care provider. However, because many analgesics are ordered to be administered on a prn basis, the decision to administer the prescribed medication frequently requires the nurse to make a judgment regarding the dose amount and time of administration. However, because many analgesics are ordered to be administered on an as-needed (prn) basis that includes range orders, the decision to administer the prescribed medication is frequently the nurse's, requiring judgment as to the dose and the time of administration. Range orders are defined as "medication orders in which the selected dose varies over a prescribed range according to the patient's situation and status" (Rosier, 2012, p. 64). For example, a prn range order for morphine 2 to 6 mg IV every 2 h prn for pain or oxycodone 5 to 10 mg PO every 4 h prn for pain provides flexibility in dosing to meet individual client analgesic needs. In the past, there was an inconsistent understanding of how to interpret and carry out prn range orders. As a result, the American Society of Pain Management Nurses and the American Pain Society recently published a position statement on the use of "as-needed" range orders for opioid analgesics. The Joint Commission approves of

Home Care Assessment Pain

PATIENT-CENTERED CARE

CLIENT

- *Level of knowledge:* pharmacologic and nonpharmacologic pain relief measures selected; adverse effects and measures to counteract these effects; warning signs to report to primary care provider
- *Self-care abilities for analgesic administration:* ability to use analgesics appropriately (e.g., to prepare correct dosages of analgesics and adhere to scheduled administration); physical dexterity to take pills or to administer intravenous medications and to store medications safely; and ability to obtain prescriptions or over-the-counter medications at the pharmacy

FAMILY

- *Caregiver availability, skills, and willingness:* primary and secondary individuals able and willing to assist with pain management; shopping if the client has a restricted activity level; ability to comprehend selected therapies (e.g., infusion pumps, imagery, massage, positioning, and relaxation techniques) and perform them or assist the client with them as needed
- *Family role changes and coping:* effect on financial status, parenting and spousal roles, sexuality, social roles

COMMUNITY

- *Resources:* availability of and familiarity with resources such as supplies, home health aid, or financial assistance

CLIENT TEACHING

Monitoring Pain in the Home Setting

- Teach client to keep a pain diary to monitor pain onset, activity before pain, pain intensity, use of analgesics or other relief measures, and so on.
- Instruct client to contact a health care professional if planned control measures are ineffective.

PAIN CONTROL

- Teach the use of preferred and selected nonpharmacologic techniques such as relaxation, guided imagery, distraction, music therapy, massage, and/or heat/cold.
- Discuss the actions, side effects, dosages, and frequency of administration of prescribed analgesics.
- Suggest ways to handle side effects of medications.
- Provide accurate information about tolerance, physical dependence, and addiction if opioid analgesics are prescribed.
- Instruct the client to use pain control measures before the pain becomes severe.
- Inform the client of the effects of untreated pain.

- Demonstrate and have the client or caregiver return demonstrate appropriate skills to administer analgesics (e.g., skin patches, injections, infusion pumps, or patient-controlled analgesia). If a home infusion pump is to be used, caregivers need to be able to:
 - a. Demonstrate stopping and starting the pump.
 - b. Change the medication cartridge and tubing.
 - c. Adjust the delivery dose.
 - d. Demonstrate site care.
 - e. Identify signs indicating the need to change an injection site.
 - f. Describe care of the pump and insertion site when the client is ambulatory, bathing, sleeping, or traveling.
 - g. Perform problem solving for pumps when alarms are activated.
 - h. Change the battery.

RESOURCES

- Provide appropriate information about how to access community resources, home care agencies, and associations that offer self-help groups and educational materials.

BOX 46–4 The Use of “As-Needed” Range Orders for Opioid Analgesics

To promote safety, it is vital for primary care providers, nurses, and pharmacists to understand and agree how to properly write, interpret, and carry out prn range orders. Therefore, each institution should develop its own policies and procedures for the use of range orders

RECOMMENDATIONS:**Prescriber:**

- The order should provide clear direction to the nurse administering the analgesic.
- The order should include a dosage range with a fixed time interval. (The past practice of ordering one to two tablets every 3 to 4 hours is no longer acceptable—there should be only one time interval.)
- There should be no duplication of different opioids by the same route (e.g., IV morphine and IV hydromorphone).
- It is unsafe to order more than one analgesic by different routes unless the orders provide clear guidelines for use. For example, prn IV hydromorphone for severe pain, PO hydrocodone for moderate pain, and PO ibuprofen for mild pain.
- Written orders for the same opioid but different routes should provide clear direction for use (e.g., use oral route unless client is NPO or nauseous/vomiting).

Nurses:

- Implementation of the range orders should be based on a thorough pain assessment and knowledge of the medication.
- It is important to consider the pharmacokinetics of the opioid, especially for the very young and the very old
- Do not administer partial doses at frequent intervals (i.e., giving oxycodone 10 mg every 2 hours when the order is for oxycodone 10 to 20 mg every 3 hours). This frequent, ineffective dose of the analgesic within the range leads to an ineffective underdose of analgesic for the client.
- Always evaluate the client’s response to the dose and interval
- If the partial dose in the range is ineffective, avoid making the client wait the full interval. Wait until the peak effect of the first dose has been reached before giving another dose.
- Make sure that the client’s response to the dose and the dosing interval is documented.

From “The Use of ‘As-Needed’ Range Orders for Opioid Analgesics in the Management of Pain: A Consensus Statement of the American Society of Pain Management Nurses and the American Pain Society,” by D. Drew et al., 2014, *Pain Management Nursing*, 15(2), pp. 551–554; and “Facing Up to the Challenge of Range Orders,” by P. K. Rosier, 2012, *Nursing*, 42(12), pp. 64–65.

the use of range orders as long as appropriate policies and procedures are in place and nurses are knowledgeable about their implementation (Rosier, 2012). These recent changes to the way prn range orders are written provide a little more structure than in the past; however, professional nursing judgment remains a key factor in relieving pain by determining which medication in what dosage would best meet

the client’s comfort needs. See Box 46–4 for additional information from the position statement on prn range orders.

Generally speaking, a combination of strategies works best for the client in pain, especially chronic pain. Some strategies need to be modified until the client obtains effective pain relief. See the Practice Guidelines for individualizing care for clients with pain.

PRACTICE GUIDELINES**Individualizing Care for Clients with Pain**

- *Establish a trusting relationship.* Convey your concern, and acknowledge that you believe that the client is experiencing pain. Saying “I believe you are in pain, and I am going to do whatever I can to help you” will promote this trusting relationship.
- *Consider the client’s ability and willingness to participate actively in pain relief measures.* Clients who are excessively fatigued, sedated, or have altered levels of consciousness are less able to participate actively. For example, a client with an altered level of consciousness or altered thought processes cannot safely or effectively use patient-controlled analgesia. In contrast, a fatigued client may express a willingness to use pain relief measures that require little effort, such as listening to music or performing relaxation techniques.
- *Use a variety of pain relief measures.* It is thought that using more than one measure has an additive, if not synergistic, effect in relieving pain. Two types of relief measures that should be part of any pain treatment plan are active (relief strategies that are self-initiated) and passive (relief strategies that require the assistance of others). Establishing rapport and client teaching are necessary components of all therapeutic encounters. Because a client’s pain may vary throughout a 24-hour period, different types of pain relief or preemptive interventions may be scheduled (e.g., medication 1 hour before dressing change, relaxation techniques with pleasant imagery after bedtime medication).
- *Provide measures to relieve pain before it becomes severe.* For example, providing an analgesic before the onset of pain is preferable to waiting for the client to report pain, when a larger dose may be required.
- *Use pain-relieving measures that the client believes are effective.* It has been recognized that clients are the authorities about their own pain. Thus, incorporating the client’s preferred methods of relieving their pain into the treatment plan should be seriously considered.
- *The selection of pain relief measures should be aligned with the client’s report of the severity of the pain.* If a client reports mild pain, an analgesic such as acetaminophen may be indicated, whereas a client who reports severe pain often requires a more potent relief measure. Telling a client to ignore the pain (e.g., through distraction techniques) when he or she is reporting severe pain is an example of a misalignment (no correlation) between the pain severity and intervention selected.
- *If a pain relief measure is ineffective, encourage the client to try it again before abandoning it.* Medications may need repeated doses to saturate plasma proteins before sufficient “free drug” is available to work on the intended target. Many nonpharmacologic measures require practice before they are effective.
- *Maintain an unbiased attitude (open mind) about what may relieve pain.* New ways to relieve pain are continually being developed. It is not always possible to explain the effectiveness of particular pain relief measures; however, using approaches the client believes will work should be considered.
- *Keep trying.* Do not ignore a client because pain persists despite failed attempts to alleviate the discomfort. In these circumstances, reassess the pain and consider other relief measures.
- *Prevent harm to the client.* Pain therapy should not increase discomfort or harm the client. Some pain relief measures may have adverse effects, such as fatigue, but they should not disable the client.
- *Educate the client and caregivers about pain.* Clients and support people need to be informed about possible causes of pain, precipitating and alleviating factors, and alternatives to drug therapy. Misconceptions also need to be corrected.

TABLE 46–5 Misconceptions About Pain

Misconception	Correction
Clients experience severe pain only when they have had major surgery.	Even after minor surgery, clients can experience intense pain.
The nurse or other health care professionals are the authorities about a client's pain.	The person who experiences the pain is the only authority about its existence and nature.
Administering analgesics regularly for pain will lead to addiction.	Clients are unlikely to become addicted to an analgesic provided to treat pain.
The amount of tissue damage is directly related to the amount of pain.	Pain is a subjective experience, and the intensity and duration of pain vary considerably among individuals.
Visible physiological or behavioral signs accompany pain and can be used to verify its existence.	Even with severe pain, periods of physiological and behavioral adaptation can occur.

Barriers to Pain Management

Misconceptions and biases about pain management involve attitudes of the nurse or the client as well as knowledge deficiencies. Clients respond to pain experiences based on their culture, personal experiences, and the meaning the pain has for them. For many people, pain is expected and accepted as a normal part of illness. Clients and families may lack knowledge of the adverse effects of pain and may have been provided incorrect information regarding the use of analgesics. Clients may not report pain because they suspect that nothing can be done, or they think the pain is not severe enough or they feel it would distract or prejudice the health care provider. Other common misconceptions are shown in Table 46–5.

Another barrier to effective pain management is the exaggerated fear of becoming addicted, especially when long-term opioid use is prescribed. Both nurses and clients often hold this fear. It is important that all individuals know the difference between tolerance, physical dependence, and addiction.

Tolerance occurs when the client's opioid dose, over time, leads to a decreased sensitivity of the drug's analgesic effect. In other

words, increasing doses of the opioid are needed to provide the same level of pain relief (Pasero & McCaffery, 2011, p. 295). **Physical dependence** is an expected physical response when a client who is on long-term opioid therapy has the opioid significantly reduced or withdrawn. The client experiences withdrawal symptoms such as nausea, vomiting, diarrhea, chills, and changes in vital signs (Oliver et al., 2012; Dunn, 2012). Pasero and McCaffery (2011) state, "physical dependence is one of the most frequently misunderstood terms and is often confused with addiction or dependence" (p. 298). They maintain that the term *dependence* should be avoided because it is used in addiction medicine as another term for addiction. Physical dependence is associated with *physiological* dependence (potential ability for withdrawal), whereas addiction is associated with a *psychological* dependence on the drug. **Addiction** is a chronic, relapsing, treatable disease influenced by genetic, psychosocial, and environmental factors (Pasero & McCaffery, 2011; Oliver et al., 2012). Dunn (2012) describes how addiction is characterized by four Cs: (a) craving for the substance, (b) lack of control over the substance, (c) compulsive use, and (d) continued use despite harm (p. 66). Pasero and McCaffery (2011) remind us that it is important for the nurse to remember the following: (a) tolerance, physical dependence, and addiction are separate conditions with each requiring different treatment (p. 33), and (b) "taking opioids for pain relief is not addiction, no matter how long an individual takes opioids or at what doses. Individuals taking opioid drugs for relief of pain are using them therapeutically" (p. 299).

Pseudoaddiction is a condition that results from the undertreatment of pain where the client may become so focused on obtaining medications for pain relief that they become angry and demanding, may "clock watch," and may otherwise seem inappropriately "drug seeking." Nurses can differentiate between pseudoaddiction and addiction if the client's negative behaviors resolve when the pain is treated effectively (Arnstein, 2010; Liberto & Fornili, 2013).

Nurses will provide care for clients who have substance abuse problems or addictions. Thus, a client could come to the acute care setting for an elective surgery, through the ED, or have cancer and the nurse will be caring for a client who has two separate problems: pain and addiction. Unfortunately, clients with a present or past history of substance abuse may suffer a great deal of pain needlessly. This is likely due to nurses' fear of addiction when administering opioid medications. Because addiction is a disease, clients must be cared for appropriately. The American Society for Pain Management Nursing

Culturally Responsive Care

PATIENT-CENTERED CARE

Clients in Pain

To provide culturally sensitive pain management, nurses must first be aware of their own personal beliefs, values, and behaviors about pain, and subsequently, be open to the cultural effects of how clients perceive and react to pain. It is important, therefore, to develop an effective and caring relationship with the client.

- Respect each client:
 - Believe the client's statement of pain.
 - Recognize that clients hold different beliefs about pain.
 - Ask about the client's beliefs and how they cope with pain.
- Respect each client's response to pain:
 - Recognize that clients have the right to respond to pain in the way they learned is appropriate.
 - Recognize that expressions of pain vary widely and no expression is good or bad, just different.
- Avoid stereotyping. Expressions of pain vary between and within cultures.

From "Culture's Effects on Pain Assessment and Management," by M. C. Narayan, 2010, *American Journal of Nursing*, 110(4), 38–47, doi:10.1097/01.NAJ.0000370157.33223.6d; and "Clinical Coach for Effective Pain Management" by P. Arnstein, 2010, Philadelphia, PA: F. A. Davis and "Compact Clinical Guide to Acute Pain Management: An Evidence-Based Approach for Nurses" by Y. D'Arcy, 2011, New York, NY: Springer.

(ASPMN) and the International Nurses Society on Addictions (IntNSA) hold the position that “patients with substance use disorders and pain have the right to be treated with dignity, respect, and the same quality of pain assessment and management as all other patients” (Oliver et al., 2012, p. 169).

It is important to first treat the pain. A myth held by nurses is that if they treat the pain, they are contributing to the addiction, but this is not true. In fact, undertreating the pain may cause clients with an addictive disorder to increase their drug use. Often, addicted clients require more pain medication than usual, often more than the nurse is comfortable giving. To best help the client, if possible, nurses should consult with a pain management expert and an addiction specialist.

Key Strategies in Pain Management

Key strategies to reduce pain include acknowledging and accepting the client’s pain, assisting support people, reducing misconceptions about pain, reducing fear and anxiety, and preventing pain.

Acknowledging and Accepting Clients’ Pain

According to the professional standards of conduct, nurses have a duty to ask clients about their pain and to believe their reports of discomfort. Challenging the client’s report of discomfort undermines the environment of trust that is an essential component in the therapeutic relationship. Consider these four ways of communicating this belief:

1. Acknowledge the possibility of the pain. “Many people with your condition are bothered by leg pain. Are you experiencing any leg discomfort? What does it feel like? How concerned/upset are you about it?”
2. Listen attentively to what the client says about the pain, restating your understanding of the reported discomfort. Adding an empathetic statement like “I’m sorry you are hurting, it must be very upsetting. I want to help you feel better” lets the client know you believe the pain is real and intend to help.
3. Convey that you need to ask about the pain because, despite some similarities, everybody’s experience is unique, for example, “Many people with your condition report having some discomforts. Do you have any pain or other discomforts now?”
4. Attend to the client’s needs promptly. It is unconscionable to believe the client’s report of pain and then do nothing. After

determining the client has pain, discuss options and plan actions for providing relief.

CLINICAL ALERT!

So what if you are fooled by a client’s self-report of pain? Evidence suggests 5% of people reporting pain are dishonest and seeking some secondary gain. By believing everyone, you will not shortchange the 95% of people who so desperately need to have help controlling their pain, providing them with competent, compassionate, and appropriate nursing care based on the best available information.

Assisting Support People

Support people often need assistance to respond in a helpful manner to the person experiencing pain. Nurses can help by giving them accurate information about the pain and providing opportunities for them to discuss their emotional reactions, which may include anger, fear, frustration, and feelings of inadequacy. Teaching the support people about the disease and medications (including warning signs to report) and nondrug pain-relieving techniques they can help with (e.g., massage, application of ice, coached relaxation techniques) may diminish their feelings of helplessness and strengthen their relationship. Support people also may need the nurse’s understanding and reassurance and perhaps access to resources that will help them cope as they add the caregiver role to an already stressful life circumstance.

Reducing Misconceptions About Pain

Reducing a client’s misconceptions about the pain and its treatment will remove one of the barriers to optimal pain relief. The nurse should explain to the client that pain is a highly individual experience and that it is only the client who really experiences the pain, although others can understand and empathize. Misconceptions are also dealt with when the nurse and client discuss the context of pain control as part of the healing process. For example, a client may refuse pain medicine out of concern for addiction, explaining that the pain is more tolerable as long as he or she remains totally still. This misconception overstates the risk of addiction (estimated at < 5% of clients without a history of substance abuse when treated for acute pain) while underestimating the risks associated with immobility (e.g., atelectasis, muscle atrophy, pressure ulcers, infections).

PRACTICE GUIDELINES

Strategies for Colleague Accountability in Pain Management

What do we do if the health care team does not respond positively to the client’s report of pain?

- Speak up! Inappropriate professional behavior will persist if not challenged. If necessary, file an “incident” or “variance” report for persistent patterns or egregious violations of standards of care. These types of behaviors (ignoring reports of pain, failing to treat or mistreating people with pain) are not only unethical, but legally indefensible because a standard of care is not being met.
- Clarify that the sensation of pain is subjective and that professionals have a duty to believe clients’ reports of their symptoms.
- Cite recommendations from evidence-based clinical practice guidelines (e.g., American Pain Society, Agency for Health Care Policy and Research), The Joint Commission standards, organization-specific documents (e.g., mission statement, patient bill of rights, practice standards), or relevant research/quality reports. As necessary, distribute or post with key passages highlighted.
- Involve key committees, managers, and administrators in studying and addressing the problem from a cost, quality, competency, and credentialing perspective.

CLINICAL ALERT!

Emphasize to the client that at times, treatment may need to balance the demands of providing pain reduction with functional improvement. Too much pain medicine might impair alertness or gait; too much pain impairs alertness and ability to move. Thus a client may have to tolerate mild pain in order to do what is necessary to maximize functioning and recovery (e.g., cough, deep breathe, and walk).

Reducing Fear and Anxiety

It is important to help relieve strong emotions capable of amplifying pain (e.g., anxiety, anger, and fear). When clients have no opportunity to talk about their pain and associated fears, their perceptions and reactions to the pain can be intensified. Often, these emotions are related to uncertainty about the future, feeling mistreated in the past, or having unmet expectations. By providing accurate information, the nurse can also reduce many of the client's fears or anxiety, while clarifying expectations can minimize frustration and anger. Specifically, client education about the range of pain that is considered normal for the condition as well as the types of discomforts that signal a potential for problems will help alleviate this fear and uncertainty.

Preventing Pain

A preventive approach to pain management involves the provision of measures to treat the pain before it occurs or before it becomes severe. **Preemptive analgesia** is the administration of analgesics *before* surgery to decrease or relieve pain *after* surgery. An example would be treating clients preoperatively with local infiltration of an anesthetic or an oral or parenteral administration of an opioid to reduce postoperative pain. This concept is controversial with little evidence-based research to support the practice (D'Arcy, 2011, p. 200).

Nurses can use a preemptive approach by providing an analgesic ATC, and supplementing with as-needed prn doses after surgery or prior to painful procedures (e.g., dressing changes, physical therapy). This strategy prevents the windup and sensitization described earlier that spreads, intensifies, and prolongs pain.

Pharmacologic Pain Management

Pharmacologic pain management involves the use of opioids (narcotics), nonopioids such as nonsteroidal anti-inflammatory drugs (NSAIDs), and coanalgesic drugs (Box 46–5). The World Health Organization (WHO), in 1986, published guidelines regarding the use of analgesics to treat cancer. They provided a logical three-step approach, also known as an analgesic ladder. The three-step ladder focuses on aligning the proper analgesic with the intensity of pain. The WHO analgesic ladder was translated into 22 languages and became one of the adopted standards for general pain therapy during the last 28 years.

World Health Organization Three-Step Analgesic Ladder

For clients with mild pain (1 to 3 on a 0-to-10 scale), step 1 of the analgesic ladder, nonopioid analgesics (with or without a coanalgesic), is the appropriate starting point. If the client has mild pain that persists or increases despite using full doses of step 1 medications, or if the pain is moderate (4 to 6 on a 0-to-10 scale), then a step 2 routine is appropriate. At the second step, an opioid for moderate pain (e.g., codeine, tramadol) or a combination of opioid and nonopioid medicine (e.g., oxycodone with acetaminophen, hydrocodone with ibuprofen)

BOX 46–5 Categories and Examples of Analgesics**NONOPIOID ANALGESICS/NSAIDS FOR MILD PAIN**

- Acetaminophen (Tylenol, Datriil)
- Acetylsalicylic acid (aspirin)
- Choline magnesium trisalicylate (Trilisate)
- Ibuprofen (Motrin, Advil)
- Indomethacin sodium trihydrate (Indocin)
- Naproxen (Naprosyn), naproxen sodium (Anaprox)
- Ketorolac (Toradol)
- Piroxicam (Feldene)
- Meloxicam (Mobic)
- Celecoxib (Celebrex) Cox II NSAID

OPIOID ANALGESICS FOR MODERATE PAIN

- Hydrocodone (Lortab, Vicodin)
- Codeine (Tylenol No. 3)
- Tramadol (Ultram, Ultracet)
- Pentazocine (Talwin)

OPIOID ANALGESICS FOR SEVERE PAIN

- Fentanyl citrate (Sublimaze, transdermal patches, Actiq lozenges)
- Hydromorphone hydrochloride (Dilaudid)
- Oxycodone (OxyContin)
- Morphine sulfate (morphine)
- Oxymorphone (Opana)
- Methadone (Dolophine)

COANALGESICS

- Tricyclic antidepressants (nortriptyline, amitriptyline)
- Anticonvulsants (gabapentin, pregabalin)
- Topical local anesthetic (Lidoderm)

is provided with or without coanalgesic medications. If the client has moderate pain that persists or increases despite using full doses of step 2 medications, or if the pain is severe (7 to 10 on a 0-to-10 scale), then a step 3 schedule is medically indicated. At the third step, an opioid for severe pain (e.g., morphine, hydromorphone, fentanyl) is administered and titrated in ATC scheduled doses until the pain is relieved.

CLINICAL ALERT!

Combining opioid and nonopioid analgesics is a useful way to manage pain, and is frequently overlooked. Each has different mechanisms of action, side effects, and toxicity profiles. Alternating the two or giving them at the same time creates no danger and often produces a synergistic rather than merely additive effect. By combining nonopioids and opioids, pain management can be enhanced, reducing doses of analgesics and decreasing the risks of side effects for both. This practice is sometimes referred to as multimodal therapy.

The WHO analgesic ladder has been the cornerstone of pain management for more than two decades. Current literature, however, is questioning if it is still a valid tool (Leung, 2012; Vargas-Schaffer, 2010; Zeppetella, 2011). Some suggest a two-step ladder; others call for a four or five-step ladder. A common theme is that the WHO analgesic ladder focuses on pharmacotherapy and ignores the emotional and cognitive aspects of pain management. Leung (2012) proposes that pain management should not be a linear approach of going up or down the narrow rungs of an analgesic ladder, but instead the rungs should be broadened horizontally to become platforms. These platforms would include the analgesics *and* other therapies to alleviate

pain (e.g., physical therapy, counseling, support group, yoga, meditation, hypnosis, relaxation therapy, and other complementary and alternative medicine [CAM] options). The use of multidrug strategies coupled with multimodal therapies may permit opioid dose reduction and improve client outcomes.

Nonopioids/NSAIDs

Nonopioids include acetaminophen and **nonsteroidal anti-inflammatory drugs (NSAIDs)** such as aspirin or ibuprofen. All are useful for the management of acute and chronic pain.

Aspirin is the most common NSAID and is available over the counter (OTC). Because it can prolong bleeding time, clients should stop taking it 1 week prior to any surgical procedure. Aspirin should never be given to children under 12 years of age due to the possibility of Reye's syndrome. The nurse must also be aware that aspirin can cause excessive anticoagulation if a client is taking the anticoagulant warfarin.

Acetaminophen (Tylenol) does not affect platelet function and rarely causes gastrointestinal (GI) distress. It does, however, have serious side effects such as hepatotoxicity and possible renal toxicity, especially with high doses or with long-term use. Studies show that even with recommended doses up to 4 grams per day, some clients may be at an increased risk for liver toxicity (Pasero & McCaffery, 2011). The U.S. Food and Drug Administration (FDA) currently require warnings against taking alcohol with acetaminophen. It is recommended that otherwise young and healthy people limit their acetaminophen consumption to less than 3 grams per day, with susceptible individuals (e.g., older adults, those with a history of alcoholism, dehydration, or liver disease) limiting their consumption to less than 2 grams per day (Arnstein, 2010; D'Arcy, 2011). Given that acetaminophen is so well tolerated, it is often an ingredient in OTC remedies (e.g., pain, fever, allergy, cough and cold preparations), so clients must be instructed to read the ingredient list of all OTC medicines they take. Box 46–6 lists common prescription medications that contain acetaminophen.

NSAIDs have anti-inflammatory, analgesic, and antipyretic effects, whereas acetaminophen has only analgesic and antipyretic effects. All NSAIDs relieve pain by inhibiting the enzyme cyclooxygenase (COX), a chemical that is activated by damaged tissue, resulting in decreased synthesis of prostaglandins. The COX-1 specific isoforms (proteins) are found in platelets, the GI tract, kidneys, and most other tissue, and are believed to be the cause of the well-known side effects of NSAIDs (e.g., GI bleed, diminished renal blood flow, and inhibited clotting).

In the 1990s a second isoform (COX-2) was found and believed to be specific only for pain and inflammation. The resulting new

“safer” (COX-2 selective) NSAIDs were tested, approved, and widely used. These drugs demonstrated significantly less GI bleeding, but uncommon cardiovascular events and rare skin problems occurred in susceptible individuals. The only COX-2 currently available in the United States is celecoxib (Celebrex). Although the COX-2 NSAIDs have fewer GI side effects, they are no safer on renal function than the COX-1 NSAIDs. All prescription NSAIDs now must carry the strong “black box” warning of the risks of using these drugs. Even nonprescription NSAIDs (e.g., aspirin, ibuprofen, naproxen) must be relabeled to warn consumers of the potential dangers of using those products.

Individual drugs in this category vary little in their analgesic potency, but do vary in their anti-inflammatory properties, metabolism, excretion, and side effects. These drugs have a ceiling effect and a narrow therapeutic index. The *ceiling effect* means that once the maximum analgesic benefit is achieved, additional amounts of the drug will not produce more analgesia; however, more toxicity may occur. The *narrow therapeutic index* indicates that there is not much margin for safety between the dose that produces a desired effect and the dose that may produce a toxic, even lethal effect. The most common side effect of NSAIDs is gastrointestinal, such as heartburn or indigestion. These effects can become toxic or lethal if silent GI bleeding occurs. Given the interference with platelet aggregation, a small stomach ulcer can bleed a great deal, making it a potentially life-threatening condition. Clients should be taught to take NSAIDs with food and a full glass of water. Routine monitoring by a health professional is indicated if these preparations are taken daily for more than a couple of weeks.

Table 46–6 lists common misconceptions about nonopioids.

Opioids

There are three primary types of opioids:

1. **Full agonists.** These pure opioid drugs bind tightly to mu receptor sites, producing maximum pain inhibition, an agonist effect. A full **agonist analgesic** includes morphine, the gold standard opioid. Other full agonists include oxycodone (e.g., Percocet, OxyContin), hydromorphone (e.g., Dilaudid), and fentanyl (Duragesic, Actiq). There is no ceiling on the level of analgesia from these drugs; their dose can be steadily increased to relieve pain. There is also no maximum daily dose limit unless they are in compound with a nonopioid analgesic drug.
2. **Mixed agonists–antagonists.** **Agonist–antagonist analgesic** drugs can act like opioids and relieve pain (agonist effect) when given to a client who has not taken any pure opioids. However, they can block or inactivate other opioid analgesics when given to a client who has been taking pure opioids (antagonist effect). These drugs include dezocine (Dalgan), pentazocine hydrochloride (Talwin), butorphanol tartrate (Stadol), and nalbuphine hydrochloride (Nubain). They block the mu receptor site and activate a kappa receptor site. If a client has been receiving a mu agonist (e.g., morphine, Percocet, or Vicodin for pain) daily for more than a couple of weeks, the administration of a mixed agonist–antagonist may result in an immediate and severe withdrawal reaction. These drugs also have a ceiling effect that limits the dose. They are not recommended for use with clients who are terminally ill. In the opioid-naïve client (individual who has not taken opioids for a week or longer) with acute pain (e.g., migraine headache), these agents have success and few side effects.

BOX 46–6 Common Prescription Pain Medications Containing Acetaminophen

MEDICATION

- Tylenol No. 3 (325 mg acetaminophen/30 mg codeine)
- Percocet (325 mg acetaminophen/5 mg oxycodone)
- Lortab (500 mg acetaminophen/5, 7.5, or 10 mg hydrocodone)
- Vicodin (500 mg acetaminophen/5 mg hydrocodone)
- Tylox (500 mg acetaminophen/5 mg oxycodone)
- Darvocet-N 100 (650 mg acetaminophen/100 mg propoxyphene)
- Vicodin ES (750 mg acetaminophen/7.5 mg hydrocodone)

TABLE 46–6 Misconceptions About Nonopioids

Misconception	Correction
Regular daily use of NSAIDs is much safer than taking opioids.	Side effects from long-term use of NSAIDs are considerably more severe and life threatening than the side effects from daily doses of opioids. The most common side effect from long-term use of opioids is constipation, whereas NSAIDs can cause gastric ulcers, increased bleeding time, and renal insufficiency. Acetaminophen can cause hepatotoxicity.
A nonopioid should not be given at the same time as an opioid.	It is safe to administer a nonopioid and opioid at the same time. Giving a dose of nonopioid at the same time as a dose of opioid poses no more danger than giving the doses at different times. In fact, many opioids are compounded with a nonopioid (e.g., Percocet [oxycodone and acetaminophen]).
Administering antacids with NSAIDs is an effective method of reducing gastric distress.	Administering antacids with NSAIDs can lessen distress but may be counterproductive. Antacids reduce the absorption and therefore the effectiveness of the NSAID by releasing the drug in the stomach rather than in the small intestine where absorption occurs.
Nonopioids are not useful analgesics for severe pain.	Nonopioids alone are rarely sufficient to relieve severe pain, but they are an important part in the total analgesic plan. One of the basic principles of analgesic therapy is: Whenever pain is severe enough to require an opioid, adding a nonopioid should be considered.
Gastric distress (e.g., abdominal pain) is indicative of NSAID-induced gastric ulceration.	Most clients with gastric lesions have no symptoms until bleeding or perforation occurs.

From *Pain Assessment and Pharmacologic Management*, by C. Pasero and M. McCaffery, 2011, St. Louis, MO: Mosby; Mosby, Inc. Reprinted with permission from Elsevier Science.

3. **Partial agonists.** Partial agonists have a ceiling effect in contrast to a full agonist. These drugs such as buprenorphine (Buprenex) block the mu receptors or are neutral at that receptor but bind at a kappa receptor site. Buprenorphine has good analgesic potency and is emerging as an alternative to methadone for opioid maintenance and narcotic treatment programs. The safety and favorable side effect profile make it an increasingly popular choice.

Opioid Analgesics for Moderate Pain These include drugs such as codeine, hydrocodone, and tramadol. Most of these drugs are combinations of a nonopioid with an opioid. These medicines are generally two to four times more potent than nonopioids alone, and share some of the risks of both drug classes. These drugs are controlled substances and must be ordered by a physician or nurse practitioner, adhering to applicable federal and state laws. They also have a ceiling effect due to the nonopioid and a maximum daily dose limit. There are advantages to giving combination drugs, such as lowering the amount of any one medicine needed in a 24-hour period, thus reducing the potential for side effects or toxicity; however, nurses need to be familiar with each medication and be aware of daily dose limits of the ingredients as well as the potential to receive duplicate medications for different clinical indications (e.g., Tylenol in the mixed drug, Tylenol for fever, and Tylenol in the headache preparation).

These opioids have a narrow therapeutic index. Codeine at doses of 30 to 60 mg produces dose-limiting GI distress in many people. A specific enzyme in the body (CYP450) is required to make codeine active in order for analgesia to be effected. About 10% of the population lack this enzyme, meaning they may not get any pain relief at all from codeine (D'Arcy, 2011).

Tramadol (Ultram, Ultracet) is considered to be a nonspecific opioid with a dual mechanism of action. It is a weak opioid agonist and also inhibits the reuptake of norepinephrine and epinephrine. The usual dose is 50 to 100 mg four times a day. Drug interactions should be reviewed. For example, the selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine, paroxetine) may inhibit tramadol metabolism. Also, it should not be administered with monoamine oxidase inhibitors (MAOIs) because it has been associated with the development of psychosis (Pasero & McCaffery, 2011, p. 361). In the past, propoxyphene (Darvon) has been listed in this category. Because of a reported 10,000 deaths associated with Darvon products due to the accumulation of metabolites, the FDA considered a public citizen petition to remove it from the market. The FDA ultimately decided to keep pain medications such as Darvon and Darvocet that contain propoxyphene on the market with the requirement that propoxyphene manufacturers increase the safety warning labels on the product (Pasero & McCaffery, 2011). Strong evidence suggests that Darvon and Darvocet should be avoided in older adults.

Opioid Analgesics for Severe Pain Pure agonist opioid analgesics include opium derivatives, such as morphine, hydromorphone, oxycodone, fentanyl, and methadone. *Opioid* is the pharmacologic class of pain relievers and is the correct medical term. Many opioids are “scheduled” as a controlled substance (narcotic) due to the potential for misuse. Pure agonist opioids relieve pain primarily by binding to mu receptors in the peripheral and central nervous systems. In addition to pain reduction, changes in mood may make the person feel more comfortable even though the pain persists. As the most potent class of pain relievers, these drugs are indicated for severe pain, or when other medications have failed to control moderately severe or

DRUG CAPSULE

Narcotic Analgesic oxycodone (OxyContin), oxycodone/acetaminophen (Percocet), oxycodone/aspirin (Percodan)**CLIENT WITH PAIN**

Opioids relieve moderate to severe pain by inhibiting the release of substance P in both central and peripheral nerves, reducing the perception of pain, producing sedation, and decreasing the emotional stress of pain.

Oxycodone is a semisynthetic derivative of codeine and a Schedule II controlled substance. It is often administered as a combination drug with acetaminophen (Percocet, Tylox) or aspirin (Percodan). It is also available as a single-agent, controlled-release medication (OxyContin).

NURSING RESPONSIBILITIES

- Assess pain prior to and 60 minutes after administration.
- Assess bowel function to prevent constipation.
- Keep track of the total amount of acetaminophen or aspirin the client is receiving when taking a combination drug. The maximum daily dose of acetaminophen is 4,000 mg

unless the client is at risk for liver problems (e.g., older adult, malnourished, or hepatic problems). For these clients, the maximum amount is lowered to 2,000 mg/day (Arnstein, 2010; D'Arcy, 2011).

CLIENT AND FAMILY TEACHING

- Take with food to decrease GI upset.
- Avoid crushing or chewing long-acting tablets (e.g., OxyContin).
- Avoid alcohol or other CNS depressants.
- Explain that the medication may cause dizziness, and instruct to make position changes slowly.
- Instruct that constipation is a common side effect. Discuss preventive measures.
- Take only as prescribed.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

worse pain. Among this class, meperidine (Demerol) has received a lot of attention in recent years as a medication to avoid because of its short half-life, toxic metabolite, and potential to induce tremors and seizures with repeated doses. It should not be used with infants and children, older adults, and clients with cancer pain or sickle cell disease (Pasero & McCaffery, 2011). Most acute care settings have taken it off their formularies for pain control.

Methadone is a synthetic opioid used for severe pain. The nurse needs to be aware of the potential for serious problems when a client is on methadone. Due to its long half-life (15 to 60 hours), there is an increased risk of sedation and respiratory depression, especially in older adults.

Opioid Side Effects When administering any analgesic, the nurse must review side effects. Side effects of the opioids typically include respiratory depression, sedation, nausea/vomiting, urinary retention, blurred vision, sexual dysfunction, and constipation. The most concerning adverse effect of opioids is respiratory depression (e.g., 8 breaths per minute or less), which usually occurs early in therapy among opioid-naïve clients, with dose escalation, or in clients with drug–drug or drug–disease interactions. Clinically, the client will appear overly sedated, and respirations will be slow and deep with periods of apnea. The nurse should assess a client's level of alertness and respiratory rate for baseline data before administering opioids. Clients will often manifest an increase in sedation *before* they manifest a decrease in respiratory rate and depth. The use of a scale to assess sedation during opioid pain management is common in hospitals in the United States. A number of sedation scales are available; thus, it is important for the nurse to know how to use their facility's choice of sedation scale. A commonly used scale is the Pasero Opioid-Induced Sedation Scale (POSS), which uses a scale ranging from 1 (alert and awake) to 4 (minimal or no response to verbal and physical stimulation). See the sedation rating scale in Box 46–7. Pasero and McCaffery (2011) suggest that an easy way for the nurse to assess sedation is to ask the client a simple question, such as “What did you have for breakfast today?” and observe the client's ability to stay awake and answer the question (p. 509). If

BOX 46–7 Pasero Opioid-Induced Sedation Scale

- S = Sleep, easy to arouse
- 1 = Awake and alert
- 2 = Slightly drowsy, easily aroused
- 3 = Frequently drowsy, arousable, drifts off to sleep during conversation
- 4 = Somnolent, minimal or no response to physical stimulation

From Pain Assessment and Pharmacologic Management, by C. Pasero and M. McCaffery, p. 510, 2011, St. Louis, MO: Mosby, Inc., with permission from Elsevier.

the client is excessively sedated, they will fall asleep in the middle of answering the question. This behavior is unacceptable and requires close monitoring of respiratory rate and sedation level. Early recognition of an increasing level of sedation or respiratory depression will enable the nurse to implement prompt, appropriate measures promptly (e.g., pulse oximetry monitoring, obtaining an order to decrease the opioid dosage).

Box 46–8 provides suggested measures to prevent and treat side effects of opioid analgesics. Tolerance to all opioid side effects usually occurs within a few days, except for constipation. Because of this, the nurse must initiate and continue measures to prevent constipation during the entire time the client receives opioids.

CLINICAL ALERT!

Constipation is an almost universal adverse effect of opioid use. All clients should receive prophylactic stimulant laxative therapy, unless contraindicated. Stool softeners are not useful alone, but are a good choice when combined with a stimulant laxative (e.g., Senokot-S). If those products are ineffective, a regimen of cathartic laxatives (e.g., bisacodyl), followed by more aggressive forms of treatment (e.g., osmotic laxatives, enema, manual disimpaction) may be necessary.

Equianalgesic Dosing

The term **equianalgesia** refers to the relative potency of various opioid analgesics compared to a standard dose of parenteral

BOX 46–8 Common Opioid Side Effects with Preventive and Treatment Measures**CONSTIPATION**

- Increase fluid intake (e.g., 6 to 8 glasses daily).
- Increase fiber and bulk-forming agents to the diet (e.g., fresh fruits and vegetables). Increasing exercise is often ineffective in controlling this type of constipation.
- Administer daily stool softeners combined with a mild laxative (e.g., Senokot-S) as a first line of prevention against constipation for clients on opioid maintenance therapy.
- Stimulants (bisacodyl), osmotic laxatives (lactulose, sorbitol, and polyethylene glycol), enemas (tap water and sodium phosphate), and even prokinetic agents (metoclopramide) may be needed for refractory cases of constipation.
- A new medication has been approved for opioid-induced constipation in end-of-life care, Relistor (methylnaltrexone bromide). It is to be given subcutaneously, when other methods prove ineffective (D'Arcy, 2011).

NAUSEA AND VOMITING

- Inform client that tolerance to this emetic effect generally develops after several days of opioid therapy.
- Provide an antiemetic: the 5HT antagonist ondansetron (Zofran), phenothiazines (Compazine, Phenergan), or the GI stimulant metoclopramide (Reglan).
- Change the dose or analgesic agent as indicated.

SEDATION

- Inform client that tolerance usually develops over 3 to 5 days.
- Consider the administration of a stimulant in the morning (e.g., caffeine, Dexedrine, or Ritalin for adult clients) or an alternative route of administration (e.g., epidural) to counteract sedation.

- Observe client for evidence of respiratory depression that may occur with sedation.

RESPIRATORY DEPRESSION

- Administer an opioid antagonist, such as naloxone hydrochloride (Narcan), cautiously by diluting 1 ampule in 10 mL of saline and then administering 1 mL/min until the respirations are equal to or more than 10/min. Make provisions for repeat administration, continuous infusion, or a longer acting version of a reversal agent because the half-life of naloxone is considerably shorter than that of most opioids being reversed.
- Remember to titrate naloxone to prevent seizures, arrhythmias, and returning pain.
- Attempt to stimulate the client to take deep breaths every 15 to 30 minutes. Stop, change, or slow the administration of opioids until respirations are restored.
- Be aware of the CNS depression risks of other medications such as hypnotics, benzodiazepines, and sedatives, especially in the opioid-naïve client.

PRURITUS

- Apply cool packs, lotion, and diversional activity.
- Administer an antihistamine, for example, diphenhydramine hydrochloride (Benadryl). Instruct client about sedation effects.
- Inform the client that tolerance also develops to pruritus within a few days; otherwise, as with other unresolved side effects, switching to another opioid may prove beneficial.

URINARY RETENTION

- May need to catheterize client, or change or lower the analgesic dose.

SAFETY ALERT!**SAFETY**

Assessing for sedation and respiratory status is critical during the first 12 to 24 hours after starting opioid therapy. The most critical period is during the peak effect of the first dose (15 minutes if administered IV; first hour after IM, oral, or rectal route). An exception is with opioids administered via the spinal route. Respiratory depression may increase over time with epidural infusions and with intrathecal analgesia; respiratory depression may manifest 24 hours after the spinal injection even after the analgesic effect has worn off. In general, the longer the client receives opioids, the wider the safety margin as the client develops a tolerance to the sedative and respiratory depressive effects of the drug.

morphine (gold standard opioid). This tool helps professionals individualize the analgesic regimen by guiding the adjustment of medication, dose, time interval, and route of administration. An equianalgesic table can be used to help provide doses of approximately equal ability to relieve pain.

CLINICAL ALERT!

Many health care professionals underestimate the effectiveness of ordinary aspirin and acetaminophen. The ordinary dose of aspirin or acetaminophen relieves as much pain as 1.5 mg of parenteral morphine, whereas standard doses of mixed analgesics (e.g., Tylenol No. 3 or Percocet) are approximately equivalent to 2.5 to 5 mg of morphine.

Coanalgesics

A **coanalgesic** (formerly known as an adjuvant) is a medication that is not classified as a pain medication. However, coanalgesics have properties that may reduce pain alone or in combination with other analgesics, relieve other discomforts, potentiate the effect of pain medications, or reduce the pain medication's side effects. Examples of coanalgesics that relieve pain are antidepressants (increase pain relief, improve mood, and improve sleep), anticonvulsants (stabilize nerve membranes, reducing excitability and spontaneous firing), and local anesthetics (block the transmission of pain signals). Anxiolytics, sedatives, and antispasmodics are examples of medicines that relieve other discomforts; however, they do not alleviate pain and thus should be used in addition to rather than instead of analgesics. Examples of medications used to reduce the side effects of analgesics include stimulants, laxatives, and antiemetics.

Coanalgesics appear to be particularly beneficial for the management of neuropathic pain. Tricyclic antidepressant drugs are prescribed for central neuropathic pain, which often manifests as pain with a burning, unusual, or stinging quality. Anticonvulsant drugs, such as gabapentin (Neurontin) or pregabalin (Lyrica), are used for peripheral neuropathic conditions that often present with a stabbing, shooting, or electrical-shock quality. Local anesthetics such as the Lidoderm patch also alleviate neuropathic as well as other types of pain, and are particularly useful for clients with the skin sensitivity known as allodynia. There is a growing scientific and clinical basis for the use of these medications in relieving pain,

especially for persistent pain that is not relieved by the analgesic classes of medication alone.

Administration of Placebos

A **placebo** is “any sham medication or procedure designed to be void of any known therapeutic value” (Arnstein, Broglio, Wuhrman, & Kean, 2011, p. 226). An example would be a sugar pill or an injection of saline. In contrast, the *placebo effect* is “the positive response some patients/participants experience after receiving a placebo” (Arnstein et al., 2011, p. 226). Some professionals try to justify the use of placebos to elicit the desirable placebo effect or in a misguided attempt to determine if the client’s pain is “real.” The use of placebos, outside the context of an approved research study, is deceptive and represents fraudulent and unethical treatment. Many professional and pain management organizations (e.g., ANA Code of Ethics for Nurses, American Society for Pain Management Nursing, American Pain Society, Oncology Nursing Society) have published position papers that adamantly oppose the use of placebos without consent.

Routes for Opiate Delivery

Opioids can be given in the following routes: oral, transnasal, transdermal, transmucosal, rectal, topical, subcutaneous, intramuscular, IV (bolus and continuous), and intraspinal (epidural and intrathecal) and as continuous local anesthetics.

Oral

Oral administration of opioids remains the preferred route of delivery because of ease of administration. Because the duration of action of most opioids is approximately 4 hours, people with chronic pain have had to awaken during the night to medicate themselves for pain. To avoid this problem, long-acting or sustained-release formulations of morphine with a duration of 8 or more hours have been developed. Examples of a long-acting morphine are MS Contin, a controlled-release tablet, and Avinza, a morphine sulfate extended-release capsule. Clients receiving long-acting morphine may also need prn “rescue” doses of immediate-release analgesics such as Actiq, the short-acting oral transmucosal fentanyl citrate (OTFC) for acute breakthrough pain. Another method of oral opiate delivery is high-concentration liquid morphine. This formulation enables clients who can swallow only small amounts to continue taking the drug orally.

Transnasal

Transnasal administration has the advantage of rapid action of the medication because of direct absorption through the vascular nasal mucosa. A commonly used agent is the mixed agonist–antagonist butorphanol (Stadol) for acute migraine headaches. Treating migraine headaches via the nasal route of administration is particularly beneficial. Nausea, vomiting, and gastroparesis often accompany migraines, therefore oral medications are contraindicated.

Transdermal

Transdermal drug therapy is advantageous in that it delivers a relatively stable plasma drug level and is noninvasive. Fentanyl (Dura-gesic) is a lipophilic synthetic opioid (i.e., binds to subcutaneous fat) and is currently available as a skin patch with various dosages (12 to 100 mcg). The nurse must remember that fentanyl is 100 times more potent than morphine and is ordered in micrograms not

milligrams. It provides drug delivery for up to 72 hours. The transdermal route is distinguished from the topical route in that the effects of the medications are systemic after the medication is absorbed. Nurses must teach clients not to use heat (e.g., hot tubs, heating pads) with the fentanyl patch, because increased absorption may result. A client with a fever may absorb the medication faster because of the vasodilation from the increased skin temperature. Used patches should be disposed of in a tamper-proof container. This is especially true in the home setting because a used patch can contain enough residual medication to harm a small child or animal if ingested (Mayo Clinic, 2012).

Transmucosal

Many clients with cancer-related pain experience breakthrough pain even though they are on a fixed schedule for pain control. The transmucosal route is helpful for breakthrough pain because the oral mucosa is well vascularized, which facilitates rapid absorption. Two forms of fentanyl are available for transmucosal delivery: OTFC (Actiq) and a fentanyl buccal tablet (FBT; Fentora).

Rectal

Several nonopiate and opiate medicines are now available in suppository form. The rectal route is particularly useful for clients who have dysphagia (difficulty swallowing) or nausea and vomiting. It is best to use commercially available rectal preparations, or have them compounded by a licensed compound pharmacist.

Topical

Topical medications work directly at the point of application on the body. They are useful for painful procedures such as lumbar punctures or bone marrow biopsies or for injections. These products can also offer effective pain relief for chronic pain syndromes such as peripheral neuropathy and/or low back pain. OTC examples include Aspercreme and LMX4 (4% lidocaine).

Prescription topical medications include EMLA cream (lidocaine and prilocaine), Synera (lidocaine and tetracaine), and Zingo (lidocaine hydrochloride powder). Lidoderm is a topical patch approved for post-herpetic neuralgia. It has also been found to be useful in other types of neuropathic pain. It must be applied on intact skin and left in place for 12 hours and then off for 12 hours.

A new form of the NSAID diclofenac (Voltaren) is now available, by prescription, for treatment of acute short-term pain due to minor strains, sprains, and contusions (bruises). It is called the Flector patch.

Subcutaneous

Although the subcutaneous route has been used extensively to deliver opioids, another technique uses subcutaneous catheters and infusion pumps to provide continuous subcutaneous infusion (CSCI) of opioids. CSCI is particularly helpful for clients (a) whose pain is poorly controlled by oral medications, (b) who are experiencing dysphagia or GI obstruction, or (c) who have a need for prolonged use of parenteral opioids. CSCI involves the use of a small, light, battery-operated pump that administers the drug through a 23- or 25-gauge butterfly needle. The needle can be inserted into the anterior chest, the subclavicular region, the abdominal wall, the outer aspects of the upper arms, or the thighs. Client mobility is

maintained with the application of a shoulder bag or holster to hold the pump. The frequency of site change ranges from 3 to 7 days. The maximum fluid volume should be less than 3 mL/h for continuous infusion (Pasero & McCaffery, 2011).

Because family caregivers must operate the pump as well as change and care for the injection site, the nurse needs to provide appropriate instruction. Caregivers need to be able to:

- Describe the basic parts and symbols of the system.
- Identify ways to determine whether the pump is working.
- Change the battery.
- Change the medication.
- Demonstrate stopping and starting the pump.
- Demonstrate tubing care, site care, and changing of the injection site.
- Identify signs indicating the need to change an injection site.
- Describe general care of the pump when the client is ambulatory, bathing, sleeping, or traveling.
- Identify actions to take to solve problems when the alarm signals.

Intramuscular

The intramuscular (IM) route should be abandoned for administration of analgesics (Pasero & McCaffery, 2011). Disadvantages include variable absorption, unpredictable onset of action and peak effect, as well as the tissue damage that may result, even if properly administered. Regardless of precautions taken, there is pain involved with administration.

Intravenous

The IV route provides the most rapid onset for pain relief with few side effects. However, just as the onset of pain relief occurs in 5 to 10 minutes, so can adverse effects, such as respiratory depression. The analgesic can be administered by IV bolus or by continuous infusion. IV medications should be given slowly to decrease adverse effects. Caution is needed to prevent the introduction of air or

bacteria into the tubing, and to prevent the introduction of medications that are incompatible with other medications dissolved in the IV solution.

Intraspinal

Another method of delivery is the infusion of opioids into the epidural or intrathecal (subarachnoid) space (Figure 46–9 ■). Analgesics administered via the intraspinal route are delivered adjacent to the opiate receptors in the dorsal horn of the spinal cord. Two commonly used medications are morphine sulfate and fentanyl. All medicines administered via the intraspinal route need to be sterile and preservative free (preservatives are neurotoxic). The major benefit of intraspinal drug therapy is superior analgesia with less medication used. The epidural space is most commonly used because the dura mater acts as a protective barrier against infection, including meningitis, and there is less risk of developing a “spinal headache.” Intraspinal catheters are not in constant contact with blood, and thus an infusion can be stopped and restarted later without concern that the catheter is no longer patent.

Intrathecal administration delivers medication directly into the cerebrospinal fluid (CSF) that bathes and nourishes the spinal cord. Medicines quickly and efficiently bind to the opioid receptor sites in the dorsal horn when administered in this fashion, speeding the onset and peak effect, while prolonging the duration of action of the analgesic. An example of how the route of administration affects the relative potency of opiates is as follows: A client who requires 300 mg of oral morphine per day to control pain will need 100 mg of parenteral morphine, 10 mg of epidural morphine, and only 1 mg of intrathecal morphine in a 24-hour period. Very little drug is absorbed by blood vessels into the systemic circulation. In fact, the drug must circulate through the CSF to be excreted. As a result, there may be a delayed onset (24 hours following the administration) of respiratory depression, because medication that has left the spinal opioid sites travels through the brain to be eliminated.

Figure 46–9 ■ Placement of intraspinal catheter in the epidural space.

In contrast, the epidural space is separated from the spinal cord by the dura mater, which acts as a barrier to drug diffusion. In addition, it is filled with fatty tissue and an extensive venous system. With this diffusion delay, some medications (especially fat-soluble medications like fentanyl) from the epidural space enter the systemic circulation via the venous plexus. Thus a higher dose of opiate is required to create the desired effect, which can produce side effects of itching, urinary retention, and/or respiratory depression. Often, an opioid (e.g., fentanyl) and a local anesthetic (e.g., bupivacaine) are combined to lower the dose of opioid needed. As a result, there may be an increase in fall risk for some clients who develop muscular weakness in their legs or orthostatic hypotension in response to the local anesthetic.

Intraspinal analgesia can be administered by three modes of operation:

1. **Bolus.** A single or repeated bolus dose(s) may be provided. When clients have spinal anesthesia (e.g., during a cesarean section), a bolus of 1 mg intrathecal preservative-free morphine can provide significant pain control for up to 24 hours. For shorter acting medications, an epidural catheter may be intact and accessed by a qualified health professional (e.g., anesthesiologist or nurse anesthetist) to administer bolus doses on an “as-needed” basis. Check your state regulations and agency policy regarding who can provide these bolus doses, how they are documented, and the postbolus monitoring procedures.
2. **Continuous infusion administered by pump.** The pump may be external (for acute or chronic pain) or surgically implanted (for chronic pain) to provide a continuous infusion of pain relievers into the epidural or intrathecal space.
3. **Continuous plus intermittent bolus.** With this mode of operation, the client receives a continuous infusion with bolus “rescue” doses administered for breakthrough pain. Often a pump with *patient-controlled epidural analgesia (PCEA)* capabilities is used for this mode of operation. This is similar to patient-controlled analgesia (detailed later) in which a basal rate may or may not be used to meet the client’s anticipated analgesic need, with the

client’s ability to request an incremental dose at set intervals by pressing a button. PCEA is often used to manage acute post-operative pain, chronic pain, and intractable cancer pain. The “walking epidurals” used for women in labor are typically PCEA devices that are programmed in the bolus mode without a continuous infusion (basal rate) set.

The anesthesiologist or nurse anesthetist inserts a needle into the intrathecal or epidural space (typically in the lumbar region) and threads a catheter through the needle to the desired level. The catheter is connected to tubing that is then positioned along the spine and over the client’s shoulder for the nurse to access. The entire catheter and tubing are taped securely to prevent dislodgment. Often an occlusive, transparent dressing is placed over the insertion site for easy identification of catheter displacement or local inflammation. Temporary catheters, used for short-term acute pain management, are usually placed at the lumbar or thoracic vertebral level and usually removed after 2 to 4 days. Permanent catheters, for clients with chronic pain, may be tunneled subcutaneously through the skin and exit at the client’s side or be connected to a pump implanted in the abdomen. Tunneling of the catheter reduces the risk of infection and displacement of the catheter. After the catheter is inserted, the nurse is responsible for monitoring the infusion and assessing the client per institutional policy. Nursing care of clients with intraspinal infusions is summarized in Table 46–7.

Misconceptions exist about the risks of spinal analgesia. This is in part due to the importance of the technique of the professional while inserting the catheter. In general, clients receiving epidural analgesia do not need to be monitored in an intensive care setting, but they do need vigilant assessment of their pain, neurologic and respiratory status, and the insertion site during the course of therapy (Pasero & McCaffery, 2011).

SAFETY ALERT!

SAFETY

As a precaution, have naloxone (Narcan), sodium chloride 0.9% diluent, and injection equipment on hand for each client receiving an opioid-containing epidural infusion.

TABLE 46–7 Nursing Interventions for Clients Receiving Analgesics Through an Epidural Catheter

Nursing Goals	Interventions
Maintain client safety.	Label the tubing, the infusion bag, and the front of the pump with tape marked EPIDURAL to prevent confusion with similar-looking IV lines. (Most epidural tubings are yellow for this reason.) Post sign above client’s bed indicating epidural is in place. Secure all connections with tape. If there is no continuous infusion, apply tape over all injection ports on the epidural line to avoid the injection of substances intended for IV administration into the epidural catheter. Do not use alcohol in any care of catheter or insertion site because it can be neurotoxic. Ensure that any solution injected or infused intraspinally is sterile, preservative free, and safe for intraspinal administration.
Maintain catheter placement.	Secure temporary catheters with tape. When bolus doses are used, gently aspirate prior to medication administration to determine catheter has not migrated into the subarachnoid space. (Expect <1 mL of fluid return in syringe.) Assist client in repositioning or moving out of bed. Teach client to avoid tugging on the catheter. Assess insertion site for leakage with each bolus dose or at least every 8–12 h.
Prevent infection.	Use strict aseptic techniques with all epidural-related procedures. Maintain sterile occlusive dressing over insertion site. Assess insertion site for signs of infection.
Maintain urinary and bowel function.	Monitor intake and output. Assess for bowel and bladder distention.
Prevent respiratory depression.	Assess sedation level and respiratory status q1h for the first 24 h and q4h thereafter. Do not administer other opioids or CNS depressants unless ordered. Keep an ampule of naloxone hydrochloride (0.4 mg) available. Notify the clinician in charge if the respiratory rate falls below 8/min or if the client is difficult to rouse.

Continuous Local Anesthetics

Continuous subcutaneous administration of long-acting local anesthetics into or near a surgical site is a technique being used to provide postoperative pain control. This technique has been used for a variety of surgical procedures, including knee arthroplasty, abdominal hysterectomy, hernia repair, and mastectomy. Nursing interventions for the client with infusion of a continuous local anesthetic include the following:

- Conduct pain assessment and documentation every 2 to 4 hours while the client is awake.
- Check the dressing every shift to ensure it is intact. The dressing is not usually changed in order to avoid dislodging the catheter. Contact the primary care provider if the dressing becomes loose.
- Check the site of the catheter. It should be clean and dry.
- Assess the client for signs of local anesthetic toxicity (e.g., cardiac arrhythmias, dizziness; ringing in the ears; a metallic taste; tingling or numbness of the lips, gums, or tongue) or neurologic deficit distal to the catheter insertion site.
- Notify the primary care provider of signs of local anesthetic toxicity or neurologic deficit. If detected early, prompt treatment should be initiated in order to prevent serious complications.

Figure 46–10 ■ PCA line introduced into the injection port of a primary IV line.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is an interactive method of pain management that permits clients to treat their pain by self-administering doses of analgesics. The IV route is the most common in an acute care setting. Its use for postoperative pain has been well documented. It is also helpful when oral pain management is not possible. The PCA mode of therapy minimizes the roller-coaster effect of peaks of sedation and valleys of pain that occur with the traditional method of prn dosing. With the parenteral routes, the client administers a predetermined dose of an opioid by an electronic infusion pump. This allows the client to maintain a more constant level of relief yet requires less medication for pain relief. PCA can be effectively used for clients with acute pain related to a surgical incision, traumatic injury, or labor and delivery, and for chronic pain as with cancer.

The prescriber orders the analgesic, dose, demand (bolus) dose interval, and lockout interval. Standardized medications and order sets are recommended. The most commonly used opioids for PCA are morphine, hydromorphone (Dilaudid), and fentanyl. Meperidine (Demerol) is no longer recommended for PCA use because of toxic CNS effects (e.g., seizures) when administered by continuous infusion (D'Arcy, 2011; Pasero & McCaffery, 2011). Whether in an acute hospital setting, an ambulatory clinic, or with home care, the nurse is responsible for the initial instruction regarding use of the PCA. To avoid incorrect pump programming, two registered nurses should double-check the initial settings and for any changes in dose or medication and both should document this on the medical record (Pasero & McCaffery, 2011). The nurse also is responsible for ongoing monitoring of the therapy (i.e., checking every 2 to 4 hours). The client's pain level, respiratory rate, sedation level, ability to understand, and use of the device must be assessed at regular intervals. Postoperative clients may also have oxygen levels or carbon dioxide levels monitored. Some PCA pumps have an in-line capnography system that monitors carbon dioxide levels while the PCA is being used (D'Arcy, 2011). Analgesic use is documented in the client's record. The most significant adverse effects are respiratory depression and hypotension; however, they occur rarely.

Although PCA pumps vary in design, they all have similar protective features. The line of the PCA pump, a syringe-type pump, is usually introduced into the injection port of a primary IV fluid line (Figure 46–10 ■). The primary care provider determines the drug concentration (amount of drug per milliliter of solution), the PCA bolus dose (amount of medication the client will receive when a bolus is self-administered), and the lockout, which is also called the delay interval (the amount of time that must pass between PCA doses). When clients need a dose of analgesic, they push a button attached to the infusion pump and a preset dose (bolus) is delivered. The lockout interval is usually set at 6 or 8 minutes for postoperative clients. This means that the client can give himself a dose of medication every 6 or 8 minutes. Even if the client pushes the button more frequently, the client will receive only one bolus dose during the lockout interval. The primary care provider can also prescribe an hour interval, which determines the maximum amount of opioid a client can receive in an hour-limit time period. Most PCA pumps can be programmed for a 1-hour or a 4-hour limit. The 1-hour limit is preferable because it allows for closer PCA monitoring by the nurse; that is, the nurse is alerted earlier if the client is not receiving adequate analgesia and requires an increase in opioid dose (Pasero & McCaffery, 2011). Many pumps are capable of delivering a basal rate (continuous infusion), with or without additional PCA doses administered by the client. This practice is no longer recommended for opioid-naïve clients due to the risk of oversedation. It is more appropriate, if not necessary, for the postoperative client who is opioid tolerant and experiencing chronic pain. This client, when NPO, may need to have their usual daily opioid oral medication dose changed to PCA delivery (D'Arcy, 2011, p. 213).

As PCA has increased in use, so have errors and other problems, such as adverse (untoward, undesirable, and usually unanticipated) events. Problems that reduce PCA safety include improper client selection, programming errors, and PCA by proxy.

Clients who use PCA must be able to understand how to use PCA and be able to physically push the button independently. Clients who are not good candidates for PCA include infants and young children who do not understand how to safely use PCA, confused older clients, individuals who are obese or have asthma or sleep apnea, and clients taking other drugs that potentiate opioids, such as muscle relaxants.

Improperly programming the PCA pump is the most common human error (Pasero & McCaffery, 2011). Examples of errors include confusing milliliters and milligrams, decimal point errors (i.e., order is for 0.5 mg and the pump is programmed for 5 mg), using the loading dose for the bolus dose, and wrong lockout settings. To increase safety upon PCA initiation, many institutions now require that two nurses independently check client ID, drug and concentration, and PCA pump settings.

PCA by proxy is a term that describes activation of the PCA pump by *anyone other than the client* (Cooney et al., 2013). For example, a well-intentioned family member may push the button when the client is sleeping or already sedated, leading to oversedation. A natural safety feature of PCA is that a client who is sleeping or sedated will not push the button and overmedicate himself. That is why it is important that the client is the only person to push the button. To counteract this, some institutions put signs on the PCA pump stating “only the client to push PCA button.”

The ASPMN differentiates between PCA by proxy (unauthorized activation of the pump) and authorized agent–controlled analgesia (AACA). AACA is a method of pain control in which a consistently available and competent individual is authorized by a

LIFESPAN CONSIDERATIONS PCA Pump

CHILDREN

- Include the parents in teaching.
- Assess the child’s ability to understand and use the client control button. Pasero and McCaffery (2011) report that “PCA has been used effectively and safely in developmentally normal children as young as 4 years old” (p. 314).
- Use distraction techniques to avoid dislodgement or disconnection by the child.
- Use pediatric elbow immobilizers (no-nos, Snuggle Wraps) if distraction is not effective in keeping the child from playing with tubing and ports.

OLDER ADULTS

- Carefully monitor for drug side effects.
- Use cautiously for individuals with impaired pulmonary or renal function.
- Assess the client’s cognitive and physical ability to use the client control button.

prescriber and properly educated to push the PCA button when the client is unable to and in response to the client’s pain (Cooney et al., 2013, p. 178). Nurse-controlled analgesia (NCA) is the term used when the authorized person is the nurse responsible for the client. The term is caregiver–controlled analgesia (CCA) when a nonprofessional individual (e.g., parent, significant other) is the authorized person. AACA is not appropriate if the client is determined to be able to use PCA.

CLIENT TEACHING

Client Self-Management of Pain

Choose a time to teach the client about pain management when the pain is controlled so that the client is able to focus on the teaching. Teaching about self-management of pain may include the following:

- Demonstrate the operation of the PCA pump and explain that the client can safely push the button without fear of overmedicating. Sometimes it helps clients who are reluctant to repeatedly push the button to know that they must dose themselves (i.e., push the button) 5 to 10 times to receive the same amount of medication (10 mg morphine equivalent) they would receive in a standard “shot.”
- Describe the use of the pain scale and encourage the client to respond in order to demonstrate understanding.
- Explore a variety of nonpharmacologic pain relief techniques that the client is willing to learn and use to promote pain relief and optimize functioning.
- Explain to the client the need to notify staff when ambulation is desired (e.g., for bathroom use) if applicable.

Nonpharmacologic Pain Management

Nonpharmacologic pain management consists of a variety of physical, cognitive–behavioral, and lifestyle pain management strategies that target the body, mind, spirit, and social interactions (Table 46–8). Physical modalities include cutaneous stimulation, ice or heat, immobilization or therapeutic exercises, transcutaneous electrical nerve stimulation (TENS), and acupuncture. Mind–body (cognitive–behavioral) interventions include distracting activities, relaxation techniques, imagery, meditation, biofeedback, hypnosis, cognitive reframing, emotional counseling, and spiritually directed approaches such as therapeutic touch or Reiki. Lifestyle management approaches include symptom monitoring, stress management, exercise, nutrition, pacing activities, disability management, and other approaches needed by many clients with persistent pain that has drastically changed their life. For further information on selected mind–body interventions and acupuncture, see Chapter 19 ∞. This discussion is limited to selected physical and cognitive–behavioral interventions.

Home Care Considerations PCA Pump

SAFETY

- Monitor for signs and symptoms of oversedation such as excessive drowsiness, slowed respiratory rate, or change in mental state.
- Do not adjust settings without consulting with the appropriate primary care provider.
- Tape to the back of the pump the following emergency contact numbers: emergency medical services, primary care provider, home care agency, and pump manufacturer.

TABLE 46-8 Nonpharmacologic Interventions for Pain Control

Target Domain of Pain Control	Intervention
Body	Reducing pain triggers, promoting comfort Massage Applying heat or ice Electrical stimulation (TENS) Positioning, bracing (selective immobilization) Acupressure Diet, nutritional supplements Exercise, pacing activities Invasive interventions (e.g., blocks) Sleep hygiene
Mind	Relaxation, imagery Self-hypnosis Pain diary, journal writing Distracting attention Repatterning thinking Attitude adjustment Reducing fear, anxiety, stress Reducing sadness, helplessness Information about pain Music therapy
Spirit	Prayer, meditation Self-reflection regarding life and pain Meaningful rituals Energy work (e.g., therapeutic touch, Reiki) Spiritual healing
Social interactions	Functional restoration Improved communication Pet therapy Family therapy Problem solving Vocational training Volunteering Support groups

Physical Interventions: Cutaneous Stimulation

The goals of physical intervention include providing comfort, altering physiological responses to reduce pain perception, and optimizing functioning. Cutaneous stimulation can provide effective temporary pain relief. It distracts the client and focuses attention on the tactile stimuli, away from the painful sensations, thus reducing pain perception. Cutaneous stimulation is also believed to interfere with the transmission and perception of pain by stimulating the large-diameter A-beta sensory nerve fibers that close the gate by activating the descending mechanisms that can reduce the intensity of pain, activate the endorphin system of pain control, and thus diminish conscious awareness of pain. Selected cutaneous stimulation techniques include the following:

- Massage
- Application of heat or cold
- Acupressure
- Contralateral stimulation.

Cutaneous stimulation can be applied directly to the painful area, proximal to the pain or distal to the pain (along the nerve path or dermatome), and contralateral (exact location, opposite side of the body) to the pain. Cutaneous stimulation is contraindicated in areas of skin breakdown or impaired neurologic functioning.

Massage Massage is a comfort measure that can aid relaxation, decrease muscle tension, and may ease anxiety because the physical contact communicates caring. It can also decrease pain intensity by increasing superficial circulation to the area. Massage can involve the back and neck, hands and arms, or feet. The use of ointments or liniments may provide localized pain relief with joint or muscle pain. Massage is contraindicated in areas of skin breakdown, suspected clots, or infections. See Skill 46-1.

Providing a Back Massage

Effleurage is a type of massage consisting of long, slow, gliding strokes. Research demonstrates that back massage can enhance client comfort, relaxation, and sleep.

PURPOSES

- To relieve muscle tension
- To decrease pain intensity
- To promote physical and mental relaxation

- Vital signs, skin color and temperature, nail bed color, and tissue perfusion of extremities as baseline data
- Adhesive allergy

ASSESSMENT

Assess

- Behaviors indicating potential need for a back massage, such as a complaint of stiffness, muscle tension in the back or shoulders, or difficulty sleeping related to tenseness or anxiety
- Whether the client is willing to have a massage, because some individuals may not enjoy a massage

- Contraindications for back massage (e.g., coagulation issues, clots, impaired skin integrity, back surgery, vertebral issues, or risk of fracture)

Providing a Back Massage – continued

PLANNING

Ensure that you have adequate time available for the massage. Although the actual skill may require only about 5 minutes, the entire process should be conducted in a calm and unhurried manner.

DELEGATION

The nurse can delegate this skill to UAP; however, the nurse should first assess for UAP's comfort and ability, any contraindications, and client willingness to participate.

IMPLEMENTATION

Preparation

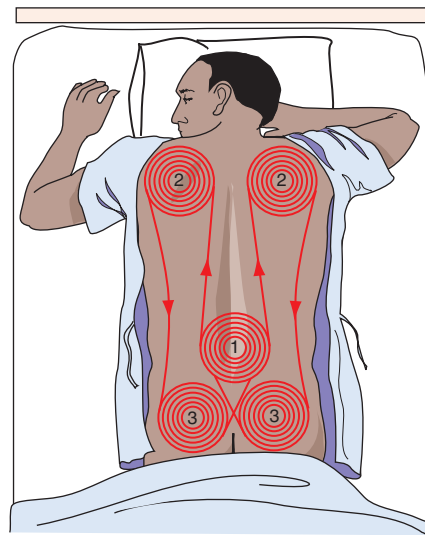

Determine (a) previous assessments of the skin, (b) special lotions to be used, and (c) positions contraindicated for the client. Arrange for a quiet environment with no interruptions to promote maximum effect of the back massage.

Performance

- Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Encourage the client to give you feedback as to the amount of pressure you are using during the back rub.
- Perform hand hygiene and observe other appropriate infection prevention procedures.
- Provide for client privacy.
- Prepare the client.
 - Assist the client to move to the near side of the bed within your reach and adjust the bed to a comfortable working height. **Rationale:** *This prevents back strain.*
 - Establish which position the client prefers. The prone position is recommended for a back rub. The side-lying position can be used if a client cannot assume the prone position.
 - Expose the back from the shoulders to the inferior sacral area. Cover the remainder of the body. **Rationale:** *This is to prevent chilling and minimize exposure.*
- Massage the back.
 - Pour a small amount of lotion onto the palms of your hands and hold it for a minute. The lotion bottle can also be placed in a bath basin filled with warm water. **Rationale:** *Back rub preparations tend to feel uncomfortably cold to people. Warming the solution facilitates client comfort.*
 - Using your palm, begin in the sacral area using smooth, circular strokes.
 - Move your hands up the center of the back and then over both scapulae.
 - Massage in a circular motion over the scapulae.
 - Move your hands down the sides of the back.
 - Massage the areas over the right and left iliac crests. Massage the back in an orderly pattern using a variety of strokes and appropriate pressure. ①
 - Apply firm, continuous pressure without breaking contact with the client's skin.

Equipment

- Lotion
- Towel for excess lotion

① One suggested pattern for a back massage.

- Repeat above for 3 to 5 minutes, obtaining more lotion as necessary.
 - While massaging the back, assess for skin redness and areas of decreased circulation.
 - Pat dry any excess lotion with a towel.
- Document that a back massage was performed and the client's response. Record any unusual findings.

SAMPLE DOCUMENTATION

6/22/2015 1400 Reports aching, intermittent back pain. Wincing and grimacing when attempting to move in bed. Rates pain at 4–5 on 0–10 scale. States uses massage to help relieve pain when at home. Back massaged. Stated the massage helped him “to relax.” Lights dimmed and door to room closed. _____ D. Aubrey, RN

1430 Reports pain at 1–2/10. States feels “much more comfortable.” Moving in bed with ease. _____ D. Aubrey, RN

EVALUATION

Compare the client's current response to his or her previous response. Is there a positive client outcome such as increased relaxation and decrease in pain and anxiety because of the back massage?

Heat and Cold Applications A warm bath, heating pads, ice bags, ice massage, hot or cold compresses, and warm or cold sitz baths in general relieve pain and promote healing of injured tissues (see Chapter 36 ∞). Cold works best when applied within the first 24 hours of injury or condition, while heat is primarily used to treat the chronic phase of an injury or condition, usually 48 hours after an acute injury.

Acupressure Acupressure developed from the ancient Chinese healing system of acupuncture. The therapist applies finger pressure to points that correspond to many of the points used in acupuncture (see Chapter 19 ∞).

Contralateral Stimulation Contralateral stimulation can be accomplished by stimulating the skin in an area opposite to the painful area (e.g., stimulating the left knee if the pain is in the right knee). The contralateral area may be scratched for itching, massaged for cramps, or treated with cold packs, heat application, or analgesic ointments. This method is particularly useful when the painful area cannot be touched because it is hypersensitive, when it is inaccessible by a cast or bandages, or when the pain is felt in a missing part (phantom pain). The nurse should explain the rationale to the client in that nerves are crossed in the spinal cord, and that is why these techniques may work contralaterally.

Immobilization/Bracing

Immobilizing or restricting the movement of a painful body part (e.g., arthritic joint, traumatized limb) may help to manage episodes of acute pain. Splints or supportive devices should hold joints in the position of optimal function and should be removed regularly in accordance with agency protocol to provide range-of-motion (ROM) exercises. Prolonged immobilization can result in joint contracture, muscle atrophy, and cardiovascular problems. Therefore, clients should be encouraged to participate in self-care activities and remain as active as possible, with frequent ROM exercises.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a method of applying low-voltage electrical stimulation directly over identified pain areas, at an acupressure point, along peripheral nerve areas that innervate the pain area, or along the spinal column. The TENS unit consists of a portable, battery-operated device with lead wires and electrode pads that are applied to the chosen area of skin (Figure 46–11 ■). Cutaneous stimulation from the TENS unit is thought to activate large-diameter fibers that modulate the transmission of the nociceptive impulse in the peripheral and central nervous systems (closing the pain “gate”), resulting in pain relief. This stimulation may also cause a release of endorphins from the CNS centers. The use of TENS is contraindicated for clients with pacemakers or arrhythmias, or in areas of skin breakdown. It is generally not used on the head or over the chest.

Cognitive–Behavioral Interventions

The goals of cognitive–behavioral interventions include providing comfort, altering psychological responses to reduce pain perception, and optimizing functioning. Selected cognitive–behavioral interventions include distraction, eliciting the relaxation response, repatterning thinking, and facilitating coping with emotions.

Distraction Distraction draws the person’s attention away from the pain and lessens the perception of pain. In some instances, it can

Figure 46–11 ■ A transcutaneous electrical nerve stimulator.
Hilary Morgan/Alamy.

BOX 46–9 Types of Distraction

VISUAL DISTRACTION

- Reading or watching television
- Video and computer games (also tactile)
- Watching a baseball game
- Guided imagery

AUDITORY DISTRACTION

- Humor
- Music

TACTILE DISTRACTION

- Slow, rhythmic breathing
- Massage
- Holding or stroking a pet or toy

INTELLECTUAL DISTRACTION

- Crossword puzzles, Sudoku number puzzles
- Card games
- Hobbies

make a client completely unaware of pain. Distraction makes the person unaware of the pain only for the amount of time and to the extent that the distracting activity holds his or her “undivided” attention. For example, a client recovering from surgery may feel no pain while watching a football game on television, yet feel pain again during commercials or when the game is over. Different types of distractions are shown in Box 46–9. Using multiple forms of distraction simultaneously adds value to the activity. For example, listening to music can be distracting; however, the value can be added by tapping to the music, singing along, or playing along on a musical instrument. Play therapy can be a distraction for children.

Eliciting the Relaxation Response Stress increases pain, in part by increasing muscle tension, activating the sympathetic nervous system, and putting the client at risk for stress-related types of pain (e.g., tension headaches). The relaxation response decreases and counteracts the harmful effects of stress, including the effect it has

on physical, cognitive, and emotional functioning. Producing this response requires more than simply helping a person to relax; rather it involves a structured technique designed to focus the mind and relax muscle groups. Basic techniques with helpful scripts are available for common techniques including progressive relaxation, breath-focus relaxation, and meditation. The nurse can coach the client, urge self-directed meditation, or provide an audiotaped guide to help elicit the relaxation response. Many clients can achieve the desired state after a few attempts, but mastery of this skill requires daily practice over a few weeks. In general, relaxation techniques by themselves do not have remarkable pain-relieving properties; however, they can reduce pain that may have been exacerbated by stress. Some clients may become more consciously aware of their pain while practicing relaxation techniques before they have learned mastery of controlling “mind chatter” and remaining mentally focused.

Once the client has mastered the basic skills for eliciting the relaxation response, techniques of imagery or self-hypnosis can be used. Both imagery and hypnosis begin with attaining a deep state of relaxation and are capable of altering the experience of pain; for example, having the client replace the pain with a feeling of pleasant numbness. Additional post-hypnotic suggestions can then be made, linking these pleasant numb sensations to coping efforts used during the day (e.g., “Every time you stop to take a slow, deep, diaphragmatic breath, you will feel this pleasant numbness instead of pain”).

Music therapy can also be useful for providing relaxation and distraction from pain (D’Arcy, 2011). With iPods and portable CD players, clients can listen to their favorite tunes as a helpful distraction from pain.

Repatterning Unhelpful Thinking Some people harbor strong self-doubts, unrealistic expectations (e.g., “I just want someone to make the pain go away”), rumination (e.g., “I keep thinking about my pain and the person who did this to me”), helplessness (e.g., “I can’t do anything”), and magnification (e.g., “My life is ruined, I’ll never be a good parent because of my pain”). These cognitive patterns have been identified as important contributors to treatment failures and the intensification of pain, disability, and depression. Nurses can help by challenging the truthfulness and helpfulness of these thoughts, and replacing them with realistic and confidence-building ones that are particularly powerful predictors of more effective coping, better clinical outcomes, and improved quality of life.

Facilitating Coping Nurses can help by intervening with clients who are anxious, are sad, or express overly pessimistic or helpless points of view. Awareness of the client’s misperceptions or unrealistic expectations also helps the professional avoid a common cause of therapeutic failure. Therapeutic communication with an emphasis on listening, providing encouragement, teaching self-management skills, sharing vicarious experiences, and persuading them to act on their own behalf are strategies that enhance coping. Helping clients to better communicate with the professional staff, family members, and friends can also promote coping. Counseling from trained professionals may be indicated for those clients with severe emotional distress, but must be offered to them in a sensitive way that does not convey the notion that pain is “in their head.” Chronic pain support groups have been effective for many clients.

Selected Spiritual Interventions

The spiritual dimension encompasses a person’s innermost concerns and values, including the ascribed purpose, meaning, and driving force in his or her life. It may include rituals that help the individual become part of a community or feel a bond with the universe that is not necessarily religious in nature. For those who express their spirituality in a religious context, it is appropriate to offer prayer, intercessory prayer (being prayed for by others), or access to meaningful rituals. For some clients, a caring presence, attentive listening, and facilitating the process of acceptance can help reduce spiritual distress, whereas other clients benefit from manipulation of energy patterns (e.g., therapeutic touch).

Some clients may view pain as a punishment from God, as illustrated in the Mexican American cultural concept of *castigo* (punishment). For them, it could be helpful to provide opportunities to discuss their situation with a culturally aware resource person well versed in theology (e.g., a clergyperson). To hold such beliefs inside without attempting to increase understanding can contribute to pain and suffering.

When using imagery techniques with clients, multisensory input relating to spiritual and religious experience can be powerfully healing. Seek understanding of the client’s needs, preferences, and fears in this area. For some, imagining themselves being held in the loving arms or presence of healing light, God, the mother Mary, Buddha, or some other figure can be very comforting.

When using relaxation breathing techniques with clients, the breath can be viewed as a direct connection with God and life energy. The word *inspiration* means “to take in the spirit.” The image of breathing in the healing spirit, and breathing out the pain, can be calming and empowering. To say to oneself while breathing in, “I am breathing in the healing power of God,” and out, “I am releasing my pain as I breathe out,” can serve as powerful, faith-based affirmations for cognitive restructuring.

Through improved spiritual insights, individuals with pain can find meaning in what seems incomprehensible and learn to cope with the intolerable. This process often begins by making peace with their past, being spiritually aware in the present, and making a commitment to go forward with life despite the pain (Arnstein, 2010). By shifting awareness from within to external sources of power, pain sufferers can transcend the limits of their pain to find new energy and a renewed sense of purpose.

Nonpharmacologic Invasive Therapies

A **nerve block** is a chemical interruption of a nerve pathway, caused by injecting a local anesthetic into the nerve. Nerve blocks are widely used during dental work. The injected drug blocks nerve pathways from the painful tooth, thus stopping the transmission of pain impulses to the brain. Nerve blocks are often used to relieve the pain of whiplash injury, lower back disorders, bursitis, and cancer. With the intention of quieting “pain generators” (irritable nerves that cause the pain), a combination of a long-acting local anesthetic and a steroid is injected adjacent to the problem nerve (e.g., lumbar epidural steroid injections, joint injections). The local anesthetic should provide relief for several hours, before the effect of the steroid begins a day or two later. Often a series of three injections is scheduled weeks or months apart. Each subsequent injection should result in a longer duration of pain relief. No more than three injections per year are recommended because of the mineral-robbing effect steroids have on bones in the area.

LIFESPAN CONSIDERATIONS Pain Management**INFANTS**

Giving an infant, particularly a very-low-birth-weight infant, a water and sucrose solution administered through a pacifier provides some pain reduction during procedures that may be painful, but should not be a substitute for anesthetic or analgesic medications.

CHILDREN

- Distract the child with toys, books, or pictures.
- Hold the child (or ask the parent to hold) to console and promote comfort.
- Explore misconceptions about pain and correct in understandable “concrete” terms. Be aware of how your explanations may be misunderstood. For example, telling a child he won’t hurt during surgery because he will be “put to sleep” will be very upsetting to a child who knows of an animal that was “put to sleep.”
- Children can use their imagination during guided imagery. Ask the child to imagine a “pain switch” (even give it a color) and to

visualize turning the switch off in the area where there is pain. A “magic glove” or “magic blanket” is an imaginary object that the child applies on areas of the body (e.g., hand, thigh, back, hip) to lessen discomfort.

OLDER ADULTS

- Promote clients’ use of pain control measures that have worked in the past for them.
- Spend time with clients and listen carefully.
- Clarify misconceptions. Encourage independence whenever possible.
- Carefully review the treatment plan to avoid drug–drug, food–drug, or disease–drug interactions.
- Physicians and nurse practitioners with advanced certification in hospice and palliative medicine (HPM) are often members of the intraprofessional team that works with the client and family to provide the best possible hospice care.

Evaluating

The goals established in the planning phase are evaluated according to specific desired outcomes, also established in that phase. To assist in the evaluation process, flow sheet records or a client diary may be helpful. A weekly log or diary can be structured in a similar fashion for the individual client. For example, columns including day, time, onset of pain, activity before pain, pain relief measure, and duration of pain can be devised to help the client and nurse determine the effectiveness of pain relief strategies.

CLINICAL ALERT!

The statement “Please tell me how I can best help you control your pain” sends a couple of subtle messages that are an important part of treatment planning and evaluation of care. First, it places the ownership and responsibility for controlling pain on the client. Second, it acknowledges that the client may be the best judge of what is needed, respecting the cultural meaning of pain and acceptable ways of expressing/controlling pain. Third, it establishes the nurse’s role in helping the client be more comfortable and in control of his or her condition.

If outcomes are not achieved, the nurse and client need to explore the reasons before modifying the care plan. The nurse might consider the following questions:

- Is adequate analgesic being given? Would the client benefit from a change in dose or in the time interval between doses or in the type of analgesic?
- Were the client’s beliefs, expectations, and values about pain therapy considered?
- Did the client understate the pain experience for some reason?
- Were appropriate instructions provided to allay misconceptions about pain management?
- Did the client and support people understand the instructions about pain management techniques?
- Is the client receiving adequate support for both physical pain and emotional distress?
- Has the client’s physical condition changed, necessitating modifications in interventions?
- Should selected intervention strategies be reevaluated?

See the Nursing Care Plan and the Concept Map.

Home Care Considerations Pain Management**PATIENT-CENTERED CARE**

- Teach the client to keep a pain diary to monitor pain onset, activity before pain, pain intensity, use of analgesics, or other relief measures and effectiveness of each measure.
- Instruct the client to contact a health care professional if planned pain control measures are ineffective.
- Teach the use of preferred and selected nonpharmacologic techniques such as relaxation, guided imagery, distraction, music therapy, and massage.
- Instruct the client to use pain control measures before the pain becomes severe.
- Inform the client of the effects of untreated pain.
- Provide appropriate information about how to access community resources, home care agencies, and associations that offer self-help groups and educational materials.

Critical Thinking Checkpoint

Mrs. Lundahl underwent abdominal surgery approximately 6 hours ago. She has a 15-cm midline incision that is covered with a dry, intact surgical dressing. On assessment, you note that Mrs. Lundahl is perspiring, lying in a rigid position, holding her abdomen, and grimacing. Her blood pressure is 150/90 mmHg, heart rate 100 beats/min, and respiratory rate 32/min. When asked to rate her pain on a scale of 0 to 10, Mrs. Lundahl rates her pain as 5 as long as she remains perfectly still. There is a sharp area of pain at her incision; however, the most bothersome pain is crampy and dull, like she was “kicked in the stomach” with severe exacerbations that come in unpredictable waves.

1. What conclusions, if any, can be drawn about Mrs. Lundahl's pain status?
2. Does Mrs. Lundahl's rating her pain as 5 mean that she is not experiencing pain severe enough to warrant intervention?
3. What type of pain is Mrs. Lundahl experiencing?
4. What interventions, in addition to pain medication, may be useful in reducing Mrs. Lundahl's pain?
5. How will you know if your interventions have been effective in reducing Mrs. Lundahl's pain?

See Critical Thinking Possibilities on student resource website.

NURSING CARE PLAN Acute Pain

Assessment Data

Nursing Assessment

Mr. C. is a 57-year-old businessman who was admitted to the surgical unit for treatment of a possible strangulated inguinal hernia. Two days ago he had a partial bowel resection. Postoperative orders include NPO, IV infusion of D₅ ½NS at 125 mL/h left arm, nasogastric tube to low intermittent suction. Mr. C. is in a dorsal recumbent (supine) position and is attempting to draw up his legs. He appears restless and is complaining of abdominal pain (7 on a scale of 0–10).

Physical Examination

Height: 188 cm (6' 3")
 Weight: 90.0 kg (200 lb)
 Temperature: 37°C (98.6°F)
 Pulse: 90 beats/min
 Respirations: 24/min
 Blood pressure: 158/82 mmHg
 Skin pale and moist, pupils dilated. Midline abdominal incision, sutures dry and intact.

Diagnostic Data

Chest x-ray and urinalysis negative, WBC 12,000

Nursing Diagnosis

Acute Pain related to tissue injury secondary to surgical intervention (as evidenced by restlessness; pallor; elevated pulse, respirations, and systolic blood pressure; dilated pupils; and report of 7/10 abdominal pain)

Desired Outcomes*

Pain Control [1605] as evidenced by often demonstrating ability to:

- Use analgesics as recommended.
- Use nonanalgesic relief measures.
- Report uncontrolled symptoms to health care professional.

Pain Level [2102] as evidenced by mild to no:

- Reported pain
- Restlessness
- Perspiration
- Change in BP, HR, R from normal baseline data.

Nursing Interventions*/Selected Activities

Pain Management [1400]

Perform a comprehensive assessment of pain to include location, characteristics, onset, duration, frequency, quality, intensity or severity, and precipitating factors of pain.

Consider cultural influences on pain response (e.g., cultural beliefs about pain may result in a stoic attitude).

Reduce or eliminate factors that precipitate or increase Mr. C.'s pain experience (e.g., fear, fatigue, monotony, and lack of knowledge).

Teach the use of nonpharmacologic techniques (e.g., relaxation, guided imagery, music therapy, distraction, and massage) before, after, and if possible during painful activities; before pain occurs or increases; and in combination with other pain relief measures.

Provide Mr. C. optimal pain relief with prescribed analgesics.

Medicate before an activity to increase participation, but evaluate the hazard of sedation.

Evaluate the effectiveness of the pain control measures used through ongoing assessment of Mr. C.'s pain experience.

Rationale

Pain is a subjective experience and must be described by the client in order to plan effective treatment.

Each person experiences and expresses pain in an individual manner using a variety of sociocultural adaptation techniques.

Personal factors can influence pain and pain tolerance. Factors that may be precipitating or augmenting pain should be reduced or eliminated to enhance the overall pain management program.

The use of noninvasive pain relief measures can increase the release of endorphins and enhance the therapeutic effects of pain relief medications.

Each client has a right to expect maximum pain relief. Optimal pain relief using analgesics includes determining the preferred route, drug, dosage, and frequency for each individual. Medications ordered on a prn basis should be offered to the client at the interval when the next dose is available.

Turning and ambulation activities will be enhanced if pain is controlled or tolerable. Assessing level of sedation should precede the activity to ensure necessary safety precautions are put in place.

Research shows that the most common reason for unrelieved pain is failure to routinely assess pain and pain relief. Many clients silently tolerate pain if not specifically asked about it.

(continued)

NURSING CARE PLAN Acute Pain—continued

Analgesic Administration [2210]

Check the medical order for drug, dose, and frequency of analgesic prescribed.

Determine analgesic selections (narcotic, nonnarcotic, or NSAID) based on type and severity of pain.

Institute safety precautions as appropriate if Mr. C. receives opioid analgesics.

Instruct Mr. C. to request prn pain medication **before** the pain is severe.

Evaluate the effectiveness of analgesic at regular, frequent intervals after each administration and especially after the initial doses, also observing for any signs and symptoms of untoward effects (e.g., constipation, nausea and vomiting, dry mouth, and respiratory depression).

Document Mr. C.'s response to analgesics and any untoward effects.

Implement actions to decrease untoward effects of analgesics (e.g., constipation and gastric irritation).

Ensures that the nurse has the right drug, right route, right dosage, right client, right frequency.

Various types of pain (e.g., acute, chronic, nociceptive, neuropathic) require different analgesic approaches. Some types of pain respond to nonopioid drugs alone, while others can be relieved by combining a low-dose opioid with a nonopioid.

Side effects of opioids include drowsiness and sedation.

Severe pain is more difficult to control and increases the client's anxiety and fatigue. The preventive approach to pain management can reduce the total 24-hour analgesic dose.

The analgesic dose may not be adequate to raise the client's pain threshold or may be causing intolerable or dangerous side effects or both. Ongoing evaluation will assist in making necessary adjustments for effective pain management.

Documentation facilitates pain management by communicating effective and noneffective pain management strategies to the entire health care team.

Constipation is the most common side effect of opioids, and a treatment plan to prevent occurrence should be instituted at the beginning of analgesic therapy. For Mr. C., constipation could result from his primary condition or his analgesia. Assess for overall GI functioning, possible complications of surgery (e.g., ileus), as well as opioid-induced constipation or NSAID-induced gastritis.

Nursing Interventions*/Selected Activities

Simple Relaxation Therapy [6040]

Consider Mr. C.'s willingness and ability to participate, preference, past experiences, and contraindications before selecting a specific relaxation strategy.

Elicit behaviors that are conditioned to produce relaxation, such as deep breathing, yawning, abdominal breathing, or peaceful imaging.

Create a quiet, nondisruptive environment with dim lights and comfortable temperature when possible.

Individualize the content of the relaxation intervention (e.g., by asking for suggestions about what Mr. C. enjoys or finds relaxing).

Demonstrate and practice the relaxation technique with Mr. C.

Evaluate and document his response to relaxation therapy.

Rationale

The client must feel comfortable trying a different approach to pain management. To avoid ineffective strategies, the client should be involved in the planning process.

Relaxation techniques help reduce skeletal muscle tension, which will reduce the intensity of the pain.

Comfort and a quiet atmosphere promote a relaxed feeling and permit the client to focus on the relaxation technique rather than external distraction.

Each person may find different images or approaches to relaxation more helpful than others. The nurse should have a variety of relaxation scripts or audiovisual aids to help clients find the best one for them.

Return demonstrations by the participant provide an opportunity for the nurse to evaluate the effectiveness of teaching sessions.

Conveys to the health care team effective strategies in reducing or eliminating pain.

Evaluation

Outcomes partially met. The client verbalizes pain and discomfort, requesting analgesics at onset of pain. States "the pain is a 2" (on a scale of 0–10) 30 minutes after an IV analgesic administration. Requests analgesic 30 minutes before ambulation. States willingness to try relaxation techniques; however, has not attempted to do so.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, indicators, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

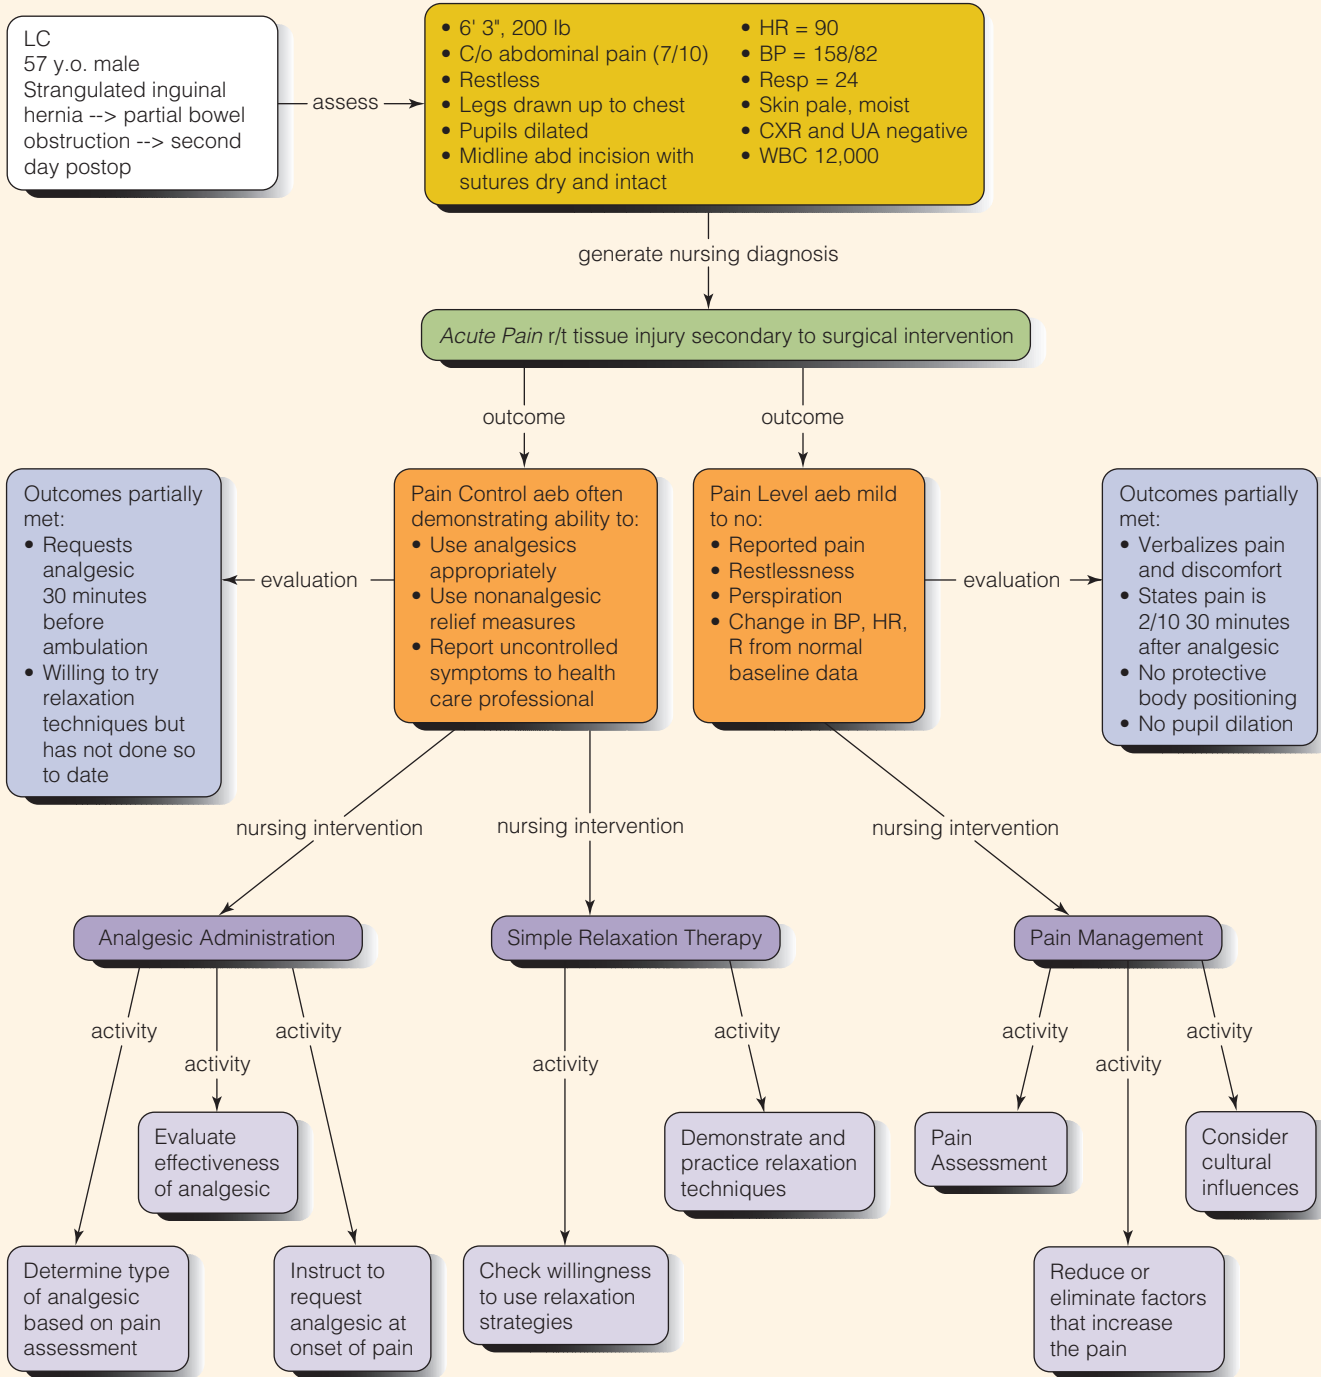

Applying Critical Thinking

1. Is there any other assessment data you would want to gather to help plan Mr. C.'s pain management?
2. Mr. C. does not have a PCA. What nursing interventions are important?
3. What kind of data would you gather prior to having a discussion with the primary care provider about options for improving pain control in this client?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Acute Pain

Chapter 46 Review

CHAPTER HIGHLIGHTS

- Pain is “whatever the person says it is, and exists whenever he says it does.” It is a subjective sensation to which no two people respond in the same way. It can directly impair health and prolong recovery from surgery, disease, and trauma.
- Types of pain may be described in terms of location, duration, intensity, and etiology.
- Pain threshold is generally similar in all people, but pain tolerance and response vary considerably among individuals.
- The physiological processes related to pain perception are described as nociception. Four processes are involved in nociception: transduction, transmission, perception, and modulation.
- For nociceptive pain to be perceived, nociceptors must be stimulated. Three types of pain stimuli are mechanical, thermal, and chemical.
- According to the gate control theory, peripheral nerve fibers carrying pain to the spinal cord can have their input modified at the spinal cord level before transmission to the brain. This theory is the basis of many pain intervention strategies, especially nonpharmacologic interventions.
- Numerous factors influence a person’s perception and reaction to pain: ethnic and cultural values, developmental stage, environment and support people, previous pain experiences, and meaning of pain.
- Pain is subjective, and the most reliable indicator of the presence or intensity of pain is the client’s self-report. Pain assessment is the fifth vital sign. Assessment of a client who is experiencing pain should include a comprehensive pain history.
- Although the nursing diagnosis given to clients experiencing pain is *Acute Pain* or *Chronic Pain*, the pain itself may be the etiology of many other nursing diagnoses.
- Overall client goals include preventing, modifying, or eliminating pain so that the client is able to partly or completely resume usual daily activities and to cope more effectively with the pain experience.
- When planning, nurses need to choose pain relief measures appropriate for the client, based on assessment data.
- Pain management includes two basic types of nursing interventions: pharmacologic and nonpharmacologic.
- Key strategies to reduce pain include acknowledging and accepting the client’s pain, assisting support people, reducing misconceptions about pain, reducing fear and anxiety, and preventing pain.
- Pharmacologic interventions, ordered by the physician (or nurse practitioner), include the use of opioids, nonopioids such as NSAIDs, and coanalgesic drugs.
- The World Health Organization recommends a three-step analgesic ladder approach to manage chronic cancer pain. This model establishes the pharmacologic foundation on which other types of pain are managed.
- Placebos should never be used to determine whether or not someone is in pain. Deceptive use of placebos is unethical.
- Analgesic medication can be delivered through a variety of routes and methods to meet the specific needs of the client. These routes include oral, transnasal, transdermal, transmucosal, rectal, topical, subcutaneous, intramuscular, IV, and intraspinal, and also as continuous local anesthetics.
- Patient-controlled analgesia enables the client to exercise control and treat the pain by self-administering doses of analgesics.
- Physical modalities of nonpharmacologic pain interventions include cutaneous stimulation such as massage, hot and cold applications, acupressure, and contralateral stimulation; immobilization/bracing; and transcutaneous electrical nerve stimulation (TENS).
- Cognitive-behavioral interventions include distraction techniques, eliciting the relaxation response, repatterning thinking, facilitating coping, and selected spiritual interventions.
- Evaluation of the client’s pain therapy includes the response of the client, the changes in the pain, and the client’s perceptions of the effectiveness of the therapy. Ongoing verbal or written feedback from the client and family is integral to this process.

TEST YOUR KNOWLEDGE

1. During the transduction phase of nociception, which method of pain control is most effective?
 1. Tricyclic antidepressants
 2. Opioids
 3. Ibuprofen
 4. Distraction
2. When a client has arrived at the nursing unit from surgery, the nurse is most likely to give priority to which of the following assessments?
 1. Pain tolerance
 2. Pain intensity
 3. Location of pain
 4. Pain history
3. A client who describes his pain as 7 on a scale of 0 to 10 is classified as having which of the following?
 1. No pain
 2. Mild pain
 3. Moderate pain
 4. Severe pain
4. A client who had abdominal surgery 4 hours ago is receiving a continuous epidural infusion of an analgesic. Which of the following observations indicates the nurse should monitor the client closely?
 1. Drowsy; drifts off to sleep before completing a sentence
 2. Respirations = 18/min
 3. Drowsy; easily aroused
 4. Pain rating 1–2/10

5. The client has an order of morphine 2.5 to 5.0 mg intravenous (IV) every 4 hours. He received 2.5 mg IV 4 hours ago for pain rated at 3 on a scale of 0 to 10. He is now watching television and visiting with family members. When asked about his pain, he rates it as a 5. His vital signs are stable. What nursing intervention is the most appropriate?
 1. Give morphine 3.5 mg IV and inform him to continue watching TV because it is a distraction from the pain.
 2. Give 2.5 mg of morphine IV to avoid the client becoming addicted.
 3. Give nothing at this time because he is not exhibiting any signs of pain.
 4. Give morphine 5.0 mg IV and reassess in 20 minutes.
6. During an admission nursing assessment, a client with diabetes describes his leg pain as a “dull, burning sensation.” The nurse recognizes this description to be characteristic of which type of pain?
 1. Physiological
 2. Somatic
 3. Visceral
 4. Neuropathic
7. Which interventions, when implemented by the nurse, would apply the gate control theory of pain? Select all that apply.
 1. Oral analgesics around the clock
 2. Massage
 3. Patient-controlled analgesia
 4. Heat or cold application
 5. Acupressure
8. Which statement best reflects the nurse’s assessment of the fifth vital sign?
 1. “Do you have any complaints?”
 2. “Are you experiencing any discomfort right now?”
 3. “Is there anything I can do for you now?”
 4. “Do you have any complaints of pain?”
9. When planning care for pain control of older clients, which principles should the nurse apply? Select all that apply.
 1. Pain is a natural outcome of the aging process.
 2. Pain perception increases with age.
 3. The client may deny pain.
 4. The nurse should avoid use of opioids.
 5. The client may describe pain as an “ache” or “discomfort.”
10. A client recovering from abdominal surgery refuses analgesia, saying that he is “fine, as long as he doesn’t move.” Which nursing diagnosis should be a priority?
 1. *Deficient Knowledge* (pain control measures)
 2. *Ineffective Health Maintenance*
 3. *Risk for Ineffective Airway Clearance*
 4. *Impaired Physical Mobility*

See Answers to Test Your Knowledge in Appendix A.

47 Nutrition

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Identify essential nutrients and their dietary sources.
2. Describe normal digestion, absorption, and metabolism of carbohydrates, proteins, and lipids.
3. Identify factors influencing nutrition.
4. Identify nutritional variations throughout the life cycle.
5. Evaluate a diet using a food guide pyramid.
6. Discuss essential components and purposes of nutritional assessment and nutritional screening.
7. Identify risk factors for and clinical signs of malnutrition.
8. Describe nursing interventions to promote optimal nutrition.
9. Discuss nursing interventions to treat clients with nutritional problems.
10. Verbalize the steps used in:
 - a. Inserting a nasogastric tube.
 - b. Removing a nasogastric tube.
 - c. Administering a tube feeding.
 - d. Administering a gastrostomy or jejunostomy tube feeding.
11. Recognize when it is appropriate to delegate aspects of feeding clients to unlicensed assistive personnel.
12. Plan, implement, and evaluate nursing care associated with nursing diagnoses related to nutritional problems.
13. Demonstrate appropriate documentation and reporting of nutritional therapy.

INTRODUCTION

Nutrition is the sum of all the interactions between an organism and the food it consumes. In other words, nutrition is what a person eats and how the body uses it. **Nutrients** are organic and inorganic substances found in foods that are required for body functioning. Adequate food intake consists of a balance of nutrients: water, carbohydrates, proteins, fats, vitamins, and minerals. Foods differ greatly in their **nutritive value** (the nutrient content of a specified amount of food), and no one food provides all essential nutrients. Nutrients have three major functions: providing energy for body processes and movement, providing structural material for body tissues, and regulating body processes.

ESSENTIAL NUTRIENTS

The body's most basic nutrient need is water. Because every cell requires a continuous supply of fuel, the most important nutritional need, after water, is for nutrients that provide fuel, or energy. The energy-providing nutrients are carbohydrates, fats, and proteins. Hunger compels people to eat enough energy-providing nutrients to satisfy their energy needs. Carbohydrates, fats, protein, minerals, vitamins, and water are referred to as **macronutrients**, because they are needed in large amounts (e.g., hundreds of grams) to provide energy. **Micronutrients** are those vitamins and minerals that are required in small amounts (e.g., milligrams or micrograms) to metabolize the energy-providing nutrients.

Carbohydrates

Carbohydrates are composed of the elements carbon (C), hydrogen (H), and oxygen (O) and are of two basic types: simple carbohydrates (sugars) and complex carbohydrates (starches and fiber). Natural sources of carbohydrates also supply vital nutrients, such as protein, vitamins, and minerals that are not found in processed foods. Processed carbohydrate foods are relatively low in nutrients in relation to the large number of calories they contain. High sugar-content (and solid fat) foods are referred to as “empty calories.” In addition, alcoholic beverages contain significant amounts of carbohydrate, but very few nutrients and, thus, they are also empty calories.

TYPES OF CARBOHYDRATES

SUGARS Sugars, the simplest of all carbohydrates, are water soluble and are produced naturally by both plants and animals. Sugars may be **monosaccharides** (single molecules) or **disaccharides** (double molecules). Of the three monosaccharides (glucose, fructose, and galactose), glucose is by far the most abundant simple sugar.

Most sugars are produced naturally by plants, especially fruits, sugar cane, and sugar beets. However, other sugars come from animal sources. For example, lactose, a combination of glucose and galactose, is found in animal milk. Processed or refined sugars (e.g., table sugar, molasses, and corn syrup) have been extracted and concentrated from natural sources.

Not all sugars have calories and not all sweeteners are sugars. Sugar substitutes are available from both natural and manufactured sources and have almost no calories. Often referred to as “artificial” sugar, non-caloric sweeteners including saccharin and aspartame are much sweeter than sugar by volume. Sugar alcohols such as erythritol and sorbitol are low in calories, do not contain ethanol (present in alcoholic beverages), and are often used in chewing gums. Some sweeteners are not easily categorized, such as the extract from the leaf of the stevia plant.

STARCHES Starches are the insoluble, nonsweet forms of carbohydrate. They are **polysaccharides**; that is, they are composed of branched chains of dozens, sometimes hundreds, of glucose molecules. Like sugars, nearly all starches exist naturally in plants, such as grains, legumes, and potatoes. Other foods, such as cereals, breads, flour, and puddings, are processed from starches.

FIBER Fiber, a complex carbohydrate derived from plants, supplies roughage, or bulk, to the diet. However, fiber cannot be digested by humans. This complex carbohydrate satisfies the appetite and helps the digestive tract to function effectively and eliminate waste. Fiber is present in the outer layer of grains, bran, and in the skin, seeds, and pulp of many vegetables and fruits.

CARBOHYDRATE DIGESTION

Major enzymes of carbohydrate digestion include ptyalin (salivary amylase), pancreatic amylase, and the disaccharidases: maltase, sucrase, and lactase. **Enzymes** are biologic catalysts that speed up chemical reactions. The desired end products of carbohydrate digestion are monosaccharides. Some simple sugars are already monosaccharides and require no digestion. Essentially, all monosaccharides are absorbed by the small intestine in healthy people.

CARBOHYDRATE METABOLISM

Carbohydrate metabolism is a major source of body energy. After the body breaks carbohydrates down into glucose, some glucose

continues to circulate in the blood to maintain blood levels and to provide a readily available source of energy. The remainder is used as energy or stored. Insulin, a hormone secreted by the pancreas, enhances the transport of glucose into cells.

STORAGE AND CONVERSION

Carbohydrates are stored either as glycogen or as fat. **Glycogen** is a large polymer (compound molecule) of glucose. Almost all body cells can store glycogen; however, most is stored in the liver and skeletal muscles, where it is available for conversion back into glucose. Glucose that cannot be stored as glycogen is converted to fat.

Proteins

Amino acids, organic molecules made up primarily of carbon, hydrogen, oxygen, and nitrogen, combine to form proteins. Every cell in the body contains some protein, and about three quarters of body solids are proteins.

Amino acids are categorized as essential or nonessential. **Essential amino acids** are those that cannot be manufactured in the body and must be supplied as part of the protein ingested in the diet. Nine essential amino acids—histidine, isoleucine, leucine, lysine, methionine, phenylalanine, tryptophan, threonine, and valine—are necessary for tissue growth and maintenance. A tenth, arginine, appears to have a role in the immune system.

Nonessential amino acids are those that the body can manufacture. The body takes amino acids derived from the diet and re-constructs new ones from their basic elements. Nonessential amino acids include alanine, aspartic acid, cystine, glutamic acid, glycine, hydroxyproline, proline, serine, and tyrosine.

Proteins may be complete or incomplete. **Complete proteins** contain all of the essential amino acids plus many nonessential ones. Most animal proteins, including meats, poultry, fish, dairy products, and eggs, are complete proteins. Some animal proteins, however, contain less than the required amount of one or more essential amino acids and therefore cannot alone support continued growth. These proteins are sometimes referred to as partially complete proteins. Examples are gelatin, which has small amounts of tryptophan, and the milk protein casein, which has only a little arginine.

Incomplete proteins lack one or more essential amino acids (most commonly lysine, methionine, or tryptophan) and are usually derived from vegetables. If, however, an appropriate mixture of plant proteins is provided in the diet, a balanced ratio of essential amino acids can be achieved. For example, a combination of corn (low in tryptophan and lysine) and beans (low in methionine) is a complete protein. Such combinations of two or more vegetables are called *complementary proteins*. Another way to take full advantage of vegetable proteins is to eat them with a small amount of animal protein. Spaghetti with cheese, rice with pork, noodles with tuna, and cereal with milk are just a few examples of combining vegetable and animal proteins.

PROTEIN DIGESTION

Digestion of protein foods begins in the stomach, where the enzyme *pepsin* breaks protein down into smaller units. However, most protein is digested in the small intestine. The pancreas secretes the proteolytic enzymes trypsin, chymotrypsin, and carboxypeptidase; glands in the intestinal wall secrete aminopeptidase and dipeptidase. These enzymes break protein down into smaller molecules and eventually into amino acids.

STORAGE

Amino acids are absorbed by active transport through the small intestine into the portal blood circulation. The liver uses amino acids to synthesize specific proteins (e.g., liver cells and the plasma proteins albumin, globulin, and fibrinogen). Plasma proteins are a storage medium that can rapidly be converted back into amino acids.

Other amino acids are transported to tissues and cells throughout the body where they are used to make protein for cell structures. In a sense, protein is stored as body tissue. The body cannot actually store excess amino acids for future use. However, a limited amount is available in the “metabolic pool” that exists because of the constant breakdown and buildup of the protein in body tissues.

PROTEIN METABOLISM

Protein metabolism includes three activities: **anabolism** (building tissue), **catabolism** (breaking down tissue), and maintaining nitrogen balance.

ANABOLISM All body cells synthesize proteins from amino acids. The types of proteins formed depend on the characteristics of the cell and are controlled by its genes.

CATABOLISM Because a cell can accumulate only a limited amount of protein, excess amino acids are degraded for energy or converted to fat. Protein degradation occurs primarily in the liver.

NITROGEN BALANCE Because nitrogen is the element that distinguishes protein from lipids and carbohydrates, nitrogen balance reflects the status of protein nutrition in the body. **Nitrogen balance** is a measure of the degree of protein anabolism and catabolism; it is the net result of intake and loss of nitrogen. When nitrogen intake equals nitrogen output, a state of nitrogen balance exists.

Lipids

Lipids are organic substances that are greasy and insoluble in water but soluble in alcohol or ether. **Fats** are lipids that are solid at room temperature; **oils** are lipids that are liquid at room temperature. In common use, the terms *fats* and *lipids* are used interchangeably. Lipids have the same elements (carbon, hydrogen, and oxygen) as carbohydrates, but they contain a higher proportion of hydrogen.

Fatty acids, made up of carbon chains and hydrogen, are the basic structural units of most lipids. Fatty acids are described as saturated or unsaturated, according to the relative number of hydrogen

ANATOMY & PHYSIOLOGY REVIEW

Digestive System

atoms they contain. **Saturated fatty acids** are those in which all carbon atoms are filled to capacity (i.e., saturated) with hydrogen; an example is butyric acid, found in butter. An **unsaturated fatty acid** is one that could accommodate more hydrogen atoms than it currently does. It has at least two carbon atoms that are not attached to a hydrogen atom; instead, there is a double bond between the two carbon atoms. Fatty acids with one double bond are called **mono-unsaturated fatty acids**; those with more than one double bond (or many carbons not bonded to a hydrogen atom) are **polyunsaturated fatty acids**. An example of a polyunsaturated fatty acid is linoleic acid, found in vegetable oil.

Based on their chemical structure, lipids are classified as simple or compound. **Glycerides**, the simple lipids, are the most common form of lipids. They consist of a glycerol molecule with up to three fatty acids attached. **Triglycerides** (which have three fatty acids) account for more than 90% of the lipids in food and in the body. Triglycerides may contain saturated or unsaturated fatty acids. Saturated triglycerides are found in animal products, such as butter, and are usually solid at room temperature. Unsaturated triglycerides are usually liquid at room temperature and are found in plant products, such as olive oil and corn oil.

Cholesterol is a fatlike substance that is both produced by the body and found in foods of animal origin. Most of the body's cholesterol is synthesized in the liver; however, some is absorbed from the diet (e.g., from milk, egg yolk, and organ meats). Cholesterol is needed to create bile acids and to synthesize steroid hormones. Along with phospholipids, large quantities of cholesterol are present in cell membranes and other cell structures.

LIPID DIGESTION

Although chemical digestion of lipids begins in the stomach, they are digested mainly in the small intestine, primarily by bile, pancreatic lipase, and enteric lipase, an intestinal enzyme. The end products of lipid digestion are glycerol, fatty acids, and cholesterol. These are immediately reassembled inside the intestinal cells into triglycerides and cholesterol esters (cholesterol with a fatty acid attached to it), which are not water soluble. For these reassembled products to be transported and used, the small intestine and the liver must convert them into soluble compounds called lipoproteins. **Lipoproteins** are made up of various lipids and a protein.

LIPID METABOLISM

Converting fat into usable energy occurs through the use of the enzyme hormone-sensitive lipase, which breaks down triglycerides in adipose cells, releasing glycerol and fatty acids into the blood. A pound of fat provides 3,500 kilocalories. Fasting individuals will obtain most of their calories from fat metabolism, but some amount of carbohydrate or protein must also be used because the brain, nerves, and red blood cells require glucose. Only the glycerol molecules in fat can be converted to glucose.

Micronutrients

A **vitamin** is an organic compound that cannot be manufactured by the body and is needed in small quantities to catalyze metabolic processes. Thus, when vitamins are lacking in the diet, metabolic deficits result. Vitamins are generally classified as fat soluble or water soluble. **Water-soluble vitamins** include C and the B-complex vitamins: B₁ (thiamine), B₂ (riboflavin), B₃ (niacin or nicotinic acid), B₆

(pyridoxine), B₉ (folic acid), B₁₂ (cobalamin), pantothenic acid, and biotin. The body cannot store water-soluble vitamins; thus, people must get a daily supply in the diet. Water-soluble vitamins can be degraded by food processing, storage, and preparation.

Fat-soluble vitamins include A, D, E, and K. The body can store these vitamins, although there is a limit to the amounts of vitamins E and K the body can store. Therefore, a daily supply of fat-soluble vitamins is not absolutely necessary. Vitamin content is highest in fresh foods consumed soon after harvest.

Minerals are found in organic compounds, as inorganic compounds, and as free ions. Calcium and phosphorus make up 80% of all mineral elements in the body. The two categories of minerals are macrominerals and microminerals. **Macrominerals** are those that people require daily in amounts over 100 mg. They include calcium, phosphorus, sodium, potassium, magnesium, chloride, and sulfur. **Microminerals** are those that people require daily in amounts less than 100 mg. They include iron, zinc, manganese, iodine, fluoride, copper, cobalt, chromium, and selenium.

Common problems associated with the mineral nutrients are iron deficiency resulting in anemia, and osteoporosis resulting from loss of bone calcium. Additional information about major minerals associated with the body's fluid and electrolyte balance is given in Chapter 52 ∞.

ENERGY BALANCE

Energy balance is the relationship between the energy derived from food and the energy used by the body. The body obtains energy in the form of calories from carbohydrates, protein, fat, and alcohol. The body uses energy for voluntary activities such as walking and talking and for involuntary activities such as breathing and secreting enzymes. A person's energy balance is determined by comparing his or her energy intake with energy output.

Energy Intake

The amount of energy that nutrients or foods supply to the body is their **caloric value**. A **calorie** is a unit of heat energy. A **small calorie (c, cal)** is the amount of heat required to raise the temperature of 1 gram of water 1 degree Celsius. This unit of measure is used in chemistry and physics. A **large calorie (Calorie, kilocalorie [Kcal])** is the amount of heat energy required to raise the temperature of 1 gram of water 15 to 16 degrees Celsius and is the unit used in nutrition (although it is not universally capitalized). In the metric system, the measure is the **kilojoule (kJ)**. One Calorie (Kcal) equals 4.18 kilojoules.

The energy liberated from the metabolism of food has been determined to be:

- 4 Calories/gram (17 kJ) of carbohydrates
- 4 Calories/gram (17 kJ) of protein
- 9 Calories/gram (38 kJ) of fat
- 7 Calories/gram (29 kJ) of alcohol.

Energy Output

Metabolism refers to all biochemical and physiological processes by which the body grows and maintains itself. Metabolic rate is normally expressed in terms of the rate of heat liberated during these chemical reactions. The **basal metabolic rate (BMR)** is the rate at which the

body metabolizes food to maintain the energy requirements of a person who is awake and at rest. The energy in food maintains the basal metabolic rate of the body and provides energy for activities such as running and walking.

Resting energy expenditure (REE) is the amount of energy required to maintain basic body functions; in other words, the calories required to maintain life. The REE of healthy individuals is generally about 1 cal/kg of body weight/h for men and 0.9 cal/kg/h for women although there is great variation among individuals. BMR is calculated by measuring the REE in the early morning, 12 hours after eating.

The actual daily expenditure of energy depends on the degree of activity of the individual. Some activities require many times the REE. Examples of approximate real caloric expenditures compared to the REE are as follows:

Light housework	210%
Walking steadily	350%
Heavy housework	400%
Laboring	500%
Average jogging/cycling/energetic swimming	700%

BODY WEIGHT AND BODY MASS STANDARDS

Maintaining a healthy or ideal body weight requires a balance between the expenditure of energy and the intake of nutrients. Generally, when energy requirements of an individual equate with the daily caloric intake, the body weight remains stable. **Ideal body weight (IBW)** is the optimal weight recommended for optimal health. To determine an individual's approximate IBW, the nurse can consult standardized tables or can quickly calculate a value using the Rule of 5 for women and the Rule of 6 for men (Box 47-1). Many standardized

tables and formulas were developed many years ago and are based on limited samples. The nurse should use great caution in suggesting that these weights apply to all clients.

Many health professionals consider the body mass index to be a more reliable indicator of a person's healthy weight. For people older than 18 years, the **body mass index (BMI)** is an indicator of changes in body fat stores and whether a person's weight is appropriate for height, and may provide a useful estimate of malnutrition. However, the results must be used with caution in people who have fluid retention (e.g., ascites or edema), athletes, or older adults. To calculate the BMI:

1. Measure the person's height in meters, e.g., 1.7 m (1 meter = 3.3 ft, or 39.6 in.)
2. Measure the weight in kilograms, e.g., 72 kg (1 kg = 2.2 pounds)
3. Calculate the BMI using the following formula:

$$BMI = \frac{\text{weight in kilograms}}{(\text{height in meters})^2}$$

or

$$\frac{72 \text{ kilograms}}{1.7 \times 1.7 \text{ meters}} = 24.9$$

Box 47-2 provides an interpretation of the results.

Another measure of body mass is percent body fat. Because BMI uses only height and weight, it can give misleading results for certain groups of clients such as athletes, frail older adults, and children. The most accurate percentage of body fat can be measured by underwater weighing and dual-energy x-ray absorptiometry (DEXA), but these methods are time consuming and expensive (Roth, 2014). Other indirect, but more practical measures include waist circumference (see Box 47-2), skinfold testing, and bioelectrical impedance analysis.

BOX 47-1 Approximating Ideal Body Weight

Rule of 5 for Females		Rule of 6 for Males	
100 lb for 5 ft of height		106 lb for 5 ft of height	
+ 5 lb for each inch over 5 ft		+ 6 lb for each inch over 5 ft	
±10% for body-frame size*		±10% for body-frame size*	
*Determine body-frame size by measuring the client's wrist circumference and applying to the table below. Add 10% for large body-frame size, and subtract 10% for small body-frame size.			
Female Wrist Measurements		Male Wrist Measurements	
Height Less Than	Height	Height More Than	Height More Than
5.2" (155 cm)	5.2"-5.5" (155-163 cm)	5.5" (163 cm)	5.5" (More Than 163 cm)
Small	Less than 5.5" (140 mm)	Less than 6.0" (152 mm)	Less than 6.25" (159 mm)
Medium	5.5"-5.75" (140-146 mm)	6"-6.25" (152-159 mm)	6.25"-6.5" (159-165 mm)
Large	More than 5.75" (146 mm)	More than 6.25" (159 mm)	More than 6.5" (165 mm)

BOX 47-2 Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risks*

	BMI (kg/m ²)	Obesity Class	Disease Risk* Relative to Normal Weight and Waist Circumference	
			Men: 102 cm (40 in.) or Less	Men > 102 cm (40 in.)
			Women: 88 cm (35 in.) or Less	Women > 88 cm (35 in.)
Underweight	<18.5	—	—	—
Normal ⁺	18.5-24.9	—	—	—
Overweight	25.0-29.9	Increased	High	High
Obesity	30.0-34.9 I	High	Very high	Very high
	35.0-39.9 II	Very high	Very high	Very high
Extreme obesity	40.0 ⁺	III	Extremely high	Extremely high

*Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.

⁺Increased waist circumference can also be a marker for increased risk even in individuals of normal weight.

From *Aim for a Healthy Weight*, National Heart, Lung, and Blood Institute, n.d., Washington, DC: U.S. Department of Health & Human Services. Retrieved from http://www.nhlbi.nih.gov/health/public/heart/obesity/lose_wt/bmi_dis.htm

FACTORS AFFECTING NUTRITION

Although the nutritional content of food is an important consideration when planning a diet, an individual's food preferences and habits are often a major factor affecting actual food intake. Habits about eating are influenced by developmental considerations, gender, ethnicity and culture, beliefs about food, personal preferences, religious practices, lifestyle, economics, medications and therapy, health, alcohol consumption, advertising, and psychological factors.

Development

People in rapid periods of growth (i.e., infancy and adolescence) have increased needs for nutrients. Older adults, on the other hand, may need fewer calories and also need some dietary changes in view of their risk for coronary heart disease, osteoporosis, and hypertension.

Sex

Nutrient requirements are different for men and women because of body composition and reproductive functions. The larger muscle mass of men translates into a greater need for calories and proteins. Because of menstruation, women require more iron than men do prior to menopause. Pregnant and lactating women have increased caloric and fluid needs.

Ethnicity and Culture

Ethnicity often determines food preferences. Traditional foods (e.g., rice for Asians, pasta for Italians, curry for Indians) are eaten long after other customs are abandoned.

Nurses should not use a “good food, bad food” approach, but rather should realize that variations of intake are acceptable under different circumstances. The only “universally” accepted guidelines are (a) to eat a wide variety of foods to furnish adequate

nutrients and (b) to eat moderately to maintain body weight. Food preference probably differs as much among individuals of the same cultural background as it does between cultures. Not all Italians like pizza, for example, and many undoubtedly enjoy Mexican food.

Beliefs About Food

Beliefs about effects of foods on health and well-being can affect food choices. Many people acquire their beliefs about food from television, magazines, and other media. Some people are reducing their intake of animal fats in response to evidence that excessive consumption of animal fats is a major risk factor in vascular disease, including heart attack and stroke.

Food fads that involve nontraditional food practices are relatively common. A **fad** is a widespread but short-lived interest or a practice followed with considerable zeal. It may be based either on the belief that certain foods have special powers or on the notion that certain foods are harmful. Food fads appeal to the individual seeking a miracle cure for a disease, the person who desires superior health, or someone who wants to delay aging. Some fad diets are harmless, but others are potentially dangerous. Determining the needs a fad diet fills for the client enables the nurse both to support these needs and to suggest a more nutritious diet.

Personal Preferences

People develop likes and dislikes based on associations with a typical food. A child who loves to visit his grandparents may love pickled crabapples because they are served in the grandparents' home. Another child who dislikes a very strict aunt grows up to dislike the chicken casserole she often prepared. People often carry such preferences into adulthood.

Culturally Responsive Care

PATIENT-CENTERED CARE

Selected Variations in Nutritional Practices and Preferences Among Different Cultures

AFRICAN AMERICAN HERITAGE

- Gifts of food are common and should never be rejected.
- Diets are often high in fat, cholesterol, and sodium.
- Being overweight may be viewed as positive.
- Popular vegetables include black-eyed peas, okra, sweet potatoes, peanuts, corn, hot and sweet peppers, green and lima beans, and collard, turnip, and mustard greens.

ARAB HERITAGE

- Many spices and herbs are used such as cinnamon, allspice, cloves, mint, ginger, and garlic.
- Meats are often skewer roasted or slow simmered; most common are lamb and chicken.
- Bread is served at every meal.
- Muslims do not eat pork, and all meats must be cooked well done.
- Food is eaten (and clients fed) with the right hand.
- Beverages are drunk after the meal, not during; alcohol is prohibited.
- Muslims fast during daylight hours during the month of Ramadan (the ninth month of the year based on the lunar calendar).

CHINESE HERITAGE

- Foods are served at meals in a specific order.
- Each region in China has its own traditional diet.
- Traditional Chinese may not want ice in their drinks.
- Foods are chosen to balance *yin* and *yang* in order to avoid indigestion.
- Soy sauce is used instead of salt.

JEWISH HERITAGE

- Dietary laws govern killing, preparation, and eating of foods.
- Meat and animal milk are not eaten at the same time; dairy substitutes (e.g., margarine) are permitted.
- Pork is one meat that is forbidden to eat.
- All blood must be drained from meats.
- Always wash hands before eating.

MEXICAN HERITAGE

- Rice, beans, and tortillas are core, essential foods.
- Larger body size may be viewed as a positive attribute.
- Sweet fruit drinks, including adding sugar to juice, are popular.
- The main meal of the day is at noontime.
- Foods are chosen according to *hot* and *cold* theory.

NAVAJO HERITAGE

- Rites of passage and ceremonies are celebrated with food.
- Herbs are used to treat many illnesses.
- Sheep are the major source of meat.
- Squash and corn are major vegetables.

Individual likes and dislikes can also be related to familiarity. Children often say they dislike a food before they sample it. Some adults are very adventuresome and eager to try new foods. Others prefer to eat the same foods repeatedly. Preferences in the tastes, smells, flavors (blends of taste and smell), temperatures, colors, shapes, and sizes of food influence a person's food choices. Some people may prefer sweet and sour tastes to bitter or salty tastes. Textures play a great role in food preferences. Some people prefer crisp food to limp food, firm to soft, tender to tough, smooth to lumpy, or dry to soggy.

Religious Practices

Religious practice also affects diet. Some Roman Catholics avoid meat on certain days, and some Protestant faiths prohibit meat, tea, coffee, or alcohol. Both Orthodox Judaism and Islam prohibit pork. Orthodox Jews observe kosher customs, eating certain foods only if they are inspected by a rabbi and prepared according to dietary laws. The nurse must plan care with consideration of such religious dietary practices.

Lifestyle

Certain lifestyles are linked to food-related behaviors. People who are always in a hurry probably buy convenience grocery items or eat restaurant meals. People who spend many hours at home may take time to prepare more meals “from scratch.” Individual differences also influence lifestyle patterns (e.g., cooking skills, concern about health). Some people work at different times, such as evening or night shifts. They might need to adapt their eating habits to this and also make changes in their medication schedules if they are related to food intake.

Muscular activity affects metabolic rate more than any other factor; the more strenuous the activity, the greater the stimulation of the metabolism. Mental activity, which requires only about 4 Kcal per hour, provides very little metabolic stimulation.

Economics

What, how much, and how often a person eats are frequently affected by socioeconomic status. For example, people with limited income, including some older adults, may not be able to afford meat and fresh vegetables. In contrast, people with higher incomes may purchase more proteins and fats and fewer complex carbohydrates. Not all individuals have the financial resources for extensive food preparation and storage facilities. The nurse should not assume that clients have their own stove, refrigerator, or freezer. In some low-income areas, food costs at small local grocery stores can be significantly higher than at large chain stores farther away.

Medications and Therapy

The effects of drugs on nutrition vary considerably. They may alter appetite, disturb taste perception, or interfere with nutrient absorption or excretion. Nurses need to be aware of the nutritional effects of specific drugs when evaluating a client for nutritional problems. The nursing history interview should include questions about the medications the client is taking. Conversely, nutrients can affect drug utilization. Some nutrients can decrease drug absorption; others enhance absorption. For example, the calcium in milk hinders absorption of the antibiotic tetracycline but enhances the absorption of the antibiotic erythromycin. Older adults are at particular risk for drug–food interactions due to the number of medications they may take,

age-related physiological changes affecting medication actions (e.g., decrease in lean-to-fat ratio, decrease in renal or hepatic function), and disease-restricted diets. Selected drug and nutrient interactions are shown in Table 47–1.

Therapies prescribed for certain diseases (e.g., chemotherapy and radiation for cancer) may also adversely affect eating patterns and nutrition. Normal cells of the bone marrow and the gastrointestinal (GI) mucosa are naturally very active and particularly susceptible to antineoplastic agents. Oral ulcers, intestinal bleeding, or diarrhea resulting from the toxicity of the antineoplastic agents used in chemotherapy can seriously diminish a person's nutritional status.

The effects of radiotherapy depend on the area that is treated. Radiotherapy of the head and neck may cause decreased salivation, taste distortions, and swallowing difficulties; radiotherapy of the abdomen and pelvis may cause malabsorption, nausea, vomiting, and diarrhea. Many clients undergoing radiotherapy feel profound fatigue and anorexia (loss of appetite).

Health

An individual's health status greatly affects eating habits and nutritional status. Missing teeth, ill-fitting dentures, or a sore mouth makes chewing food difficult. Difficulty swallowing (**dysphagia**) due to a painfully inflamed throat or a stricture of the esophagus can prevent a person from obtaining adequate nourishment. Disease processes and surgery of the GI tract can affect digestion, absorption, metabolism, and excretion of essential nutrients. GI and other diseases also create nausea, vomiting, and diarrhea, all of which can adversely affect a person's appetite and nutritional status. Gallstones, which can block the flow of bile, are a common cause of impaired lipid digestion. Metabolic processes can be impaired by diseases of the liver. Diseases of the pancreas can affect glucose metabolism or fat digestion. Autoimmune and genetic disorders such as celiac disease and irritable bowel syndrome may be worsened when eating foods containing wheat or gluten.

Between 30 million and 50 million Americans have lactose intolerance (also called lactose maldigestion), a shortage of the enzyme lactase, which is needed to break down the sugar in milk. Certain populations are more widely affected, especially African Americans, American Indians, Ashkenazi Jews, and Asian Americans, although they may not always show symptoms (DeBruyne & Pinna, 2014).

Alcohol Consumption

The calories in alcoholic drinks include both those of the alcohol itself and of the juices or other beverages added to the drink. These can constitute large numbers of calories, for example, 150 calories for a regular 12-ounce beer, and 160 calories for a “screwdriver” (1.5 ounces vodka plus 4 ounces orange juice). Drinking alcohol can lead to weight gain through adding these calories to the regular diet plus the effect of alcohol on fat metabolism. A small amount of the alcohol is converted directly to fat. However, the greater effect is that the remainder of the alcohol is converted into acetate by the liver. The acetate released to the bloodstream is used for energy instead of fat and the fat is then stored.

Excessive alcohol use contributes to nutritional deficiencies in several ways. Alcohol may replace food in a person's diet, and it can depress the appetite. Excessive alcohol can have a toxic effect on the intestinal mucosa, thereby decreasing the absorption of nutrients.

TABLE 47-1 Selected Drug–Nutrient Interactions

Drug	Effect On Nutrition
Acetylsalicylic acid (aspirin)	Decreases serum folate and folacin nutrition. Increases excretion of vitamin C, thiamine, potassium, amino acids, and glucose. May cause nausea and gastritis.
Antacids containing aluminum or magnesium hydroxide	Decrease absorption of phosphate and vitamin A. Inactivate thiamine. May cause deficiency of calcium and vitamin D. Increase excretion of sodium, potassium, chloride, calcium, magnesium, zinc, and riboflavin.
Thiazide diuretics	May cause anorexia, nausea, vomiting, diarrhea, or constipation. Decrease absorption of vitamin B ₁₂ . May cause diarrhea, nausea, or vomiting.
Potassium chloride	Increases excretion of potassium, magnesium, and calcium. May cause anorexia, nausea, or vomiting. Is incompatible with protein hydrolysates.
Laxatives	May cause calcium and potassium depletion. Mineral oil and phenolphthalein (Ex-Lax) decrease absorption of vitamins A, D, E, and K.
Antihypertensives	Hydralazine may cause anorexia, vomiting, nausea, and constipation. Methyldopa increases need for vitamin B ₁₂ and folate. May cause dry mouth, nausea, vomiting, diarrhea, and constipation.
Anti-inflammatory agents	Colchicine decreases absorption of vitamin B ₁₂ , carotene, fat, lactose, sodium, potassium, protein, and cholesterol. Prednisone decreases absorption of calcium and phosphorus.
Antidepressants	Amitriptyline increases food intake (large amounts may suppress intake).
Antineoplastics	Can cause nausea, vomiting, anorexia, malabsorption, and diarrhea.
Nutrient	Effect on Drugs
Grapefruit	Can cause toxicity when taken with a variety of medications including amiodarone, carbamazepine, cisapride, cyclosporine, diazepam, nifedipine, saquinavir, statins, terfenadine, verapamil.
Vitamin K	Can decrease the effectiveness of warfarin (Coumadin).
Tyramine (found in aged cheeses, tap beer, dried sausages, fermented soy, sauerkraut)	In combination with monoamine oxidase inhibitor (MAOI) medications, e.g., isocarboxazid (Marplan), isoniazid, linezolid, phenelzine, tranylcypromine, creates sudden increase in epinephrine leading to headaches, increased pulse and blood pressure, and possible death.
Milk	Interferes with absorption of tetracycline antibiotics.

The need for vitamin B increases, because it is used in alcohol metabolism. Alcohol can impair the storage of nutrients and increase nutrient catabolism and excretion.

Several studies have shown health benefits of moderate alcohol consumption. Examples include reduced risk of cardiovascular disease, strokes, dementia, diabetes, and osteoporosis. However, any benefits of alcohol must be weighed against the many harmful effects, and the possibility of alcohol abuse.

Advertising

Food producers try to persuade people to change from the product they currently use to the brand of the producer. Popular actors are often used in television, radio, Internet, and print to influence consumers' choices. Advertising is thought to influence people's food choices and eating patterns to a certain extent. Of note is that such products as alcoholic beverages, coffee, frozen foods, and soft drinks are more heavily advertised than such products as bread, vegetables, and fruits. Convenience foods (frozen or packaged and easy to prepare) and take-out (fast) foods are heavily advertised. Children's television show commercials often promote snack foods, candy, soda, and sugared cereals over fresh, healthy foods. Australia, Canada, Sweden, and

Great Britain have adopted regulations prohibiting food advertising on programs targeting audiences of young children.

There has been an increase in advertising that targets older adults in particular and encourages use of herbs and supplements. Some products are nutritionally safe, whereas others are not and can cause interactions with medications they might be taking or cause unexpected side effects. The cost of some of these supplements is also usually high, is generally not covered by health insurance, and may take money that the person could spend for healthier food.

Psychological Factors

Although some people overeat when stressed, depressed, or lonely, others eat very little under the same conditions. Anorexia and weight loss can indicate severe stress or depression. Anorexia nervosa and bulimia are severe psychophysiological conditions seen most frequently in female adolescents.

NUTRITIONAL VARIATIONS THROUGHOUT THE LIFE CYCLE

Nutritional requirements vary throughout the life cycle. Guidelines follow for the major developmental stages.

Neonate to 1 Year

The neonate's fluid and nutritional needs are met by breast milk or formula. Fluid needs of infants are proportionately greater than those of adults because of a higher metabolic rate, immature kidneys, and greater water losses through the skin and the lungs. Therefore, fluid balance is a critical factor. Under normal environmental conditions, infants do not need additional water beyond that obtained from breast or bottle formula feedings; however, neonates in very warm environments may require additional fluids.

The total daily nutritional requirement of the newborn is about 80 to 100 mL of breast milk or formula per kilogram of body weight. The newborn infant's stomach capacity is about 90 mL, and feedings are required every 2 1/2 to 4 hours.

The newborn infant is usually fed "on demand." **Demand feeding** means that the child is fed when hungry rather than on a set time schedule. This method tends to decrease the problem of overfeeding or underfeeding the infant. The newborn who is hungry usually cries and exhibits tension in the entire body. During feeding, the infant sucks readily and needs burping after each ounce of formula or after 5 minutes of breast-feeding.

Infants demonstrate satisfaction by slowing their sucking activity or by falling asleep. Infants should not be coaxed into finishing the feeding. This could lead to discomfort or overfeeding. When feeding is completed, healthy infants can be placed in a supine position for sleep during the first 6 months of life to reduce the risk of sudden infant death syndrome (SIDS).

Regurgitation, or spitting up, during or after a feeding is a common occurrence during the first year. Although this may concern parents, it does not usually result in nutritional deficiency. Demonstration of adequate weight gain should reassure parents that the infant is receiving adequate nutrition.

Adding solid food to the diet usually takes place between 4 and 6 months of age. Six-month-old infants can consume solid food more readily because they can sit up, can hold a spoon, and have decreased sucking and tongue protrusion reflexes. Solid foods (strained or pureed) are generally introduced in the following order: cereals (rice before oat and wheat), fruits, vegetables (yellow before green), and strained meats. Foods are introduced one at a time, usually with only one new food introduced every 5 days to ensure that the infant tolerates the food and demonstrates no allergy to it. This sequence can vary according to cultural preferences. With the eruption of teeth at about 7 to 9 months, the infant is ready to chew and can experience different textures of food. At this time, the infant enjoys finger foods, such as skinless fruit cut into small pieces to prevent choking, dry cereal, or toast.

Because honey can contain spores of *Clostridium botulinum* and this has been a source of infection (and death) for infants, children less than 12 months old should not be fed honey. According to the Centers for Disease Control and Prevention (CDC) (2011), honey is safe for persons 1 year of age and older.

At about 6 months of age, infants require iron supplementation to prevent **iron deficiency anemia**. Iron deficiency anemia is a form of **anemia** (decrease in red blood cells) caused by inadequate supply of iron for synthesis of hemoglobin. Cow's milk is low in iron and, thus, iron-fortified cereals or formulas are usually recommended by 6 months of age and are continued until the child reaches 18 months.

Weaning from the breast or bottle to the cup takes place gradually and is usually achieved by 12 to 24 months of age. It is recommended that infants be breast-fed exclusively for 6 months and then until 1 year

of age or longer as desired (American Academy of Pediatrics, 2012). Some infants have difficulty giving up the bottle, particularly at naptime or bedtime. Parents should be warned that having the bottle in bed could lead to **bottle mouth syndrome**. The term describes decay of the teeth caused by constant contact with sweet liquid from the bottle. Some dentists advocate brushing or cleaning the infant's teeth to prevent bottle mouth syndrome, especially for the infant who requires a bottle only at naptime or bedtime. Weaning from the bottle can be facilitated by diluting the formula with water increasingly until the infant is drinking plain water. By the age of 1, most infants can be completely fed on table food, and milk intake is about 20 ounces per day.

Toddler

Because of a maturing GI tract, toddlers can eat most foods and adjust to three meals each day. Toddlers' fine motor skills are sufficiently well developed for them to learn how to feed themselves. Before the age of 20 months, most toddlers require help with glasses and cups because their wrist control is limited. By age 3, when most of the deciduous teeth have emerged, the toddler can bite and chew adult table food.

Developing independence may be exhibited through the toddler's refusal of certain foods. Meals should be short because of the toddler's brief attention span and environmental distractions. Often toddlers display their liking of rituals by eating foods in a certain order, cutting foods a specific way, or accompanying certain foods with a particular drink.

The toddler is less likely to have fluid imbalances than the infant. The toddler's GI function is more mature, and the percentage of fluid body weight is lower. A healthy toddler weighing 15 kg (33 lb) needs about 1,250 mL of fluid per 24 hours.

During the toddler stage, the caloric requirement is 1,000 to 1,400 Kcal/day. From 1 to 2 years of age, the toddler may eat a combination of prepared toddler foods and some table foods. Parents should be instructed to read labels carefully and be aware that table foods offer more variety and are less expensive and more nutritious than prepared toddler foods. The need for adequate iron, calcium, and vitamins C and A, which are common toddler deficiencies, should also be discussed.

The following suggestions may help parents meet the child's nutritional needs and promote effective parent-child interactions: (a) Make mealtime a pleasant time by avoiding tensions at the table and discussions of bad behavior; (b) offer a variety of simple, attractive foods in small portions, and avoid meals that combine foods into one dish, such as a stew; (c) do not use food as a reward or punish a child who does not eat; (d) schedule meals, sleep, and snack times that will allow for optimum appetite and behavior; and (e) avoid the routine use of sweet desserts.

Preschooler

The preschooler eats adult foods. Parents should become informed about the diet of their child in day care or preschool settings so that they can ensure that the child's total nutritional needs are being met. Children at this age are very active and may rush through meals to return to playing. Active children often require snacks between meals. Cheese, fruit, yogurt, raw vegetables, and milk are good choices. The 4-year-old still requires parents' help in cutting meat and may spill milk when pouring from a large container. Parents also need to teach the preschooler how to use utensils and should provide them with the opportunity to practice (e.g., buttering bread). However, 4- and 5-year-olds often use their fingers to pick up food. Children at this age may enjoy helping in the kitchen, and both girls and boys should be encouraged to do so.

The preschooler is even less at risk than the toddler for fluid imbalances. The average 5-year-old weighing 20 kg (45 lb) requires at least 75 mL of liquid per kilogram of body weight per day, or 1,500 mL every 24 hours.

School-Age Child

School-age children require a balanced diet including approximately 1,600 to 2,200 Kcal/day. They can eat three meals a day and one or two nutritious snacks. Children need a protein-rich food at breakfast to sustain the prolonged physical and mental effort required at school. Children who skip breakfast become inattentive and restless by late morning and have decreased problem-solving ability. Undernourished children become fatigued easily and face a greater risk of infection, resulting in frequent absences from school.

The average healthy 8-year-old weighing 30 kg (66 lb) requires about 1,750 mL of fluid per day. Many school-age children have only one meal a day with their family, at dinner. Mealtime should be a social time enjoyed by all, and parents should encourage good eating habits. Parents should be aware that children learn many of their food habits by observing their parents. Eating a balanced diet should be the norm for both parent and child.

The school-age child generally eats lunch at school. The child may bring lunch from home or get lunch at the school. Many dietary problems stem from this independence in food choices. Children may trade their food, not eat lunch at all, or buy sweets or junk food with their lunch money. Parents should discuss with the child the foods that they should eat and continue to provide a balanced diet in the home setting.

Poor eating habits may cause obesity. Childhood obesity is an increasing problem. More than 18% of American children ages 6 to 18 are overweight (at or above the 95% for BMI) (Ogden, Carroll, Kit, & Flegal, 2012). Obesity in school-age children tends to result in adult obesity and all the related health risks. It is both caused by and results in decreased activity and psychosocial problems. Obese children may be ridiculed and discriminated against by peers. Such behavior reinforces low self-esteem. The CDC's Division of Adolescent and School Health has established many programs to address both prevention and treatment of childhood obesity. The goal of treatment for children who are overweight is to reduce weight gain, allowing their weight to increase more slowly than their height. Counseling and teaching for parents should include the following:

- Reviewing the child's eating habits, including snacks
- Altering meal content
- Using rewards other than food
- Promoting regular exercise.

Adolescent

The adolescent's need for nutrients and calories increases, particularly during the growth spurt. In particular, the need for protein, calcium, vitamin D, iron, and B vitamins increases during adolescence. An adequate diet for an adolescent is 1 quart of milk per day and appropriate amounts of meat, vegetables, fruits, breads, and cereals. Calcium intake during adolescent years (1,200 to 1,500 mg/day) may help decrease osteoporosis (a decrease in bone density) in later life. Peak bone mineralization occurs on average at 12.5 years in girls and 14.0 years in boys when 40% of total adult bone mass is accumulated. The majority of adolescents do not get enough calcium (Roth, 2014).

Many parents observe that teenagers, particularly boys, seem to eat all the time. Teenagers have active lifestyles and irregular eating

patterns. They tend to diet or snack frequently, often eating high-calorie foods such as soft drinks, ice cream, and fast foods. Parents and nurses can promote better lifelong eating habits by encouraging teenagers to eat healthy snacks. Parents can provide healthy snacks such as fruits and cheese and limit the junk food available in the home. The teenager's food choices relate to physical, social, and emotional factors and impulses and may not be influenced by teaching. Nurses need to advise parents to help adolescents take responsibility for their decisions in many areas of life, and to avoid conflicts that relate to food.

Common problems related to nutrition and self-esteem among adolescents include obesity, anorexia nervosa, and bulimia. Obesity continues to be a problem in the adolescent period. Depression is not unusual among adolescents who are obese. Treatment of obesity in this age group includes education on nutrition and assessment of psychosocial problems that may produce overeating.

Under social pressure to be slim, some adolescents severely limit their food intake to a level significantly below that required to meet the demands of normal growth. Sometimes, the adolescent may develop an eating disorder, such as anorexia or bulimia. These disorders are considered to be related to the need for control. **Anorexia nervosa** is characterized by a prolonged inability or refusal to eat, rapid weight loss, and emaciation in individuals who continue to believe they are fat. People with anorexia may also induce vomiting and use laxatives and diuretics to remain thin. **Bulimia** is an uncontrollable compulsion to consume enormous amounts of food (binge) and then expel it by self-induced vomiting or by taking laxatives (purge). These illnesses are most effectively treated in the early stages by psychotherapy. Hospitalization may be necessary when the effects of starvation become life threatening.

Young Adult

Many young adults are aware of the food groups but may not be knowledgeable about how many servings of each group they need or how much a serving constitutes. The nurse should provide the young adult client with resources such as a chart or list that contains the foods and the amounts needed in each category.

Young adult females need to maintain adequate iron intake. Many women do not ingest sufficient dietary iron each day. To prevent iron deficiency anemia, menstruating females should ingest 18 mg of iron daily. The nurse should instruct the female client to include iron-rich foods, such as organ meats (liver and kidneys), eggs, fish, poultry, leafy vegetables, and dried fruits, in her daily diet. Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide. In addition, the World Health Organization (WHO) recommends folate/folic acid supplements for all women of child-bearing ability. Because folate can prevent neural tube defects in the fetus but must be taken prior to and during the early portion of the pregnancy, the United States and more than 50 other countries have mandated folic acid supplementation of enriched grain products.

Calcium is needed in young adulthood to maintain bones and help decrease the chances of developing osteoporosis in later life. Along with calcium, the person must have adequate vitamin D, necessary for the calcium to enter the bloodstream. Vitamin D is made in the skin on exposure to the sun. If the person does not get sufficient sun exposure (15 minutes three times each week), supplements may be indicated.

Obesity may occur during the young adult years as the active teen becomes the sedentary adult but does not decrease caloric intake. The young adult who is overweight or obese is at risk for hypertension, a major health problem for this age group.

DRUG CAPSULE

Mineral ferrous sulfate (Slow-Fe, Feosol), ferrous gluconate (Fergon)**CLIENT WITH IRON DEFICIENCY ANEMIA**

Iron is required for the formation of red blood cells. When iron stores are low, the body cannot produce enough red blood cells and anemia can develop. Symptoms of iron deficiency anemia include fatigue, listlessness, anorexia, and pallor. Although iron deficiency anemia is not the only kind of anemia, it is possibly the most common and one of the easiest to treat. Immediate and timed-release forms are available.

NURSING RESPONSIBILITIES

- Administer on an empty stomach, 1 hour before or 2 hours after meals, with a full glass of water. If the client experiences gastric upset, administer with or after food. The immediate-release formulation is administered up to three times per day.
- Vitamin C increases absorption of iron from the stomach. Some preparations contain both iron and vitamin C.
- Administer at least 2 hours apart from antacids, ciprofloxacin, tetracycline, and several other medications. Consult a drug handbook for possible drug interactions.
- Liquid forms should be diluted in a glass of water or juice and sipped through a straw to prevent staining of the teeth.
- Shake suspension forms well before each use; take with a full glass of water.

- Iron comes in different dose strengths and may require adjustment for optimal effect.

CLIENT AND FAMILY TEACHING

- Take the medication on an empty stomach, 1 hour before or 2 hours after meals, with a full glass of water. If upset stomach occurs, take with or after food, but not with coffee, tea, eggs, or milk because these decrease absorption. Do not lie down for 30 minutes after taking the tablet or capsule.
- Sustained-release capsules and tablets must be swallowed whole. Do not crush or chew them because side effects may be increased.
- Common side effects may include nausea, stomach cramps, vomiting, and constipation. These should decrease within a few days even while continuing the iron.
- Stools will turn green-black, and this is normal.
- Do not stop taking the medication, even if you feel stronger.
- Do not take iron without consulting the primary care provider if you have a history of intestinal problems.
- Store at room temperature, away from moisture and sunlight. Keep away from children. Accidental overdose can be fatal.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

Hypertension and obesity are 2 of more than 40 risk factors identified in the development of cardiovascular (CV) disease. Preventing these risk factors and lowering the risk of CV disease are critical. Low-fat and/or low-cholesterol diets play a significant role in both the prevention and treatment of CV disease.

Middle-Aged Adult

The middle-aged adult should continue to eat a healthy diet, following the recommended portions of the food groups, with special attention to protein and calcium intake, and limiting cholesterol and caloric intake. Two or three liters of fluid should be included in the daily diet. Postmenopausal women need to ingest sufficient calcium and vitamin D to reduce osteoporosis, and antioxidants such as vitamins A, C, and E may be helpful in reducing the risks of heart disease in women. Although iron supplements are no longer needed, the amount in a multivitamin is not harmful.

Middle-aged adults who gain weight may not be aware of some common facts about this age period. Decreased metabolic activity and decreased physical activity mean a decrease in caloric need. The nurse's role in nutritional health promotion is to counsel clients to prevent obesity by reducing caloric intake and participating in regular exercise. Clients should also be warned that being overweight is a risk factor for many chronic diseases, such as diabetes and hypertension, and for problems of mobility, such as arthritis.

For the client who requires additional resources, a variety of programs is frequently available. Most programs use behavior modification techniques and group support to assist clients in reaching their goals. Clients should seek medical advice before considering any major changes in their diets.

During late middle age, gastric juice secretions and free acid gradually decline. Some individuals may complain of "heartburn" (acid indigestion) or an increase in belching. They may determine that certain foods disagree with them. Clients should be advised to develop sensible eating habits and avoid fried or fatty foods.

Older Adults

The older adult requires the same basic nutrition as the younger adult. However, fewer calories are needed by older adults because of the lower metabolic rate and the decrease in physical activity.

Some older adults may need more carbohydrates for fiber and bulk, but most nutrient requirements remain relatively unchanged. Such physical changes as tooth loss and impaired sense of taste and smell may affect eating habits. Decreased saliva and gastric juice secretion may also affect a person's nutrition.

Psychosocial factors may also contribute to nutritional problems. Some older adults who live alone do not want to cook for themselves or eat alone. They may adopt poor dietary habits. Other factors, such as lack of transportation, poor access to stores, and inability to prepare the food also affect nutritional status. Loss of spouse, anxiety, depression, dependence on others, and lowered income all affect eating habits (Table 47–2). Guidelines to include high-nutrient foods compatible with the nutritional needs of older adults are summarized in Client Teaching and in the Nutritional Reference Guide. Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide. Also see Lifespan Considerations on pages 1138–1139.

STANDARDS FOR A HEALTHY DIET

Various daily food guides have been developed to help healthy people meet the daily requirements of essential nutrients and to facilitate meal planning. Food group plans emphasize the general types or groups of foods rather than the specific foods, because related foods are similar in composition and often have similar nutrient values. For example, all grains, whether wheat or oats, are significant sources of carbohydrate, iron, and the B vitamin thiamine. Food guides currently used include *Dietary Guidelines for Americans* and the U.S. Department of Agriculture's (USDA's) Food Guidance System (MyPlate, MyPyramid, food guide pyramids).

TABLE 47–2 Problems Associated with Nutrition in Older Adults

Problems	Nursing Interventions
Difficulty chewing	Encourage regular visits to the dentist to have dentures repaired, refitted, or replaced. Chop fruits and vegetables finely; shred green, leafy vegetables; select ground meat, poultry, or fish.
Lowered glucose tolerance	Eat more complex carbohydrates (e.g., breads, cereals, rice, pasta, potatoes, and legumes) rather than sugar-rich foods.
Decreased social interaction, loneliness	Promote appropriate social interaction at meals, when possible. Encourage the client and family to take an interest in food preparation and serving, perhaps as an activity they can do together. Encourage family or caregivers to present the food at a dining table with place mats, tablecloths, and napkins to trigger eating associations for the older adult. If food preparation is not possible, suggest community resources, such as Meals-on-Wheels. Suggest picnics in the yard or inviting friends over for meals.
Loss of appetite and senses of smell and taste	Eat essential, nutrient-dense foods first; follow with desserts and low-nutrient-density foods. Review dietary restrictions, and find ways to make meals appealing within these guidelines. Eat small meals frequently instead of three large meals a day.
Limited income	Suggest using generic brands and coupons. Substitute milk, dairy products, and beans for meat. Avoid convenience foods if able to cook. Buy foods that are on sale and freeze for future use. Suggest community resources and nutrition programs.
Difficulty sleeping at night	Have the major meal at noon instead of in the evening. Avoid tea, coffee, or other stimulants in the evening.

CLIENT TEACHING**Nutrition for Older Adults**

- *Include each food group on the Food Pyramid/MyPlate.*

For example, a 65-year-old female of average height and weight who performs less than 30 minutes of exercise per day requires 1,600 Kcal consisting of the following:

Grains	5 ounces
Vegetables	2 cups
Fruits	1.5 cups
Milk, yogurt, and cheese	3 cups
Meat and beans	5 ounces

- *Reduce caloric intake.* Caloric needs generally decrease in older adults often because of decreased activity. Older adults need to consume nutrient-dense foods and avoid foods that are high in calories but have few nutrients.
- *Reduce fat consumption.* Use leaner cuts of meat, and limit portions to 4 to 6 oz per day. (But be sure intake of meat is sufficient, because older adults often consume inadequate amounts of these foods.) Broil, boil, or bake foods instead of frying them. Use low-fat milk and cheese; limit intake of butter, margarine, and salad dressings.
- *Reduce consumption of empty calories.* Substitute fruit or puddings made with low-fat milk in place of pastry, cookies, and rich desserts.

- *Reduce sodium consumption for clients who have hypertension or other cardiac problems.* Avoid canned soups, ketchup, and mustard. Avoid salted, smoked, cured, and pickled meats (e.g., ham and bacon), poultry, and fish. Do not add salt when cooking foods or at the table.
- *Ensure adequate calcium intake (at least 800 mg) to prevent bone loss.* Milk, cheese, yogurt, cream soups, puddings, and frozen milk products are good sources. Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide and see the Major Food Sources of Calcium table.
- *Ensure adequate vitamin D intake.* Vitamin D is essential to maintain calcium homeostasis. Include some milk, because other dairy products are not usually fortified with vitamin D. If milk cannot be tolerated because of a lactose deficiency, provide vitamin supplements.
- *Ensure adequate iron intake.* Iron intake in older people may be compromised by such factors as increased incidence of GI disturbance, chronic diarrhea, regular aspirin use, and possible reduction in meat consumption. Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide and see the Major Food Sources of Iron table.
- *Consume fiber-rich foods to prevent constipation and minimize use of laxatives.* Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide and see the Fiber-Rich Foods table. Because fiber-rich foods provide bulk and a feeling of fullness, they help people control their appetites and lose weight.

LIFESPAN CONSIDERATIONS Nutrition**CHILDREN**

- Children learn eating habits from their parents. It is the parents' responsibility to be good nutritional role models, both in terms of what they eat and how they incorporate food into their lifestyle.
- During the preschool and early school-age years, children learn lifelong eating habits. It is the parents' responsibility to provide the child with adequate amounts of nutritious foods in an environment that is relaxed and comfortable for eating. It is the

child's responsibility to decide what and how much of the nutritious foods to eat. Parents should be counseled that eating can become a source of conflict if the parent tries to tell the child what and how much to eat, or if the child tries to tell the parent what foods should be eaten. Children's access to "junk food" should be limited, but completely forbidding a food may also create conflict.

- Adolescents who are vegan or vegetarians are at risk for some nutritional deficits.

LIFESPAN CONSIDERATIONS Nutrition—continued**OLDER ADULTS**

Most older adults take several medications. Considerations for potential problems include the following:

- Some foods interact adversely or decrease the effectiveness of certain medications, such as foods high in vitamin K and the anticoagulant warfarin (Coumadin). Older adults should not change their diet significantly without consulting the health care provider since drug dosage may have been based on the older adult's previous dietary intake.
- Some medications increase appetite, such as glucocorticoids.
- Some medications decrease appetite by their actions or by causing an unpleasant taste.
- Certain tablets should not be crushed to be given by mouth or by gastric tubes, such as enteric-coated or slow-release medications.

Conditions such as neuromuscular disorders and dementia can make it difficult for older adults to eat or to be fed. Safety should

always be a priority concern with attention paid to prevent aspiration. All health care personnel and family caregivers should be taught proper techniques to reduce this risk. Effective techniques include:

- Use the chin-tuck method when feeding clients with dysphagia. Have them flex the head toward the chest when swallowing to decrease the risk of aspiration into the lungs.
- Use foods of prescribed consistency. Many older adults can swallow foods with thicker consistency more easily than thin liquids.
- Try to focus on food preferences—the family can help provide this information.
- Try to maintain mealtime as a positive social occasion with conversations and extra attention to having a pleasant environment.

Economic factors may influence older adults' nutritional status if they cannot afford food, especially if a prescribed diet requires expensive supplements. Inexpensive or convenience foods such as canned soups are often high in fat and sodium.

Dietary Guidelines for Americans

This guide is published by the USDA every 5 years, and the 2010 edition contains recommendations for the total diet that allows food choices that result in a nutrient-rich and calorie-balanced intake. Key points of the latest dietary guidelines follow:

- Shift to more plant-based foods such as vegetables, fruits, grains, beans, and nuts.
- Significantly reduce foods with added sugars and solid fats.
- Engage in regular physical activity.
- Consume foods, including milk products, each day that increase commonly insufficient nutrients: vitamin D, calcium, potassium, and fiber.
- Keep daily total fat intake within 20% to 35% of total calories, less than 7% from saturated fatty acids and less than 300 mg cholesterol. (See also Client Teaching for ways to reduce fat intake.)
- Consume less than 1,500 mg of sodium per day.
- If you drink alcohol, do so in moderation (one drink per day for women and two drinks per day for men).

These dietary recommendations are intended to help achieve the nutritional goals stated in *Healthy People 2020* (U.S. Department of Health and Human Services, 2013). Those goals include 22 specific nutritional objectives, such as the following:

- Reduce the incidence of obese adults (target = 30.5%) and children (target = 14.5%).
- Increase the proportion of persons ages 2 years and older who consume no more than 2,300 mg of sodium daily.
- Prevent inappropriate weight gain in youth and adults.
- Reduce consumption of calories from solid fats and added sugars in the population ages 2 years and older (target = 29.8%).

THE FOOD GUIDE PYRAMID AND MYPLATE

The Food Guide Pyramid is a graphic aid developed by the USDA as a guide in making daily food choices. On the pyramid, the food groups—grains, vegetables, fruits, milk, and meat and beans—are drawn from the base of the pyramid to the apex. This indicates that activity, moderation, personalization, proportionality, variety, and gradual improvement are the keys to good nutrition (Figure 47-1 ■).

CLIENT TEACHING**Reducing Dietary Fat**

- Cook meat by grilling, baking, broiling, or microwaving rather than frying.
- Substitute popcorn or pretzels for such snacks as potato chips, cheese puffs, and corn chips.
- Read labels. Some crackers, for example, are high in fat; others are not.
- Limit desserts high in fat, such as candy, ice cream, cake, and cookies.
- Substitute hard candies for chocolate bars.
- Use skim or reduced-fat milk instead of whole milk, for drinking as well as in recipes.
- Use less butter or margarine on breads.
- Remove fat from meat and skin from chicken before cooking.
- Eat less meat; eat more fish.
- Use less dressing, or use low-fat dressings, on salads.
- Eat plant sources of protein (e.g., kidney, lima, and navy beans).
- Use nuts as a source of protein, but since they are high in fat, use to replace meat rather than in addition.

There are many variations of the standard food pyramid. Examples include the pyramid for young children, the Healthy Eating Pyramid from the Harvard School of Public Health, an Asian food pyramid, and a pyramid for older adults. Food guide pyramids or other shaped diagrams exist for many cultures, and Georgia State University has translated the original pyramid into more than 36 languages.

In May 2011, First Lady Michelle Obama introduced the MyPlate icon as a simpler reminder of how to implement the dietary guidelines. This depiction, and the website that accompanies it, promote getting more fruits and vegetables, whole grains, and low-fat dairy foods into the diet (Figure 47-2 ■). Although it may replace the pyramid in many settings, both diagrams are consistent with the *Dietary Guidelines*.

Using and following the guide does not guarantee that a person will consume the necessary levels of all essential nutrients. For example, someone who chooses cooked and low-fiber fruits and vegetables might not have an adequate intake of dietary fiber even though the recommended number of servings is eaten. However, the

Anatomy of MyPyramid

One size doesn't fit all

USDA's new MyPyramid symbolizes a personalized approach to healthy eating and physical activity. The symbol has been designed to be simple. It has been developed to remind consumers to make healthy food choices and to be active every day. The different parts of the symbol are described below.

Activity

Activity is represented by the steps and the person climbing them, as a reminder of the importance of daily physical activity.

Moderation

Moderation is represented by the narrowing of each food group from bottom to top. The wider base stands for foods with little or no solid fats or added sugars. These should be selected more often. The narrower top area stands for foods containing more added sugars and solid fats. The more active you are, the more of these foods can fit into your diet.

Personalization

Personalization is shown by the person on the steps, the slogan, and the URL. Find the kinds and amounts of food to eat each day at MyPyramid.gov.

Proportionality

Proportionality is shown by the different widths of the food group bands. The widths suggest how much food a person should choose from each group. The widths are just a general guide, not exact proportions. Check the Web site for how much is right for you.

Variety

Variety is symbolized by the 6 color bands representing the 5 food groups of the Pyramid and oils. This illustrates that foods from all groups are needed each day for good health.

Gradual Improvement

Gradual improvement is encouraged by the slogan. It suggests that individuals can benefit from taking small steps to improve their diet and lifestyle each day.

USDA U.S. Department of Agriculture

From U.S. Department of Agriculture, 2013.

food guide is easy to follow, and people who eat a variety of foods from each group, in the suggested amounts, are likely to come close to recommended nutrient levels.

Recommended Dietary Intake

The Committee on the Scientific Evaluation of Dietary Reference Intakes of the Institute of Medicine publishes dietary reference intakes (DRIs) tables, which contain four sets of reference values: estimated average requirements (EARs), recommended dietary allowances (RDAs), adequate intakes (AIs), and tolerable upper intake levels (ULs). Definitions of these terms are found in Box 47-3. The values for RDAs and AIs in the tables are modified for different age groups and according to gender. The effect of illness or injury (increasing the need for nutrients) and the variability among individuals within any given subgroup are not taken into account in the DRIs.

Consumers most commonly learn recommended dietary intake information from the U.S. Food and Drug Administration (FDA) nutrition labels. Food labeling is required for most prepared foods, such as breads, cereals, canned and frozen foods, snacks, desserts, and drinks. Nutrition labeling for raw produce (fruits and vegetables) and fish is voluntary. Everyone must learn how to read and interpret these labels.

In Figure 47-3 ■, the section at the top of the label ❶ indicates serving size and number of servings in the container. The remaining

BOX 47-3 Definitions for Dietary Reference Value Tables

Dietary reference intakes (DRIs) are the standards for nutrient recommendations that include the following values:

- *Estimated average requirement (EAR)*: the average daily nutrient intake value estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group
- *Recommended dietary allowance (RDA)*: the average daily nutrient intake level sufficient to meet the nutrient requirement of nearly all (97% to 98%) healthy individuals in a particular life stage and gender group
- *Adequate intake (AI)*: used when RDA cannot be determined; a recommended average daily nutrient intake level based on

observed or experimentally determined approximations or estimates of nutrient intake for a group (or groups) of healthy people that are assumed to be adequate

- *Tolerable upper intake level (UL)*: the highest average daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in a particular life stage and gender group. As intake increases above the UL, the potential risk of adverse health effects increases.

Figure 47-3 ■ The Nutrition Facts label.

From *How to Understand and Use the Nutrition Facts Label*, by the U.S. FDA/Center for Food Safety & Applied Nutrition, 2004. Retrieved from <http://www.fda.gov/Food/IngredientsPackagingLabeling/LabelingNutrition/ucm274593.htm>

information on the label indicates the values for *each serving*. If the person consumes a container that has more than one serving, the person must multiply the values to determine the real nutrient content. The next section 2 indicates the number of total calories and calories from fat per serving. Based on a 2,000-calorie diet, a serving with 40 calories is considered low, 100 calories moderate, and 400 calories high. Section 3 has those nutrients that should be minimized: fats, cholesterol, and sodium. A “% Daily Value” (DV) of 5% or less is low, and 20% or more is high. When adding the % DV from all foods eaten in one day, the goal is to keep the total below 100%. Packaged foods must list *trans-fat* content. *Trans-fats* are created when unsaturated oils are hydrogenated to create a solid form and are used in frying foods, margarine, and many snack products. They are also present in meat and dairy fats. *Trans-fats* have been shown to increase cholesterol and contribute to heart disease. The next section 4 includes fiber, vitamins, and minerals commonly insufficient in American diets. When adding the percent values from all foods eaten in one day, the goal is for the total DV of each of these to be at least 100%. The footnote 5 indicates the approximate DVs for fat cholesterol, sodium, total carbohydrate, and fiber for 2,000- and 2,500-calorie diets. The 2,000-calorie values are used for the % DV numbers in the upper sections 6. Note that the % DV on this label has not yet been revised to reflect the 2010 dietary guidelines.

If the label on a food is missing, consumers can retrieve the information from several websites.

Vegetarian Diets

People may become vegetarians for economic, health, religious, ethical, or ecologic reasons. There are two basic vegetarian diets: those that use only plant foods (vegan) and those that include milk, eggs, or dairy products. Some people eat fish and poultry but not beef, lamb, or pork; others eat only fresh fruit, juices, and nuts; and still others eat plant foods and dairy products but not eggs. Go to nursing.pearsonhighered.com to download the Nutritional Reference Guide to see the Types of Vegetarian Diets table.

Vegetarian diets can be nutritionally sound if they include a wide variety of foods and if proper protein and vitamin and mineral supplementation are provided. Because the proteins found in plant foods are incomplete proteins, vegetarians must eat complementary protein foods to obtain all of the essential amino acids. A plant protein can be complemented by combining it with a different plant protein. The combination produces a complete protein (Box 47–4). Obtaining complete proteins is especially important for growing children and pregnant and lactating women, whose protein needs are high. Generally, legumes (starchy beans, peas, lentils) have complementary relationships with grains, nuts, and seeds. Complementary foods must be eaten in the same meal. Diets such as the fruitarian diet do not provide sufficient amounts of essential nutrients and are not recommended for long-term use.

Foods of animal origin are the best source of vitamin B₁₂. Therefore, vegans need to obtain this vitamin from other sources: brewer’s yeast, foods fortified with vitamin B₁₂, or a vitamin supplement. Because iron from plant sources is not absorbed as efficiently as iron from meat, vegans should eat iron-rich foods (e.g., green leafy vegetables, whole grains, raisins, and molasses) and iron-enriched foods. They should eat a food rich in vitamin C at each meal to enhance iron absorption. Calcium deficiency is a concern only for strict vegetarians. It can be prevented by including in the diet soybean

BOX 47–4 Combinations of Plant Proteins That Provide Complete Proteins

Grains plus legumes = complete protein.
 Legumes plus nuts or seeds = complete protein.
 Grains, legumes, nuts, or seeds plus milk or milk products (e.g., cheese) = complete protein.

Grains	Legumes	Nuts and Seeds
Brown rice	Black beans	Almonds
Barley	Kidney beans	Brazil nuts
Corn meal	Lima beans	Cashews
Millet	Soybeans	Pecans
Oats/oatmeal	Lentils	Walnuts
Rye	Tofu	Pumpkin seeds
Whole wheat	Black-eyed peas	Sesame seeds
	Split peas	Sunflower seeds
Examples	Black-eyed peas and rice	
	Lentil soup and whole-wheat bread	
	Beans and tortillas	
	Lima beans and sesame seeds	
	Cereal with milk	
	Macaroni with cheese	

milk and tofu (soybean curd) fortified with calcium and leafy green vegetables.

ALTERED NUTRITION

Malnutrition is commonly defined as the lack of necessary or appropriate food substances, but in practice includes both undernutrition and overnutrition. **Overnutrition** refers to a caloric intake in excess of daily energy requirements, resulting in storage of energy in the form of adipose tissue. As the amount of stored fat increases, the individual becomes overweight or obese. A person is said to be **overweight** when the BMI is between 25 and 29.9 kg/m² and **obese** when the BMI is >30 kg/m² (National Heart, Lung, and Blood Institute, n.d.).

Excess body weight increases the stress on body organs and predisposes people to chronic health problems such as hypertension and diabetes mellitus. Obesity that interferes with mobility or breathing is referred to as morbid obesity. Obese individuals may also manifest undernourishment in important nutrients (e.g., essential vitamins or minerals) even though excess calories are ingested.

Undernutrition refers to an intake of nutrients insufficient to meet daily energy requirements because of inadequate food intake or improper digestion and absorption of food. An inadequate food intake may be caused by the inability to acquire and prepare food, inadequate knowledge about essential nutrients and a balanced diet, discomfort during or after eating, dysphagia, anorexia, nausea, vomiting, and so on. Improper digestion and absorption of nutrients may be caused by an inadequate production of hormones or enzymes or by medical conditions resulting in inflammation or obstruction of the GI tract.

Inadequate nutrition is associated with marked weight loss, generalized weakness, altered functional abilities, delayed wound healing, increased susceptibility to infection, decreased immunocompetence, impaired pulmonary function, and prolonged length of hospitalization. In response to undernutrition, carbohydrate reserves, stored as

liver and muscle glycogen, are mobilized. However, these reserves can only meet energy requirements for a short time (e.g., 24 hours) and then body protein is mobilized.

Protein-calorie malnutrition (PCM), seen in starving children of underdeveloped countries, is now also recognized as a significant problem of clients with long-term deficiencies in caloric intake (e.g., those with cancer and chronic disease). Characteristics of PCM are depressed visceral proteins (e.g., albumin), weight loss, and visible muscle and fat wasting.

Protein stores in the body are generally divided into two compartments: somatic and visceral. Somatic protein consists largely of skeletal muscle mass; it is assessed most commonly by conducting anthropometric measurements such as the mid-arm circumference (MAC) and the mid-arm muscle area (MAMA). (See the *Anthropometric Measurements* section on page 1144.) Visceral protein includes plasma protein, hemoglobin, several clotting factors, hormones, and antibodies. It is usually assessed by measuring serum protein levels such as albumin and transferrin, discussed in the *Biochemical (Laboratory) Data* section of *Assessing*, which follows.

●○○ NURSING MANAGEMENT

Assessing

A nutritional assessment identifies clients at risk for malnutrition and those with poor nutritional status. In most health care facilities, the responsibility for nutritional assessment and support is shared by the primary care provider, the dietitian, and the nurse. A comprehensive nutritional assessment is often performed by a nutritionist or a dietitian, and the primary care provider. Components of a nutritional assessment are shown in Table 47–3 and may be remembered as ABCD data: anthropometric, biochemical, clinical, and dietary.

Nutritional Screening

Because a comprehensive nutritional assessment is time consuming and expensive, various levels and types of assessment are available. Nurses perform a nutritional screen. A nutritional screen is an assessment performed to identify clients at risk for malnutrition or those who are malnourished. For clients who are found to be at moderate or high risk for malnutrition (Box 47–5), follow-up is provided in the

TABLE 47–3 Components of a Nutritional Assessment

	Screening Data	Additional In-Depth Data

*The potential effects of some medications on nutrition are shown in Table 47–1 on page 1134.

form of a comprehensive assessment by a dietitian. Medicare standards for nursing homes require that any resident who experiences unplanned or undesired weight loss of 5% or more in 1 month, 7.5% or more in 3 months, or 10% or more in 6 months receive a full nutritional assessment by a nurse.

Nurses carry out nutritional screens through routine nursing histories and physical examinations. Custom-designed screens for a particular population (e.g., older adults and pregnant women) and specific disorders (e.g., cardiac disease) are available.

Screening tools such as the Patient-Generated Subjective Global Assessment (PG-SGA; Figure 47-4 ■) and the Nutrition Screening Initiative (NSI) can be incorporated into the nursing history. The PG-SGA is a method of classifying clients as either well nourished, moderately malnourished, or severely malnourished based on a dietary history and physical examination. It was established primarily for use with cancer clients, but has been widely tested and is appropriate for both inpatient and outpatient clients with various diagnoses.

The NSI is an ongoing project of the American Academy of Family Physicians, the American Dietetic Association, the National Council on Aging, and other organizations to promote nutrition screening and improved nutritional care for older adults. The NSI estimates that approximately half of hospitalized, nursing home, and

home care older adults are malnourished. The NSI screens older adults using a nutrition checklist that contains nine warning signs of conditions that can interfere with good nutrition (Box 47-6).

Nursing History

As mentioned earlier, nurses obtain considerable nutrition-related data in the routine admission nursing history. Data include but are not limited to the following:

- Age, sex, and activity level
- Difficulty eating (e.g., impaired chewing or swallowing)
- Condition of the mouth, teeth, and presence of dentures
- Changes in appetite
- Changes in weight
- Physical disabilities that affect purchasing, preparing, and eating
- Cultural and religious beliefs that affect food choices
- Living arrangements (e.g., living alone) and economic status
- General health status and medical condition
- Medication history.

Anthropometric Measurements

Anthropometric measurements are noninvasive techniques that aim to quantify body composition. A **skinfold measurement**

Scored Patient-Generated Subjective Global Assessment (PG-SGA)

History Boxes 1-4 are designed to be completed by the patient.
[Boxes 1-4 are referred to as the PG-SGA Short Form (SF)]

Patient ID Information

1. Weight (See Worksheet 1)

In summary of my current and recent weight:

I currently weigh about _____ pounds
I am about _____ feet _____ tall

One month ago I weighed about _____ pounds
Six months ago I weighed about _____ pounds

During the past two weeks my weight has:

decreased ⁽¹⁾ not changed ⁽⁰⁾ increased ⁽⁰⁾ Box 1

2. Food Intake: As compared to my normal intake, I would rate my food intake during the past month as:

unchanged ⁽⁰⁾
 more than usual ⁽⁰⁾
 less than usual ⁽¹⁾

I am now taking:

normal food but less than normal amount ⁽¹⁾
 little solid food ⁽²⁾
 only liquids ⁽³⁾
 only nutritional supplements ⁽³⁾
 very little of anything ⁽⁴⁾
 only tube feedings or only nutrition by vein ⁽⁰⁾ Box 2

3. Symptoms: I have had the following problems that have kept me from eating enough during the past two weeks (check all that apply):

<input type="checkbox"/> no problems eating ⁽⁰⁾	<input type="checkbox"/> vomiting ⁽³⁾
<input type="checkbox"/> no appetite, just did not feel like eating	<input type="checkbox"/> nausea ⁽¹⁾
<input type="checkbox"/> constipation ⁽¹⁾	<input type="checkbox"/> diarrhea ⁽³⁾
<input type="checkbox"/> mouth sores ⁽²⁾	<input type="checkbox"/> dry mouth ⁽¹⁾
<input type="checkbox"/> things taste funny or have no taste ⁽¹⁾	<input type="checkbox"/> smells bother me ⁽¹⁾
<input type="checkbox"/> problems swallowing ⁽²⁾	<input type="checkbox"/> feel full quickly ⁽¹⁾
<input type="checkbox"/> pain; where? ⁽¹⁾ _____	<input type="checkbox"/> fatigue ⁽¹⁾
<input type="checkbox"/> other** ⁽¹⁾ _____	

** Examples: depression, money, or dental problems Box 3

4. Activities and Function:

Over the past month, I would generally rate my activity as:

normal with no limitations ⁽⁰⁾
 not my normal self, but able to be up and about with fairly normal activities ⁽¹⁾
 not feeling up to most things, but in bed or chair less than half the day ⁽²⁾
 able to do little activity and spend most of the day in bed or chair, pretty much bedridden, rarely out of bed ⁽³⁾

BOX 47-6 Nutritional Screening Tool

Read the statement. Circle the number in the Yes column for those that apply to you. Total your nutritional assessment.

If you scored 0-2: Good! Recheck your nutritional score in 6 months.

If you scored 3-5: You are at moderate nutritional risk. See what can be done to improve your eating habits and lifestyle. Recheck your score in 3 months.

If you scored 6 or above: You are at high nutritional risk. Take this checklist to your doctor, nurse practitioner, or home health nurse. Ask for help to improve your nutritional health.

Nutritional Assessment Statements	Yes
I have an illness or condition that made me change the kind or amount of food I eat.	2
I eat fewer than two meals per day.	3
I eat few fruits, vegetables, or milk products.	2
I have three or more drinks of beer, liquor, or wine almost every day.	2

I have tooth or mouth problems that make it hard for me to eat.	2
I do not always have enough money to buy the food I need.	4
I eat alone most of the time.	1
I take three or more different prescribed or over-the-counter drugs a day.	1
Without wanting to, I have lost or gained 10 pounds in the last 6 months.	2
I am not always physically able to shop, cook, or feed myself.	2
Total	<input style="width: 50px;" type="text"/>

Reprinted with permission by the Nutrition Screening Initiative, a project of the American Dietetic Association, funded in part by a grant from Ross Products Division, Abbott Laboratories, Inc.

Figure 47-5 ■ Measuring the triceps skinfold.

Figure 47-6 ■ Measuring the mid-arm circumference.

is performed to determine fat stores. The most common site for measurement is the triceps skinfold (TSF). The fold of skin measured includes subcutaneous tissue but not the underlying muscle. It is measured in millimeters using special calipers. To measure the TSF, locate the midpoint of the upper arm (halfway between the acromion process and the olecranon process), then grasp the skin on the back of the upper arm along the long axis of the humerus (Figure 47-5 ■). Placing the calipers 1 cm (0.4 in.) below the nurse's fingers, measure the thickness of the fold to the nearest millimeter.

The **mid-arm circumference (MAC)** is a measure of fat, muscle, and skeleton. To measure the MAC, ask the client to sit or stand with the arm hanging freely and the forearm flexed to horizontal. Measure the circumference at the midpoint of the arm, recording the measurement in centimeters, to the nearest millimeter (e.g., 24.6 cm) (Figure 47-6 ■).

The **mid-arm muscle area (MAMA)** is then calculated by using reference tables or by using a formula that incorporates the TSF

TABLE 47-4 Standard Values for Anthropometric Measurements for Adults

Measurement	Male	Female
Triceps skinfold	12 mm	20 mm
Mid-arm circumference	32 cm	28 cm
Mid-arm muscle area	54 cm ²	30 cm ²

From "Overview of Undernutrition," in *The Merck Manual Online*, 2012, by R. S. Porter and J. L. Kaplan (Eds.). Retrieved from http://www.merckmanuals.com/professional/nutritional_disorders/undernutrition/overview_of_undernutrition.html.

and the MAC. The MAMA is an estimate of lean body mass, or skeletal muscle reserves. If tables are not available, the nurse uses the following formula to calculate the MAMA from the triceps skinfold and MAC direct measurements:

$$\text{MAMA (cm}^2\text{)} = \frac{[\text{midarm circumference (cm)} - (3.14 \times \text{TSF cm})]^2}{4\pi} - 10 \text{ (males) or } -6.5 \text{ (females)}$$

Standard values for anthropometric measurements for adults are shown in Table 47-4.

Changes in anthropometric measurements occur slowly and reflect chronic rather than acute changes in nutritional status. They are used, therefore, to monitor the client's progress for months to years rather than days to weeks. Ideally, initial and subsequent measurements need to be taken by the same clinician. In addition, measurements obtained need to be interpreted with caution. Fluctuations in hydration status that often occur during illness can influence the accuracy of results. In addition, normal standards often do not account for normal changes in body composition such as those that occur with aging.

Biochemical (Laboratory) Data

Laboratory tests provide objective data to the nutritional assessment, but because many factors can influence these tests, no single test specifically predicts nutritional risk or measures the presence or degree of a nutritional problem. The tests most commonly used are serum proteins, urinary urea nitrogen and creatinine, and total lymphocyte count.

Serum Proteins

Serum protein levels provide an estimate of visceral protein stores. Tests commonly include hemoglobin, albumin, transferrin, and total iron-binding capacity. A low hemoglobin level may be evidence of iron deficiency anemia. However, abnormal blood loss or a pathologic process such as GI cancer must be ruled out before iron deficiency related to diet is confirmed.

Albumin, which accounts for over 50% of the total serum proteins, is one of the most common visceral proteins evaluated as part of the nutritional assessment. Because there is so much albumin in the body and because it is not broken down very quickly (i.e., it has a half-life of 18 to 20 days), albumin concentrations change slowly. A low serum albumin level is a useful indicator of prolonged protein depletion rather than acute or short-term

changes in nutritional status. However, many conditions besides malnutrition can depress albumin concentration, such as altered liver function, hydration status, and losses from open wounds and burns.

Transferrin binds and carries iron from the intestine through the serum. Because it has a shorter half-life than albumin (8 to 9 days), transferrin responds more quickly to protein depletion than albumin. Serum transferrin can be measured directly or by a total iron-binding capacity (TIBC) test, which indicates the amount of iron in the blood to which transferrin can bind. Transferrin levels below normal are found with protein loss, iron deficiency anemia, pregnancy, hepatitis, or liver dysfunction.

Prealbumin, also referred to as thyroxine-binding albumin or transthyretin, has the shortest half-life and smallest body pool and is, therefore, the most responsive serum protein to rapid changes in nutritional status. Prealbumin levels of 15 to 35 mg/dL are normal, below 15 indicates clients at risk, and below 11 indicates that aggressive nutritional intervention is needed.

Urinary Tests

Urinary urea nitrogen and urinary creatinine are measures of protein catabolism and the state of nitrogen balance. **Urea**, the chief end product of amino acid metabolism, is formed from ammonia detoxified by the liver, circulated in the blood, and transported to the kidneys for excretion in urine. Urea concentrations in the blood and urine, therefore, directly reflect the intake and breakdown of dietary protein, the rate of urea production in the liver, and the rate of urea removal by the kidneys.

The state of nitrogen balance is determined by comparing the nitrogen intake (grams of protein) to the nitrogen output over a 24-hour period. A positive nitrogen balance exists when intake exceeds nitrogen output; a negative nitrogen balance occurs when output exceeds nitrogen intake. Protein intake must be accurately recorded and kidney function must be normal to ensure the validity of a urinary urea nitrogen test.

Urinary creatinine reflects a person's total muscle mass because creatinine is the chief end product of the creatine produced when energy is released during skeletal muscle metabolism. The rate of creatinine formation is directly proportional to the total muscle mass. Creatinine is removed from the bloodstream by the kidneys and excreted in the urine at a rate that closely parallels its formation. The greater the muscle mass, the greater the excretion of creatinine. As skeletal muscle atrophies during malnutrition, creatinine excretion decreases. Urinary creatinine is influenced by protein intake, exercise, age, sex, height, renal function, and thyroid function.

Total Lymphocyte Count

Certain nutrient deficiencies and forms of PCM can depress the immune system. The total number of lymphocyte white blood cells decreases as protein depletion occurs.

Clinical Data (Physical Examination)

Physical examination reveals some nutritional deficiencies and excesses besides obvious weight changes. Assessment focuses on rapidly proliferating tissues such as skin, hair, nails, eyes, and mucosa but also includes a systematic review comparable to any routine physical

examination. See Clinical Manifestations and Figure 47-7 ■ for signs associated with malnutrition. These signs must be viewed as suggestive of malnutrition because the signs are nonspecific. For example, red conjunctiva may indicate an infection rather than a nutritional deficit, and dry, dull hair may be related to excessive exposure to the sun rather than severe protein-energy malnutrition. To confirm malnutrition, clinical findings need to be substantiated with laboratory tests and dietary data.

Calculating Percentage of Weight Loss

Accurate assessment of the client's height, current body weight (CBW), and usual body weight (UBW) is essential. Although the client's CBW can be compared with an ideal body weight discussed earlier, the IBW is based on healthy people and does not account for changes in the client's body composition that accompany illness or reflect any changes in weight. The client's UBW better indicates weight change and the possibility of malnutrition. Calculation and interpretation of the percentage of deviation from UBW and the percentage of weight loss are shown in Box 47-7. An important aspect of weight assessment, obtained during the nursing history, is a description of weight change. The nurse should document any weight loss or gain, the duration of the change, and whether the weight change was intentional or unintentional.

Dietary Data

Dietary data includes the client's usual eating patterns and habits; food preferences, allergies, and intolerances; frequency, types, and quantities of foods consumed; and social, economic, ethnic, or religious factors influencing nutrition. Factors may include, but are not limited to, living and eating companions, ability to purchase and prepare food, availability of refrigeration and cooking facilities, income, and effect of religion and ethnicity on food choices.

Four possible methods for collecting dietary data are a 24-hour food recall, a food frequency record, a food diary, and a diet history.

For a **24-hour food recall**, the nurse asks the client to recall all of the food and beverages the client consumes during a typical 24-hour period when at home. The data obtained are then generally evaluated according to the Food Guide to judge overall adequacy.

A **food frequency record** is a checklist that indicates how often general food groups or specific foods are eaten. Frequency may be categorized as times/day, times/week, times/month, or frequently, seldom, never. This record provides information about the types of foods eaten but not the quantities. When specific foods or nutrients are suspected of being deficient or excessive, the health care professional may use a selective food frequency that focuses, for example, on fat, fruit, vegetable, or fiber intake.

A **food diary** is a detailed record of measured amounts (portion sizes) of all food and fluids a client consumes during a specified period, usually 3 to 7 days.

A **diet history** is a comprehensive time-consuming assessment of a client's food intake that involves an extensive interview by a nutritionist or dietitian. It includes characteristics of foods usually eaten and the frequency and amount of food consumed. It may include a 24-hour recall, a food frequency record, and a food diary. Medical and psychosocial factors are also assessed to evaluate their impact on

nutritional requirements, food habits, and choices. Data obtained are analyzed by computer and translated into caloric and nutrient intake. Results are compared with the DRIs appropriate for the client's age, sex, and condition.

Diagnosing

NANDA International (Herdman & Kamitsuru, 2014) includes the following diagnostic labels for nutritional problems:

- *Imbalanced Nutrition: Less Than Body Requirements*
- *Obesity*
- *Overweight*
- *Readiness for Enhanced Nutrition*

Many other NANDA nursing diagnoses may apply to certain individuals, because nutritional problems often affect other areas of human functioning. In this case, the nutritional diagnostic label may be used as the etiology of other diagnoses. Examples include:

- *Activity Intolerance* related to inadequate intake of iron-rich foods resulting in iron deficiency anemia
- *Constipation* related to inadequate fluid intake and fiber intake
- *Chronic Low Self-Esteem* related to obesity

- *Risk for Infection* related to immunosuppression secondary to insufficient protein intake.

Planning

Major goals for clients with or at risk for nutritional problems include the following:

- Maintain or restore optimal nutritional status.
- Promote healthy nutritional practices.
- Prevent complications associated with malnutrition.
- Decrease weight.
- Regain specified weight.

Specific nursing activities associated with each of these goals can be selected to meet the individual needs of the client. See the Nursing Care Plan and Concept Map at the end of this chapter.

Planning for Home Care

To provide for continuity of care, the nurse must consider the client's need for assistance with nutrition. Some clients will need help with eating, purchasing food, and preparing meals; others will need instructions about nutrition therapy.

CLINICAL MANIFESTATIONS

Malnutrition

Area of Examination (Possible Cause)	Signs Associated with Malnutrition
General appearance and vitality	Apathetic, listless, looks tired, easily fatigued
Weight	Overweight or underweight
Skin	Dry, flaky, or scaly; pale or pigmented; presence of petechiae or bruises; lack of subcutaneous fat; edema
Nails	Brittle, pale, ridged, or spoon shaped (iron)
Hair	Dry, dull, sparse, loss of color, brittle (Figure 47–7A)
Eyes	Pale or red conjunctiva, dryness, soft cornea, dull cornea, night blindness (vitamin A deficiency)
Lips	Swollen, red cracks at side of mouth, vertical fissures (B vitamins) (Figure 47–7C)
Tongue	Swollen, beefy red or magenta colored (B vitamins); smooth appearance (B vitamins deficiency); decrease or increase in size
Gums	Spongy, swollen, inflamed; bleed easily (vitamin C deficiency)
Muscles	Underdeveloped, flaccid, wasted, soft
GI system	Anorexia, indigestion, diarrhea, constipation, enlarged liver, protruding abdomen
Nervous system	Decreased reflexes, sensory loss, burning and tingling of hands and feet (B vitamins), mental confusion or irritability

Home care planning incorporates an assessment of the client's and family's abilities for self-care, financial resources, and the need for referrals and home health services. The Home Care Assessment box covers nutritional problems and needs. A major aspect of discharge planning involves the instructional needs of the client and family (see Client Teaching).

Implementing

Nursing interventions to promote optimal nutrition for hospitalized clients are often provided in collaboration with the primary care provider who writes the diet orders and the dietitian who informs clients about special diets. The nurse reinforces this instruction and, in addition, creates an atmosphere that encourages eating, provides assistance with eating, monitors the client's appetite and food intake, administers enteral and parenteral feedings, and consults with the primary care provider and dietitian about nutritional problems that arise.

In the community setting, the nurse's role is largely educational. Nurses promote optimal nutrition at health fairs, in schools, at prenatal classes, and with well or ill clients and support people in their homes. In the home setting, nurses also initiate nutritional screens, refer clients at risk to appropriate resources, instruct clients about enteral and parenteral feedings, and offer nutrition counseling as needed. Nutrition counseling involves more than providing information. The nurse must help clients integrate diet changes into their lifestyle and provide strategies to motivate them to change their eating habits.

All dietary instructions must be individually designed to meet the client's intellectual ability, motivation level, lifestyle, culture, and economic status. Both nutritionists and dietitians help to adapt a diet to suit the client. Simple verbal instructions need to be given and reinforced with written material. Family and support persons must be included in the dietary instruction.

Assisting with Special Diets

Alterations in the client's diet are often needed to treat a disease process such as diabetes mellitus, to prepare for a special examination or surgery, to increase or decrease weight, to restore nutritional deficits, or to allow an organ to rest and promote healing. Diets are modified in one or more of the following aspects: texture, kilocalories, specific nutrients, seasonings, or consistency.

Hospitalized clients who do not have special needs eat the regular (standard or house) diet, a balanced diet that supplies the metabolic requirements of a sedentary person (about 2,000 Kcal). Most agencies offer clients a daily menu from which to select their meals for the next day; others provide standard meals to each client on the general diet.

BOX 47-7

Calculating and Interpreting the Percentage of Deviation from Usual Body Weight and the Percentage of Weight Loss

CALCULATING PERCENTAGE OF USUAL BODY WEIGHT

$$\% \text{ Usual body weight} = \frac{\text{current weight}}{\text{usual body weight}} \times 100$$

Mild malnutrition	85–90%
Moderate malnutrition	75–84%
Severe malnutrition	Less than 74%

CALCULATING PERCENTAGE OF WEIGHT LOSS

$$\% \text{ Weight loss} = \frac{\text{usual weight} - \text{current weight}}{\text{usual weight}} \times 100$$

Significant Weight Loss	Severe Weight Loss
5% over 1 mo	Greater than 5% over 1 mo
7.5% over 3 mo	Greater than 7.5% over 3 mo
10% over 6 mo	Greater than 10% over 6 mo

Home Care Assessment Nutrition

PATIENT-CENTERED CARE

CLIENT/ENVIRONMENT

- *Self-care abilities:* Assess ability to feed self, to purchase food, and to prepare meals.
- *Adaptive feeding aids required:* Determine need for special drinking cups, plates, or feeding utensils.
- *Instructional needs:* Consider nutritional requirements (e.g., Food Guide Pyramid/MyPlate, dietary guidelines, special diet), adaptive aids available, recommended lifestyle variations, and management of enteral/parenteral nutrition.
- *Physical environment:* Assess adequacy of water, electricity, refrigeration, and telephone facilities; and presence of clean, secure area to store and set up enteral/parenteral equipment as needed.

FAMILY

- *Caregiver availability, skills, and willingness:* Assess whether primary and secondary individuals are able to assist with food purchase, meal preparation, and feeding and able to comprehend and administer special diets or enteral/parenteral nutrition required.
- *Family role changes and coping:* Consider effect on parenting and spousal roles, financial resources, and social roles.

- *Alternate potential primary or respite caregivers:* Consider the availability of other caregivers, for example, other family members, volunteers, church members, paid caregivers, or house-keeping services; available community respite care (adult day care, senior centers) and so on.

COMMUNITY

- *Current knowledge, use, and experience with community resources:* Review nutritional counseling services; home health agencies for enteral/parenteral nutrition support; dietitian or nutritionist for planning appropriate meals for prescribed diet, ways to include ethnic food preferences into the diet, and providing written meal plans; medical equipment and supply companies; financial assistance services; and support and educational services such as:
 - Weight management programs (e.g., Weight Watchers)
 - American Dietetic Association for information on all nutrition topics
 - National Eating Disorders Association
 - Meals-on-Wheels.

CLIENT TEACHING**Healthy Nutrition**

- Instruct clients about the content of a healthy diet based on the Food Guide Pyramid/MyPlate and *Dietary Guidelines for Americans*
- Encourage clients, particularly older clients, to reduce dietary fat (see Client Teaching on reducing dietary fat, page 1139).
- Instruct strict vegetarians about proper protein complementation and additional vitamin and mineral supplementation.
- Discuss foods high in specific nutrients required such as protein, iron, calcium, vitamin C, and fiber.
- Discuss importance of properly fitted dentures and dental care.
- Discuss safe food preparation and preservation techniques as appropriate.

DIETARY ALTERATIONS

- Explain the purpose of the diet.
- Discuss allowed and excluded foods.
- Explain the importance of reading food labels when selecting packaged foods.
- Include family or significant others.
- Reinforce information provided by the dietitian or nutritionist as appropriate.
- Discuss herbs and spices as alternatives to salt and substitutes for sugar.

FOR CLIENTS WHO ARE OVERWEIGHT

- Discuss physiological, psychological, and lifestyle factors that predispose to weight gain.
- Provide information about desired weight range and recommended calorie intake.
- Discuss principles of a well-balanced diet and high- and low-calorie foods.
- Encourage intake of low-calorie, caffeine-free beverages, and plenty of water.
- Discuss ways to adapt eating practices by using smaller plates, taking smaller servings, chewing each bite a specified number of times, and putting fork down between bites.
- Discuss ways to control the desire to eat by taking a walk, drinking a glass of water, or doing slow deep-breathing exercises.

- Discuss the importance of exercise and help the client plan an exercise program.
- Discuss stress reduction techniques.
- Provide information about available community resources (e.g., weight-loss groups, dietary counseling, exercise programs, self-help groups).

FOR CLIENTS WHO ARE UNDERWEIGHT

- Discuss factors contributing to inadequate nutrition and weight loss.
- Discuss recommended calorie intake and desired weight range.
- Provide information about the content of a balanced diet.
- Provide information about ways to increase calorie intake (e.g., high-protein or high-calorie foods and supplements).
- Discuss ways to manage, minimize, or alter the factors contributing to malnourishment.
- If appropriate, discuss ways to purchase low-cost nutritious foods.
- Provide information about community agencies that can assist in providing food (e.g., Meals-on-Wheels).

PREVENTING FOODBORNE ILLNESS

- Reinforce hygienic handling of food and dishes:
 - Wash hands before preparing foods.
 - Wash hands and all dishes, utensils, and cutting boards with hot water and soap after contact with raw meats.
 - Defrost frozen foods in the refrigerator.
 - Cook beef, poultry, and eggs thoroughly. Use a cooking thermometer.
 - Refrigerate leftovers promptly (at 40°F [5°C] or less) and keep no more than 3 to 5 days.
 - Wash or peel raw fruits and vegetables.
 - Do not use foods from containers that have been damaged or have opened seals.
 - Follow the rules “keep hot foods hot and cold foods cold” and “when in doubt, throw it out.”
- Recommend the client consider a preventive vaccination for hepatitis A.
- Instruct clients to seek medical attention for prolonged vomiting, fever, abdominal pain, or severe diarrhea following a meal.

A variation of the regular diet is the light diet, designed for postoperative and other clients who are not ready for the regular diet. Foods in the light diet are plainly cooked and fat is usually minimized, as are bran and foods containing a great deal of fiber.

Diets modified in consistency are often given to clients before and after surgery or procedures or to promote healing in clients with GI distress. These diets include clear liquid, full liquid, soft, and diet as tolerated. In some agencies, GI surgery clients are not permitted red-colored liquids or candy since, if vomited, the color may be confused with blood.

Clear Liquid Diet

This diet is limited to water, tea, coffee, clear broths, ginger ale, or other carbonated beverages, strained and clear juices, and plain gelatin. Note that “clear” does not necessarily mean “colorless.” This diet provides the client with fluid and carbohydrate (in the form of sugar), but does not supply adequate protein, fat, vitamins, minerals, or calories. It is a short-term diet (24 to 36 hours) provided for clients after certain surgeries or in the acute stages of infection, particularly of the GI tract. The major objectives of this diet are to relieve thirst, prevent dehydration, and minimize stimulation of the GI tract. Examples of foods allowed in clear liquid diets are shown in Box 47–8.

Full Liquid Diet

This diet contains only liquids or foods that turn to liquid at body temperature, such as ice cream (see Box 47–8). Full liquid diets are often eaten by clients who have GI disturbances or cannot tolerate solid or semisolid foods. This diet is not recommended for long-term use because it is low in iron, protein, and calories. In addition, its cholesterol content may be high because of the amount of cow’s milk offered. Clients who must receive only liquids for long periods are usually given a nutritionally balanced oral supplement, such as Ensure or Sustacal. The full liquid diet is monotonous and difficult for clients to accept. Planning six or more feedings per day may encourage a more adequate intake.

Soft Diet

The soft diet is easily chewed and digested. It is often ordered for clients who have difficulty chewing and swallowing. It is a low-residue

(low-fiber) diet containing very few uncooked foods; however, restrictions vary among agencies and according to individual tolerance. Examples of foods that can be included in a soft or semisolid diet are shown in Box 47–8. The **pureed diet** is a modification of the soft diet. Liquid may be added to the food, which is then blended to a semisolid consistency.

Diet as Tolerated

“Diet as tolerated” is ordered when the client’s appetite, ability to eat, and tolerance for certain foods may change. For example, on the first postoperative day a client may be given a clear liquid diet. If no nausea occurs, normal intestinal motility has returned as evidenced by active bowel sounds and client reports passing gas, and the client feels like eating, the diet may be advanced to a full liquid, light, or regular diet.

Modification for Disease

Many special diets may be prescribed to meet requirements for disease processes or altered metabolism. For example, a client with diabetes mellitus may need a diet recommended by the American Diabetes Association, an obese client may need a calorie-restricted diet, a cardiac client may need sodium and cholesterol restrictions, and a client with allergies will need a hypoallergenic diet.

Some clients must follow certain diets (e.g., the diabetic diet) for a lifetime. If the diet is long term, the client must understand the diet and also develop a healthy, positive attitude toward it. Assisting clients and support persons with special diets is a function shared by the dietitian or nutritionist and the nurse. The dietitian informs the client and support persons about the specific foods allowed and not allowed and assists the client with meal planning. The nurse reinforces this instruction, assists the client to make changes, and evaluates the client’s responses.

Dysphagia

Some clients may have no difficulty with choosing a healthy diet, but be at risk for nutritional problems due to dysphagia. These clients may have inadequate solid or fluid intake, be unable to swallow their medications, or aspirate food or fluids into the lungs—causing pneumonia. Clients at risk for dysphagia include older adults, those who have experienced a stroke, clients with cancer who have

BOX 47–8 Examples of Foods for Clear Liquid, Full Liquid, and Soft Diets

Clear Liquid	Full Liquid	Soft
Coffee, regular and decaffeinated	All foods on clear liquid diet plus:	All foods on clear and full liquid diets, plus:
Tea	Milk and milk drinks	Meat: all lean, tender meat, fish, or poultry (chopped, shredded); spaghetti sauce with ground meat over pasta
Carbonated beverages	Puddings, custards	Meat alternatives: scrambled eggs, omelet, poached eggs; cottage cheese and other mild cheese
Bouillon, fat-free broth	Ice cream, sherbet	Vegetables: mashed potatoes, sweet potatoes, or squash; vegetables in cream or cheese sauce; other cooked vegetables as tolerated (e.g., spinach, cauliflower, asparagus tips), chopped and mashed as needed; avocado
Clear fruit juices (apple, cranberry, grape)	Vegetable juices	Fruits: cooked or canned fruits; bananas, grapefruit and orange sections without membranes, applesauce
Other fruit juices, strained	Refined or strained cereals (e.g., cream of rice)	Breads and cereals: enriched rice, barley, pasta; all breads; cooked cereals (e.g., oatmeal)
Popsicles	Cream, butter, margarine	Desserts: soft cake, bread pudding
Gelatin	Eggs (in custard and pudding)	
Sugar, honey	Smooth peanut butter	
Hard candy	Yogurt	

had radiation therapy to the head and neck, and others with cranial nerve dysfunction. Consider dysphagia if the client exhibits the following behaviors: coughs, chokes, or gags while eating; complains of pain when swallowing; has a gurgling voice; requires frequent oral suctioning.

Nurses may be the first persons to detect dysphagia and are in an excellent position to recommend further evaluation; implement specialized feeding techniques and diets; and work with clients, family members, and other health care professionals to develop a plan to assist the client with difficulties. If the client condition suggests dysphagia, the nurse should review the history in detail; interview the client or family; assess the mouth, throat, and chest; and observe the client swallowing. Although absence of or a reduced gag reflex indicates the client will have difficulty swallowing, the presence of the gag reflex should not be interpreted to indicate that swallowing will not be impaired.

A multidisciplinary group has developed the National Dysphagia Diet (NDD), which delineates standards of food textures (American Dietetic Association, 2002). The four levels of liquid foods are thin, nectar-like, honey-like, and spoon-thick liquids. The four levels of semisolid/solid foods are pureed, mechanically altered, advanced/mechanically soft, and regular/general. In consultation with the dietitian, occupational therapist, swallowing specialist, speech-language pathologist, and/or primary care provider, these levels can be used to determine a consistent approach to a particular client's dysphagia. For example, a mechanically soft diet may result in lower pneumonia rates than a pureed diet in clients who have had a stroke and a history of aspiration pneumonia. Early detection and intervention can prevent the adverse outcomes of dysphagia in most clients.

Stimulating the Appetite

Physical illness, unfamiliar or unpalatable food, environmental and psychological factors, and physical discomfort or pain may depress the appetites of many clients. A short-term decrease in food intake usually is not a problem for adults; over time, however, it leads to weight loss, decreased strength and stamina, and other nutritional problems. Decreased food intake is often accompanied by a decrease in fluid intake, which may cause fluid and electrolyte problems. Stimulating a person's appetite requires the nurse to determine the reason for the lack of appetite and then deal with the problem. Some general interventions for improving the client's appetite are summarized in Box 47–9.

Assisting Clients with Meals

Because clients in health care agencies are frequently confined to their beds, meals are brought to the client. The client receives a tray that has been assembled in a central kitchen. Nursing personnel may be responsible for giving out and collecting the trays; however, in most settings this is done by dietary personnel. Long-term care facilities and some hospitals serve meals to mobile clients in a special dining area. Guidelines for providing meals to clients are summarized in Box 47–10.

Individuals who frequently require help with their meals include older adults who are weakened, individuals with disabilities such as visual impairment, those who must remain in a back-lying position,

BOX 47–9 Improving Appetite

- Provide familiar food that the person likes. Often the relatives of clients are pleased to bring food from home but may need some guidance about special diet requirements.
- Select small portions so as not to discourage the client.
- Avoid unpleasant or uncomfortable treatments immediately before or after a meal.
- Provide a tidy, clean environment that is free of unpleasant sights and odors. A soiled dressing, a used bedpan, an uncovered irrigation set, or even used dishes can negatively affect the appetite.
- Encourage or provide oral hygiene before mealtime. This improves the client's ability to taste.
- Relieve illness symptoms that depress appetite before mealtime; for example, give an analgesic for pain or an antipyretic for a fever or allow rest for fatigue.
- Reduce psychological stress. A lack of understanding of therapy, the anticipation of an operation, and fear of the unknown can cause anorexia. Often, the nurse can help by discussing feelings with the client, giving information and assistance, and allaying fears.

or those who cannot use their hands. The client's nursing care plan will indicate that assistance is required with meals.

The nurse must be sensitive to clients' feelings of embarrassment, resentment, and loss of autonomy. Whenever possible, the nurse should help clients feed themselves rather than feed them. Some clients become depressed because they require help and because they believe they are burdensome to busy nursing personnel. Although feeding a client is time consuming, nurses should try to appear unhurried and convey that they have ample time. Sitting at the bedside is one way to convey this impression. If the client is to be fed by unlicensed assistive personnel, the nurse must ensure that the same standards are met.

When feeding a client, ask in which order the client would like to eat the food. If the client cannot see, tell the client which food is being given. Always allow ample time for the client to chew and swallow the food before offering more. Also, provide fluids as requested or, if the client cannot communicate, offer fluids after every three or four mouthfuls of solid food. Make the time a pleasant one, choosing topics of conversation that are of interest to clients who want to talk.

Although normal utensils should be used whenever possible, special utensils may be needed to assist a client to eat. For clients who have difficulty drinking from a cup or glass, a straw often permits them to obtain liquids with less effort and less spillage. Special drinking cups are also available. One model has a spout; another is specially designed to permit drinking with less tipping of the cup than is normally required.

Many adaptive feeding aids are available to help clients maintain independence. A standard eating utensil with a built-up or widened handle helps clients who cannot grasp objects easily. Utensils with wide handles can be purchased, or a regular eating utensil can be modified by taping foam around the handle. The foam increases friction and steadies the client's grasp. Handles may be bent or angled to compensate for limited motion. Collars or bands that prevent the utensil from being dropped can be attached to the end of the handle

BOX 47-10 Providing Client Meals

- Offer the client assistance with hand washing and oral hygiene before a meal.
- If it is permitted, assist the client to a comfortable position in bed or in a chair, whichever is appropriate.
- Clear the overbed table so there is space for the tray. If the client must remain in a lying position in bed, arrange the overbed table close to the bedside so the client can see and reach the food.
- Check each tray for the client's name, the type of diet, and completeness. Do not leave an incorrect diet for a client to eat.
- Assist the client as required (e.g., remove the food covers, butter the bread, pour the tea, and cut the meat).
- For a client with a visual impairment, identify the placement of the food as you would describe the time on a clock (Figure 47-8 ■). For instance, the nurse might say, "The potatoes are at eight o'clock, the chicken at 12 o'clock, and the green beans at 4 o'clock."
- After the client has completed the meal, observe how much and what the client has eaten and the amount of fluid taken. Use a standard tool to estimate the amount eaten in relation to a typical meal. For example, if served a donut and hot chocolate for breakfast, although the client may have eaten both of these, they certainly do not represent 100% of a nutritious breakfast.
- If the client is on a special diet or is having problems eating, record the amount of food eaten and any pain, fatigue, or nausea experienced.

Figure 47-8 ■ For a client who is visually impaired, the nurse can use the clock system to describe the location of food on the plate.

and fit over the client's hand. Clients requiring pureed or liquid diets are sometimes fed with a feeding syringe.

Plates with rims and plastic or metal plate guards enable the client to pick up the food by first pushing it against this raised edge. A suction cup or damp sponge or cloth may be placed under the dish to keep it from moving while the client is eating. No-spill mugs and two-handled drinking cups are especially useful for individuals with impaired hand coordination. Stretch terry cloth and knitted or crocheted glass covers enable the client to keep a secure grasp on a glass. Lidded tip-proof glasses are also available. Figures 47-9 ■ and 47-10 ■ show some of these aids.

Figure 47-9 ■ Left to right: glass holder, cup with hole for nose, two-handled cup holder.

Special Community Nutritional Services

In many places, community programs have been developed to help special groups meet nutritional needs. For older adults who cannot prepare meals or leave their homes, ready-to-eat meals or frozen dinners are delivered to the home by local organizations. Meals-on-Wheels is one such well-known organization.

Figure 47-10 ■ Dinner plate with guard attached and lipped plate facilitate scooping; wide-handled spoon and knife facilitate grip.

For people who can prepare meals but have physical disabilities and cannot shop for groceries, grocery delivery services are available.

For the poor in the United States, the USDA funds the Supplemental Nutrition Assistance Program. Through this program, people with low incomes can use stamps to purchase food at any approved grocery store. The value of the food stamps provided depends on the size and income of the family.

Enteral Nutrition

Alternative feeding methods that ensure adequate nutrition include **enteral** (through the GI system) methods. Enteral nutrition (EN), also referred to as total enteral nutrition (TEN), is provided when the client cannot ingest foods or the upper GI tract is impaired and the transport of food to the small intestine is interrupted. Enteral feedings are administered through nasogastric and small-bore feeding tubes, or through gastrostomy or jejunostomy tubes.

Enteral Access Devices

Enteral access is achieved by means of nasogastric or nasointestinal (nasoenteric) tubes, or gastrostomy or jejunostomy tubes.

A **nasogastric tube** is inserted through one of the nostrils, down the nasopharynx, and into the alimentary tract. Traditional firm, large-bore nasogastric tubes (i.e., those larger than 12 Fr in diameter) are placed into the stomach. Examples are the Levin tube, a flexible rubber or plastic, single-lumen tube with holes near the tip, and the Salem sump tube, with a double lumen (Figure 47–11 ■). The larger lumens allow delivery of liquids to the stomach or removal of gastric contents. When the Salem tube is used for suction of gastric contents, the smaller vent lumen (the proximal port is often referred to as the *blue pigtail*) allows for an inflow of atmospheric air, which prevents a vacuum if the gastric tube adheres to the wall of the stomach. Irritation of the gastric mucosa is thereby avoided. Softer, more flexible and less irritating small-bore feeding tubes (SBFTs), smaller than 12 Fr in diameter, are frequently used for enteral nutrition (Figure 47–12 ■).

Nasogastric tubes are used for feeding clients who have adequate gastric emptying, and who require short-term feedings. They are not

Figure 47–11 ■ *Left*, Single-lumen Levin tube. *Right*, Double-lumen Salem sump tube with filter on air vent port.

Figure 47–12 ■ A polyurethane feeding tube designed for nasogastric and nasoduodenal feeding with a weighted tip for easier insertion. The feeding port is incompatible with luer lock or IV connections, reducing the risk of accidental connection or infusion. Tubes can be 8Fr–12Fr and 36”–55” long.
Courtesy Covidien.

advised for feeding clients without intact gag and cough reflexes since the risk of accidental placement of the tube into the lungs is much higher in those clients. Skill 47–1 provides guidelines for inserting a nasogastric tube. Skill 47–4 later in this chapter outlines the steps for removing a nasogastric tube.

Inserting a Nasogastric Tube

PURPOSES

- To administer tube feedings and medications to clients unable to eat by mouth or swallow a sufficient diet without aspirating food or fluids into the lungs
- To establish a means for suctioning stomach contents to prevent gastric distention, nausea, and vomiting
- To remove stomach contents for laboratory analysis
- To lavage (wash) the stomach in case of poisoning or overdose of medications

ASSESSMENT

- Check for history of nasal surgery or deviated septum. Assess patency of nares.
- Determine presence of gag reflex.
- Assess mental status or ability to participate in the procedure.

Inserting a Nasogastric Tube – continued

PLANNING

Before inserting a nasogastric tube, determine the size of tube to be inserted and whether the tube is to be attached to suction.

DELEGATION

Insertion of a nasogastric tube is an invasive procedure requiring application of knowledge (e.g., anatomy and physiology, risk factors) and problem solving. In some agencies, only health care providers with advanced training are permitted to insert nasogastric tubes that require use of a stylet. Delegation of this skill to unlicensed assistive personnel (UAP) is not appropriate. The UAP, however, can assist with the oral hygiene needs of a client with a nasogastric tube.

INTERPROFESSIONAL PRACTICE

Inserting a nasogastric tube may be within the scope of practice for some other health care providers such as physician assistants (PAs). Although the PA may verbally communicate their actions and plan to the health care team members, the nurse must also know where to locate their documentation in the client's medical record.

IMPLEMENTATION

Preparation

- Assist the client to a high-Fowler's position if his or her health condition permits, and support the head on a pillow. **Rationale:** *It is often easier to swallow in this position and gravity helps the passage of the tube.*
- Place a towel or disposable pad across the chest.

Performance

1. Prior to performing the insertion, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. The passage of a gastric tube is unpleasant because the gag reflex is activated during insertion. Establish a method for the client to indicate distress and a desire for you to pause the insertion. Raising a finger or hand is often used for this.
2. Perform hand hygiene and observe other appropriate infection prevention procedures (e.g., clean gloves).
3. Provide for client privacy.
4. Assess the client's nares.
 - Apply clean gloves.
 - Ask the client to hyperextend the head, and, using a flashlight, observe the intactness of the tissues of the nostrils, including any irritations or abrasions.
 - Examine the nares for any obstructions or deformities by asking the client to breathe through one nostril while occluding the other.
 - Select the nostril that has the greater airflow.
5. Prepare the tube.
 - If a small-bore tube is being used, ensure stylet or guidewire is secured in position. **Rationale:** *An improperly positioned stylet or guidewire can traumatize the nasopharynx, esophagus, and stomach.*
 - If a large-bore tube is being used, place the tube in a basin of warm water while preparing the client. **Rationale:** *This allows the tubing to become more pliable and flexible. However, if the softened tube becomes difficult to control, it may be helpful to place the distal end in a basin of ice water to help it hold its shape.*

Equipment

- Large- or small-bore tube (nonlatex preferred)
- Nonallergenic adhesive tape, 2.5 cm (1 in.) wide
- Commercial securement device, if available
- Clean gloves
- Water-soluble lubricant
- Facial tissues
- Glass of water and drinking straw
- 20- to 50-mL catheter-tip syringe
- Basin
- pH test strip or meter
- Bilirubin dipstick
- Stethoscope
- Disposable pad or towel
- Antireflux valve for air vent if Salem sump tube is used
- Suction apparatus
- Safety pin and elastic band
- Clamp or plug (optional)
- CO₂ detector (optional)

1 Measuring the appropriate length to insert a nasogastric tube.

6. Determine how far to insert the tube.
 - Use the tube to mark off the distance from the tip of the client's nose to the tip of the earlobe and then from the tip of the earlobe to the tip of the xiphoid. **1 Rationale:** *This length approximates the distance from the nares to the stomach. This distance varies among individuals.*
 - Mark this length with adhesive tape if the tube does not have markings.
7. Insert the tube.
 - Lubricate the tip of the tube well with water-soluble lubricant or water to ease insertion. In some agencies, topical

Inserting a Nasogastric Tube—continued

lidocaine anesthetic is used on the tube or in the client's nose to numb the area (Uri, Yosefov, Haim, Behrbalk, & Halpern, 2011). **Rationale:** A water-soluble lubricant dissolves if the tube accidentally enters the lungs. An oil-based lubricant, such as petroleum jelly, will not dissolve and could cause respiratory complications if it enters the lungs.

- Insert the tube, with its natural curve downward, into the selected nostril. Ask the client to hyperextend the neck, and gently advance the tube toward the nasopharynx. **Rationale:** Hyperextension of the neck reduces the curvature of the nasopharyngeal junction.
 - Direct the tube along the floor of the nostril and toward the midline. **Rationale:** Directing the tube along the floor avoids the projections (turbinates) along the lateral wall.
 - Slight pressure and a twisting motion are sometimes required to pass the tube into the nasopharynx, and some client's eyes may water at this point. **Rationale:** Tears are a natural body response. Provide the client with tissues as needed.
 - If the tube meets resistance, withdraw it, relubricate it, and insert it in the other nostril. **Rationale:** The tube should never be forced against resistance because of the danger of injury.
 - Once the tube reaches the oropharynx (throat), the client will feel the tube in the throat and may gag and retch. Ask the client to tilt the head forward, and encourage the client to drink and swallow. **Rationale:** Tilting the head forward facilitates passage of the tube into the posterior pharynx and esophagus rather than into the larynx; swallowing moves the epiglottis over the opening to the larynx. ②
 - If the client gags, stop passing the tube momentarily. Have the client rest, take a few breaths, and take sips of water to calm the gag reflex.
 - In cooperation with the client, pass the tube 5 to 10 cm (2 to 4 in.) with each swallow, until the indicated length is inserted.
 - If the client continues to gag and the tube does not advance with each swallow, withdraw it slightly, and inspect the throat by looking through the mouth. **Rationale:** The tube may be coiled in the throat. If so, withdraw it until it is straight, and try again to insert it.
 - If a CO₂ detector is used, after the tube has been advanced approximately 30 cm (12 in.), draw air through the detector. Any change in color of the detector indicates placement of the tube in the respiratory tract. Immediately withdraw the tube and reinsert.
8. Ascertain correct placement of the tube.
- Nasogastric tubes are radiopaque, and position can be confirmed by x-ray. If a SBFT is used, leave the stylet or guidewire in place until correct position is verified by x-ray. This is the only definitive method of verifying feeding tube tip placement. If an x-ray is not feasible, at least two of the following methods should be used.

② Swallowing closes the epiglottis.

- Aspirate stomach contents, and check the pH, which should be acidic. **Rationale:** Testing pH is a reliable way to determine location of a feeding tube. Gastric contents are commonly pH 1 to 5; 6 or greater would indicate the contents are from lower in the intestinal tract or in the respiratory tract. However, pH may not discriminate between gastric and esophageal placement (Steptter, 2012).
 - Aspirate can also be tested for bilirubin. Bilirubin levels in the lungs should be almost zero, while levels in the stomach will be approximately 1.5 mg/dL and in the intestine more than 10 mg/dL.
 - Historically, nurses placed a stethoscope over the client's epigastrium and injected 10 to 30 mL of air into the tube while listening for a whooshing sound. This method does not guarantee tube position.
 - If the signs indicate placement in the lungs, remove the tube and begin again.
 - If the signs do not indicate placement in the lungs or stomach, advance the tube 5 cm (2 in.), and repeat the tests.
9. Secure the tube by taping it to the bridge of the client's nose.
- If the client has oily skin, wipe the nose first with alcohol to defat the skin.
 - Apply a commercial securement device
- or
- Cut 7.5 cm (3 in.) of tape, and split it lengthwise at one end, leaving a 2.5-cm (1-in.) tab at the end.
 - Place the tape over the bridge of the client's nose, and bring the split ends either under and around the tubing, or under the tubing and back up over the nose. ③ Ensure that the tube is centrally located prior to securing with tape to maximize airflow and prevent irritation to the side of the nares. **Rationale:** Taping in this manner prevents the tube from pressing against and irritating the edge of the nostril.

SAFETY ALERT!

SAFETY

If the stylet has been removed, never reinsert it while the tube is in place. **Rationale:** The stylet is sharp and could pierce the tube and injure the client or cut off the tube end.

Inserting a Nasogastric Tube – continued

3 Taping a nasogastric tube to the bridge of the nose.

10. Once correct position has been determined, attach the tube to a suction source or feeding apparatus as ordered, or clamp the end of the tubing.

11. Secure the tube to the client's gown.

- Loop an elastic band around the end of the tubing, and attach the elastic band to the gown with a safety pin.

or

- Attach a piece of adhesive tape to the tube, and pin the tape to the gown. **Rationale:** *The tube is attached to prevent it from dangling and pulling.*

If a Salem sump tube is used, attach the antireflux valve to the vent port (if used) and position the port above the client's waist. **Rationale:** *This prevents gastric contents from flowing into the vent lumen.*

- Remove and discard gloves.
- Perform hand hygiene.

12. Document relevant information: the insertion of the tube, the means by which correct placement was determined, and client responses (e.g., discomfort or abdominal distention).

13. Establish a plan for providing daily nasogastric tube care.

- Inspect the nostril for discharge and irritation.
- Clean the nostril and tube with moistened, cotton-tipped applicators.
- Apply water-soluble lubricant to the nostril if it appears dry or encrusted.
- Change the adhesive as required.
- Give frequent mouth care. Due to the presence of the tube, the client may breathe through the mouth.

14. If suction is applied, ensure that the patency of both the nasogastric and suction tubes is maintained.

- Irrigation of the tube may be required at regular intervals. In some agencies, irrigations must be ordered by the primary care provider. Prior to each irrigation, recheck tube placement.
- If a Salem sump tube is used, follow agency policies for irrigating the vent lumen with air to maintain patency of the suctioning lumen. Often, a sucking sound can be heard from the vent port if it is patent.
- Keep accurate records of the client's fluid intake and output, and record the amount and characteristics of the drainage.

15. Document the type of tube inserted, date and time of tube insertion, type of suction used, color and amount of gastric contents, and the client's tolerance of the procedure.

SAMPLE DOCUMENTATION

11/5/15 1030 #8 Fr feeding tube inserted without difficulty through R nare with stylet in place. To x-ray to check placement. Radiologist reports tube tip in stomach. Stylet removed. Aspirate pH 4. Tube secured to nose. Pt. verbalizes understanding of need to not pull on tube. _____ L. Traynor, RN

EVALUATION

Conduct appropriate follow-up, such as degree of client comfort, client tolerance of the nasogastric tube, correct placement of nasogastric tube in stomach, client understanding of restrictions, color

and amount of gastric contents if attached to suction, or stomach contents aspirated.

LIFESPAN CONSIDERATIONS Inserting a Nasogastric Tube

INFANTS AND YOUNG CHILDREN

- Restraints may be necessary during tube insertion and throughout therapy. Restraints will prevent accidental dislodging of the tube.
- Place the infant in an infant seat or position the infant with a rolled towel or pillow under the head and shoulders.
- When assessing the nares, obstruct one of the infant's nares and feel for air passage from the other. If the nasal passageway is very small or is obstructed, an orogastric tube may be more appropriate.

- Measure appropriate nasogastric tube length from the nose to the tip of the earlobe and then to the point midway between the umbilicus and the xiphoid process.
- If an orogastric tube is used, measure from the tip of the earlobe to the corner of the mouth to the xiphoid process.
- Do not hyperextend or hyperflex an infant's neck. Hyperextension or hyperflexion of the neck could occlude the airway.
- Tape the tube to the area between the end of the nares and the upper lip as well as to the cheek.

Although the focus of this chapter is nutrition, nasogastric tubes may be inserted for reasons other than to provide a route for feeding the client, including these:

- To prevent nausea, vomiting, and gastric distention following surgery. In this case, the tube is attached to a suction source.
- To remove stomach contents for laboratory analysis.
- To lavage (wash) the stomach in cases of poisoning or overdose of medications.

A **nasoenteric (nasointestinal) tube**, a longer tube than the nasogastric tube (at least 40 cm [15.75 in.] for an adult), is inserted through one nostril down into the upper small intestine. See Figure 47–13A ■. Some agencies require specially trained nurses or primary care providers to perform this procedure. Nasoenteric tubes are used for clients who are at risk for aspiration. Clients at risk for aspiration are those who manifest the following:

- Decreased level of consciousness
- Poor cough or gag reflexes
- Inability to participate in the procedure
- Restlessness or agitation.

Gastrostomy and **jejunostomy** devices are used for long-term nutritional support, generally more than 6 to 8 weeks. Tubes are placed surgically or by laparoscopy through the abdominal wall into the stomach

Figure 47–13 ■ Placements for enteral access: A, for nasoenteric/nasointestinal tubes; B, for gastrostomy and jejunostomy tubes.

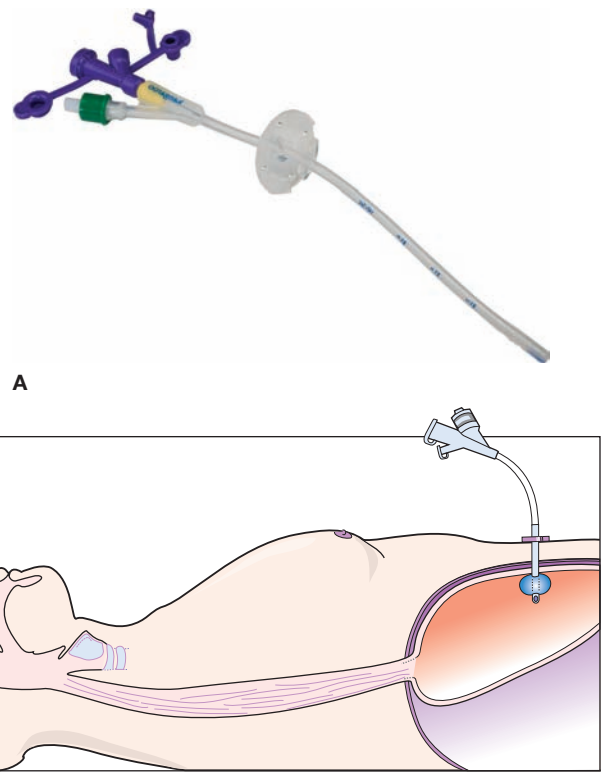

Figure 47–14 ■ Percutaneous endoscopic gastrostomy (PEG) tube. A, Courtesy Covidien.

Figure 47–15 ■ Percutaneous endoscopic jejunostomy (PEJ) tube.

(gastrostomy) or into the jejunum (jejunostomy). See Figure 47–13B ■. A **percutaneous endoscopic gastrostomy (PEG)** (Figure 47–14 ■) or **percutaneous endoscopic jejunostomy (PEJ)** (Figure 47–15 ■) is created by using an endoscope to visualize the inside of the stomach, making a puncture through the skin and subcutaneous tissues of the abdomen into the stomach, and inserting the PEG or PEJ catheter through the puncture.

The surgical opening is sutured tightly around the tube or catheter to prevent leakage. Care of this opening before it heals requires surgical asepsis. The catheter has an external bumper and an internal inflatable retention balloon to maintain placement. When the tract is established (about 1 month), the tube or catheter can be removed and reinserted for each feeding. Alternatively, a skin-level tube can be used that remains in place (Figure 47–16 ■). A feeding set is attached when needed.

Figure 47-16 ■ Low-profile gastrostomy feeding tubes.
Courtesy Covidien.

Testing Feeding Tube Placement

Before feedings are introduced, tube placement is confirmed by radiography, particularly when a small-bore tube has been inserted or when the client is at risk for aspiration. After placement is confirmed, the nurse marks the tube with indelible ink or tape at its exit point from the nose and documents the length of visible tubing for baseline data. The nurse is responsible, however, for verifying tube placement (i.e., GI placement versus respiratory placement) before each intermittent feeding and at regular intervals (e.g., at least once per shift) when continuous feedings are being administered.

Methods nurses use to check tube placement include the following:

1. **Aspirate GI secretions.** Because small-bore tubes offer more resistance during aspirations than large-bore tubes and are more likely to collapse when negative pressure is applied, it may not be possible to obtain an aspirate. If obtained, gastric secretions tend to be a grassy-green, off-white, or tan color; intestinal fluid is stained with bile and has a golden yellow or brownish green color.
2. **Measure the pH of aspirated fluid.** Testing the pH of aspirates can help distinguish gastric from respiratory and intestinal placement as follows:
 - Gastric aspirates tend to be acidic and have a pH of 1 to 4 but may be as high as 6 if the client is receiving medications that control gastric acid.
 - Small intestine aspirates generally have a pH equal to or higher than 6.
 - Respiratory secretions are more alkaline with values of 7 or higher. However, there is a slight possibility of respiratory placement when the pH reading is as low as 5.

Therefore, when pH readings are 5 or higher, radiographic confirmation of tube location needs to be considered, especially in clients with diminished cough and gag reflexes.
3. **Confirm length of tube insertion with the insertion mark.** If more of the tube is now exposed, the position of the tip should be questioned.

Currently, the most effective method is radiographic verification of tube placement. Repeated x-ray studies, however, are not feasible in terms of cost. More research is required to devise effective alternatives, especially for placement of small-bore tubes. In the meantime, nurses should (a) ensure initial radiographic verification of small-bore tubes, (b) aspirate contents when possible and check their acidity, (c) closely observe the client for signs of obvious distress, and (d) consider tube dislodgment after episodes of coughing, sneezing, and vomiting.

Enteral Feedings

The type and frequency of feedings and amounts to be administered are ordered by the primary care provider. Liquid feeding mixtures are available commercially or may be prepared by the dietary department in accordance with the primary care provider's orders. A standard formula provides 1 Kcal per milliliter of solution with protein, fat, carbohydrate, minerals, and vitamins in specified proportions.

Enteral feedings can be given intermittently or continuously. Intermittent feedings are the administration of 300 to 500 mL of enteral formula several times per day. The stomach is the preferred site for these feedings, which are usually administered over at least 30 minutes. Initial intermittent feedings should be no more than 120 mL. If tolerated, increase by 120 mL each feeding until the goal is reached (DeBruyne & Pinna, 2014). Bolus intermittent feedings are those that use a syringe to deliver the formula into the stomach. Because the formula is delivered rapidly by this method, it is not usually recommended but may be used in long-term situations if the client tolerates it. These feedings must be given only into the stomach; the client must be monitored closely for distention and aspiration.

Continuous feedings are generally administered over a 24-hour period using an infusion pump (often referred to as a kangaroo pump) that guarantees a constant flow rate (Figure 47-17 ■). Initial intermittent feedings should be no more than 60 mL per hour. If tolerated,

Figure 47-17 ■ An enteric feeding pump.

increase by 20 mL each feeding until the goal is reached (DeBruyne & Pinna, 2014). Continuous feedings are essential when feedings are administered in the small bowel. Pumps are also used when smaller bore gastric tubes are in place or when gravity flow is insufficient to instill the feeding.

Cyclic feedings are continuous feedings that are administered in less than 24 hours (e.g., 12 to 16 hours). These feedings, often administered at night, allow the client to attempt to eat regular meals through the day. Because nocturnal feedings may use higher nutrient densities and higher infusion rates than the standard continuous feeding, particular attention needs to be given to monitoring fluid status and circulating volume.

Enteral feedings are administered to clients through open or closed systems. Open systems use an open-top container or a syringe for administration. Enteral feedings for use with open systems are provided in flip-top cans or powdered formulas that are reconstituted with sterile water. Sterile water, rather than tap water, reduces the risk of microbial contamination. Open systems should have no more than 8 to 12 hours of formula poured at one time (DeBruyne & Pinna, 2014). At the completion of this time, remaining formula should be discarded and the container rinsed before new formula is poured. The bag and tubing should be replaced every 24 hours. Closed systems consist of a prefilled container that is spiked with enteral tubing and attached to the enteral access device. Prefilled containers can hang safely for 48 hours if sterile technique is used. Closed system materials are more expensive than open system materials, but if nursing care costs are included, closed systems are less expensive (Phillips, Roman, & Glassman, 2013).

A rare but potentially fatal complication of tube feeding is **refeeding syndrome**—a combination of fluid and electrolyte shifts that can occur after a lengthy period of malnutrition or starvation. This syndrome can occur when the starving body converts from creating glucose from carbohydrates to creating it from protein stores since carbohydrate was unavailable. The body's reaction to the sudden presence of glucose and synthesis of protein leads to the shifts. People at high risk for developing refeeding syndrome are those with chronic alcoholism, anorexia nervosa, massive weight loss, cancer clients receiving chemotherapy, or anyone who has gone 7 to 10 days without food. The nurse takes a detailed history and examines laboratory data that can indicate malnutrition, such as albumin and prealbumin levels. Serum potassium, calcium, phosphate, and magnesium levels must be checked and supplemented until within normal levels before feeding. Some experts suggest beginning feeding for at-risk clients with less than the desired amount and increasing to the full desired daily feeding slowly (DeBruyne & Pinna, 2014).

Skill 47–2 provides the essential steps involved in administering a tube feeding, and Skill 47–3 indicates the steps involved in administering a gastrostomy or jejunostomy tube feeding.

CLINICAL ALERT!

Enteral feedings should be started postoperatively in surgical clients without the need to wait for flatus or a bowel movement (Metheny, Mills, & Stewart, 2012).

Administering a Tube Feeding

PURPOSES

- To restore or maintain nutritional status
- To administer medications

ASSESSMENT

Assess

- For any clinical signs of malnutrition or dehydration.
- For allergies to any food in the feeding. If the client is lactose intolerant, check the tube feeding formula. Notify the primary care provider if any incompatibilities exist.
- For the presence of bowel sounds.
- For any problems that suggest lack of tolerance of previous feedings (e.g., delayed gastric emptying, abdominal distention, diarrhea, cramping, or constipation).

PLANNING

Before commencing a tube feeding, determine the type, amount, and frequency of feedings and tolerance of previous feedings.

DELEGATION

Administering a tube feeding requires application of knowledge and problem solving and it is not usually delegated to UAP. Some agencies, however, may allow a trained UAP to administer a feeding if allowed by law (for example, in California, UAPs are prohibited from performing tube feedings by the Nursing Practice Act). In any case, it is the responsibility of the nurse to assess tube placement and determine that the tube is patent, reinforce major points, such as making sure the client is sitting upright, and instruct the UAP to report any difficulty administering the feeding or any complaints voiced by the client.

Equipment

- Correct type and amount of feeding solution
- 60-mL catheter-tip syringe
- Emesis basin
- Clean gloves
- pH test strip or meter
- Large syringe or calibrated plastic feeding bag with label and tubing that can be attached to the feeding tube or prefilled bottle with a drip chamber, tubing, and a flow-regulator clamp
- Measuring container from which to pour the feeding (if using open system)
- Water (60 mL unless otherwise specified) at room temperature
- Feeding pump as required

INTERPROFESSIONAL PRACTICE

Administering a tube feeding is generally not performed by other health care providers, although it may not be prohibited by their scope of practice.

SAFETY ALERT!

SAFETY

Do not add colored food dye to tube feedings. Previously, blue dye was often added to assist in recognition of aspiration. However, the FDA reports cases of many adverse reactions to the dye, including toxicity and death.

Administering a Tube Feeding—continued

IMPLEMENTATION

Preparation

Assist the client to a Fowler's position (at least 30° elevation) in bed or a sitting position in a chair, the normal position for eating. If a sitting position is contraindicated, a slightly elevated right side-lying position is acceptable. **Rationale:** *These positions enhance the gravitational flow of the solution and prevent aspiration of fluid into the lungs.*

Performance

- Prior to performing the feeding, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Inform the client that the feeding should not cause any discomfort but may cause a feeling of fullness.
 - Perform hand hygiene and observe other appropriate infection prevention procedures (e.g., clean gloves).
 - Provide privacy for this procedure if the client desires it. Tube feedings are embarrassing to some people.
 - Assess tube placement.
 - Apply clean gloves.
 - Attach the syringe to the open end of the tube and aspirate. Check the pH.
 - Allow 1 hour to elapse before testing the pH if the client has received a medication.
 - Use a pH meter rather than pH paper if the client is receiving a continuous feeding. Follow agency policy if the pH is equal to or greater than 6.
 - Assess residual feeding contents.
 - If the tube is placed in the stomach, aspirate all contents and measure the amount before administering the feeding. **Rationale:** *This is done to evaluate absorption of the last feeding; that is, whether undigested formula from a previous feeding remains. If the tube is in the small intestine, residual contents cannot be aspirated.*
 - If 100 mL (or more than half the last feeding) is withdrawn, check with the nurse in charge or refer to agency policy before proceeding. The precise amount is usually determined by the primary care provider's order or by agency policy. **Rationale:** *At some agencies, a feeding is delayed when the specified amount or more of formula remains in the stomach.*
- or
- Reinstill the gastric contents into the stomach if this is the agency policy or primary care provider's order. **Rationale:** *Removal of the contents could disturb the client's electrolyte balance.*
 - If the client is on a continuous feeding, check the gastric residual every 4 to 6 hours or according to agency protocol.
- Administer the feeding.
 - Before administering feeding:
 - Check the expiration date of the feeding.
 - Warm the feeding to room temperature. **Rationale:** *An excessively cold feeding may cause abdominal cramps.*
 - When an open system is used, clean the top of the feeding container with alcohol before opening it. **Rationale:** *This minimizes the risk of contaminants entering the feeding syringe or feeding bag.*

Feeding Bag (Open System)

- Apply a label that indicates the date, time of starting the feeding, and nurse's initials on the feeding bag. Hang the labeled bag from an infusion pole about 30 cm (12 in.)

1 Using a calibrated plastic bag to administer a tube feeding.

above the tube's point of insertion into the client. **Rationale:** *At this height, the formula should run at a safe rate into the stomach or intestine.*

- Clamp the tubing and add the formula to the bag.
- Open the clamp, run the formula through the tubing, and reclamp the tube. **Rationale:** *The formula will displace the air in the tubing, thus preventing the instillation of excess air into the client's stomach or intestine.*
- Attach the bag to the feeding tube 1 and regulate the drip by adjusting the clamp to the drop factor on the bag (e.g., 20 drops/mL) if not placed on a pump.

Syringe (Open System)

- Remove the plunger from the syringe and connect the syringe to a pinched or clamped nasogastric tube. **Rationale:** *Pinching or clamping the tube prevents excess air from entering the stomach and causing distention.*
- Add the feeding to the syringe barrel. 2

2 Using the barrel of a syringe to administer a tube feeding.

Administering a Tube Feeding—continued

3 Feeding set with spike and tubing. Note, the port on the cap can only be accessed using this special safety screw spike to prevent accidental connection using intravenous tubing.

Courtesy Covidien.

- Permit the feeding to flow in slowly at the prescribed rate. Raise or lower the syringe to adjust the flow as needed. Pinch or clamp the tubing to stop the flow for a minute if the client experiences discomfort. **Rationale:** Quickly administered feedings can cause flatus, cramps, and/or vomiting.

Prefilled Bottle with Drip Chamber (Closed System)

- Remove the screw-on cap from the container and attach the administration set with tubing. 3
 - Close the clamp on the tubing.
 - Hang the container on an intravenous (IV) pole about 30 cm (12 in.) above the tube's insertion point into the client. **Rationale:** At this height, the formula should run at a safe rate into the stomach or intestine.
 - Squeeze the drip chamber to fill it to one third to one half of its capacity.
 - Open the tubing clamp, run the formula through the tubing, and reclamp the tube. **Rationale:** The formula will displace the air in the tubing, thus preventing the instillation of excess air.
 - Attach the feeding set tubing to the feeding tube and regulate the drip rate to deliver the feeding over the desired length of time or attach to a feeding pump.
7. If another bottle is not to be immediately hung, flush the feeding tube before all of the formula has run through the tubing.
- Instill 50 to 100 mL of water through the feeding tube or medication port. **Rationale:** Water flushes the lumen of the tube, preventing future blockage by sticky formula.
 - Be sure to add the water before the feeding solution has drained from the neck of a syringe or from the tubing of an administration set. **Rationale:** Adding the water before the syringe or tubing is empty prevents the instillation of air into the stomach or intestine and thus prevents unnecessary distention.
8. Clamp the feeding tube.
- Clamp the feeding tube before all of the water is instilled. **Rationale:** Clamping prevents air from entering the tube.
9. Ensure client comfort and safety.
- Secure the tubing to the client's gown. **Rationale:** This minimizes pulling of the tube, thus preventing discomfort and dislodgment.

- Ask the client to remain sitting upright in Fowler's position or in a slightly elevated right lateral position for at least 30 minutes. **Rationale:** These positions facilitate digestion and movement of the feeding from the stomach along the alimentary tract, and prevent the potential aspiration of the feeding into the lungs.
 - Check the agency's policy on the frequency of changing the nasogastric tube and the use of smaller lumen tubes if a large-bore tube is in place. **Rationale:** These measures prevent irritation and erosion of the pharyngeal and esophageal mucous membranes.
10. Dispose of equipment appropriately.
- If the equipment is to be reused, wash it thoroughly with soap and water so that it is ready for reuse.
 - Change the equipment every 24 hours or according to agency policy.
 - Remove and discard gloves.
 - Perform hand hygiene.
11. Document all relevant information.
- Document the feeding, including amount and kinds of fluids administered (feeding plus any water used to flush the tubing), duration of the feeding, and assessments of the client.
 - Record the volume of the feeding and water administered on the client's intake and output record.
12. Monitor the client for possible problems.
- Carefully assess clients receiving tube feedings for problems.
 - To prevent dehydration, give the client supplemental water in addition to the prescribed tube feeding as ordered.

Variation: Continuous-Drip Feeding

- Clamp the tubing at least every 4 to 6 hours, or as indicated by agency protocol or the manufacturer, and aspirate and measure the gastric contents. Then flush the tubing with 30 to 50 mL of water. **Rationale:** This determines adequate absorption and verifies correct placement of the tube. If placement of a small-bore tube is questionable, a repeat x-ray should be done.
- Determine agency protocol regarding withholding a feeding. Many agencies withhold the feeding if more than 75 to 100 mL of feeding is aspirated.
- To prevent spoilage or bacterial contamination, do not allow the feeding solution to hang longer than 12 hours for an open system and 48 hours for a closed system. Check agency policy or manufacturer's recommendations regarding time limits.
- Follow agency policy regarding how frequently to change the feeding bag and tubing. Changing the feeding bag and tubing every 24 hours reduces the risk of contamination.

SAMPLE DOCUMENTATION

11/5/15 1330 Aspirated 20 mL pale yellow fluid from NG tube, pH 4.5. Pt. in Fowler's position. 1 L room-temperature ordered formula begun @ 60 mL/hour on pump. No nausea reported. _____

_____ L. Traynor, RN

Administering a Tube Feeding—continued

EVALUATION

Perform a follow-up examination of the following:

- Tolerance of feeding (e.g., nausea, cramping)
- Bowel sounds
- Regurgitation and feelings of fullness after feedings
- Weight gain or loss
- Fecal elimination pattern (e.g., diarrhea, flatulence, constipation)

- Skin turgor
- Urine output and specific gravity
- Glucose and acetone in urine.

Relate findings to previous assessment data if available. Report significant deviations from normal to the primary care provider.

SKILL 47-2

Administering a Gastrostomy or Jejunostomy Feeding

PURPOSES

See Skill 47-2.

ASSESSMENT

See Skill 47-2.

Planning

Before beginning a gastrostomy or jejunostomy feeding, determine the type and amount of feeding to be instilled, frequency of feedings, and any pertinent information about previous feedings (e.g., the positioning in which the client best tolerates the feeding).

DELEGATION

See Skill 47-2.

INTERPROFESSIONAL PRACTICE

See Skill 47-2.

Equipment

- Correct amount of feeding solution
- Graduated container and tubing with clamp to hold the feeding
- 60-mL catheter-tip syringe

For a Tube That Remains in Place

- Mild soap and water
- Clean gloves
- Petrolatum, zinc oxide ointment, or other skin protectant
- Precut 4×4 gauze squares
- Uncut 4×4 gauze squares
- Paper tape

For Tube Insertion

- Clean gloves
- Moisture-proof bag
- Water-soluble lubricant
- Feeding tube (if needed)

SKILL 47-3

IMPLEMENTATION

Preparation

See Skill 47-2.

Performance

1. Prior to performing the feeding, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss how the results will be used in planning further care or treatments.
2. Perform hand hygiene and observe other appropriate infection prevention procedures (e.g., clean gloves).
3. Provide for client privacy.
4. Insert a feeding tube, if one is not already in place.
 - Wearing gloves, remove the dressing. Then discard the dressing and gloves in the moisture-proof bag.
 - Perform hand hygiene
 - Apply new clean gloves.
 - Lubricate the end of the tube, and insert it into the ostomy opening 10 to 15 cm (4 to 6 in.).
5. Check the location and patency of the tube.
 - Determine correct placement of the tube by aspirating secretions and checking the pH.
 - Follow agency policy for amount of residual formula. This may include withholding the feeding, rechecking in 3 to 4 hours, or notifying the primary care provider if a large residual remains.
6. Administer the feeding.
 - Hold the barrel of the syringe 7 to 15 cm (3 to 6 in.) above the ostomy opening.
 - Slowly pour the solution into the syringe and allow it to flow through the tube by gravity.
 - Just before the syringe is empty, add 30 mL of water.

Rationale: *Water flushes the tube and preserves its patency.*

 - If the tube is to remain in place, hold it upright, remove the syringe, and then clamp or plug the tube to prevent leakage.
 - If a tube was inserted for the feeding, remove it.
 - Remove and discard gloves.
 - Perform hand hygiene.

Continued on page 1164

Administering a Gastrostomy or Jejunostomy Feeding—continued

7. Ensure client comfort and safety.
 - After the feeding, ask the client to remain in the sitting position or a slightly elevated right lateral position for at least 30 minutes. **Rationale:** *This minimizes the risk of aspiration.*
 - Assess status of peristomal skin. **Rationale:** *Gastric or jejunal drainage contains digestive enzymes that can irritate the skin. Document any redness and broken skin areas.*
 - Check orders about cleaning the peristomal skin, applying a skin protectant, and applying appropriate dressings. Generally, the peristomal skin is washed with mild soap and water at least once daily. The tube may be rotated between thumb and forefinger to release any sticking and promote tract formation. Petrolatum, zinc oxide ointment, or other skin protectant may be applied around the stoma, and precut 4×4 gauze squares may be placed around the tube. The precut squares are then covered with regular 4×4 gauze squares, and the tube is coiled over them and taped in place.
 - Observe for common complications of enteral feedings: aspiration, hyperglycemia, abdominal distention, diarrhea, and fecal impaction. Report findings to primary care provider. Often, a change in formula or rate of administration can correct problems.
 - When appropriate, teach the client how to administer feedings and when to notify the health care provider concerning problems.
8. Document all assessments and interventions.

SAMPLE DOCUMENTATION

1/24/15 2045 No fluid aspirated from gastrostomy tube. Pt. in Fowler's position. 30 mL water flowed freely by gravity through tube. 250 mL room-temperature Ensure formula given over 20 minutes. No complaints of discomfort. _____ L. Traynor, RN

EVALUATION

See Skill 47-2.

Evidence-Based Practice Is There a Difference in Effectiveness and Safety Between NG and PEG tubes?

EVIDENCE-BASED PRACTICE

This article is an update to the 2010 Cochrane Review on the same subject. Gomes et al. (2012) examined controlled studies comparing nasogastric tubes to PEG tubes used for feeding clients who had swallowing disorders. Because the use of these tubes is very common, it is important to know if there are differences in the incidence or severity of complications associated with their use. The major outcomes studied were intervention failures such as displacement, feeding interruption, blockage or leakage; nutritional status, mortality, complications and adverse events (e.g., aspiration, hemorrhage, pneumonia, wound infection, sinusitis, fistula); and time on enteral nutrition, quality of life, length of hospital stay, and costs and economic issues.

This review concluded that PEG tubes are associated with fewer serious complications than NG tubes. However, there were

no differences in overall number of complications or mortality, and the use of PEG tubes is considerably more resource intensive and expensive.

IMPLICATIONS

One limitation of this review is the shortage of well-controlled studies. Only 686 clients were included in the combined review. Thus, more research is needed. However, the review does not conflict with the findings of previous reviews. Nurses must remember the difference between statistical differences and clinical differences in research findings. In cases where the expertise or human and financial resources do not allow for the use of PEG tubes, NG tubes are shown to be an effective alternative—especially if robust interventions are used to minimize the incidence of preventable complications.

LIFESPAN CONSIDERATIONS Administering a Tube Feeding

INFANTS AND YOUNG CHILDREN

- Feeding tubes may be removed after each feeding and reinserted at the next feeding to prevent irritation of the mucous membrane, nasal airway obstruction, and stomach perforation that may occur if the tube is left in place continuously. Check agency practice.
- Formula should not be allowed to hang more than 4 hours (DeBruyne & Pinna, 2014).
- Position a small child or infant in your lap, provide a pacifier, and hold and cuddle the child during feedings. This promotes comfort, supports the normal sucking instinct of the infant, and facilitates digestion.

OLDER ADULTS

- Physiological changes associated with aging may make the older adult more vulnerable to complications associated with

enteral feedings. Decreased gastric emptying may necessitate checking frequently for gastric residual. Diarrhea from administering the feeding too fast or at too high a concentration may cause dehydration. If the feeding has a high concentration of glucose, assess for hyperglycemia because with aging, the body has a decreased ability to handle increased glucose levels.

- Conditions such as hiatal hernia and diabetes mellitus may cause the stomach to empty more slowly. This increases the risk of aspiration in a client receiving a tube feeding. Checking for gastric residual more frequently can help document this if it is an ongoing problem. Changing the formula or the rate of administration, repositioning the client, or obtaining a primary care provider's order for a medication to increase stomach emptying may resolve this problem.

Home Care Considerations Administering a Tube Feeding

PATIENT-CENTERED CARE

- Teach and provide the client or caregiver the rationale for how to assess for tube placement using pH measurement before administering the feeding. Instruct regarding actions to take if the pH is greater than 5.
- Provide instructions and rationale for care of the tube and insertion site.
- Discuss strategies for hanging formula containers if an IV pole is unavailable or inconvenient.
- Plan for optimal timing of feedings to allow for daily activities. Many clients can tolerate having the majority of their feedings run during sleep so they are free from the equipment during the day.
- Teach signs and symptoms to report to the primary care provider or home health nurse.

TABLE 47-5 Assessing Clients Receiving Tube Feedings

Assessments	Rationale
Allergies to any food in the feeding	Common allergenic foods include milk, sugar, water, eggs, and vegetable oil.
Bowel sounds before each feeding or, for continuous feedings, every 4 to 8 hours	To determine intestinal activity.
Correct placement of tube before feedings	To prevent aspiration of feedings.
Presence of regurgitation and feelings of fullness after feedings	May indicate delayed gastric emptying, need to decrease quantity or rate of the feeding, or high fat content of the formula.
Dumping syndrome: nausea, vomiting, diarrhea, cramps, pallor, sweating, heart palpitations, increased pulse rate, and fainting after a feeding	Clients with a jejunostomy may experience these symptoms, which result when hypertonic foods and liquids suddenly distend the jejunum. To make the intestinal contents isotonic, body fluids shift rapidly from the client's vascular system.
Abdominal distention, at least daily (Measure abdominal girth at the umbilicus.)	Abdominal distention may indicate intolerance to a previous feeding.
Diarrhea, constipation, or flatulence	The lack of bulk in liquid feedings may cause constipation. The presence of hypertonic or concentrated ingredients may cause diarrhea and flatulence.
Urine for sugar and acetone	Hyperglycemia may occur if the sugar content of the feeding is too high.
Hematocrit and urine specific gravity	Both hematocrit and urine specific gravity increase as a result of dehydration.
Serum BUN and sodium levels	Feeding formula may have a high protein content. If a high protein intake is combined with an inadequate fluid intake, the kidneys may not be able to excrete nitrogenous wastes adequately.

Before administering a tube feeding, the nurse must determine any food allergies of the client and assess tolerance to previous feedings. Table 47-5 lists essential assessments to conduct before administering tube feedings. The nurse must also check the expiration date on a commercially prepared formula or the preparation date and time of agency-prepared solution, discarding any formula that has passed the expiration date or that was prepared more than 24 hours previously.

Feedings are usually administered at room temperature unless the order specifies otherwise. The nurse warms the specified amount of solution in a basin of warm water or leaves it to stand for a while until it reaches room temperature. Because a formula that is warmed can grow microorganisms, it should not hang longer than the manufacturer recommends. Continuous-feeding formulas should be kept

cold; excessive heat coagulates feedings of milk and egg, and hot liquids can irritate the mucous membranes. However, excessively cold feedings can reduce the flow of digestive juices by causing vasoconstriction and may cause cramps. Guidelines for teaching clients and families regarding administration of tube feedings in the home are found in Client Teaching.

Managing Clogged Feeding Tubes

Even if feeding tubes are flushed with water before and after feedings and medications, small-bore tubes still become clogged—especially SBFTs. This can occur when the feeding container runs dry, solid medication is not adequately crushed, or medications are mixed with formula. Even the important practice of aspirating to check residual volume increases the incidence of clogging. To avoid the necessity of

CLIENT TEACHING

Tube Feedings

Clients and caregivers need the following instructions to manage these feedings:

- *Preparation of the formula.* Include name of the formula and how much and how often it is to be given; the need to inspect the formula for expiration date and leaks and cracks in bags or cans; how to mix or prepare the formula, if needed; and aseptic techniques such as cleansing the container's top with alcohol before opening it, and changing the syringe administration set and reservoir every 24 hours.
- *Proper storage of the formula.* Include the need to refrigerate diluted or reconstituted formula and formula that contains additives.
- *Administration of the feeding.* Include proper hand cleansing technique, how to fill and hang the feeding bag, operation of an

infusion pump if indicated, the feeding rate, and client positioning during and after the feeding.

- *Management of the enteral or parenteral access device.* Include site care, aseptic precautions, dressing change, as indicated, how the site should look normally, and flushing protocols (e.g., type of irrigant and schedule).
- *Daily monitoring needs.* Include temperature, weight, and intake and output.
- *Signs and symptoms of complications to report.* Include fever, increased respiratory rate, decrease in urine output, increased stool frequency or diarrhea, and altered level of consciousness.
- *Whom to contact about questions or problems.* Include emergency telephone numbers of home care agency, nursing clinician and/or primary care provider, or other 24-hour on-call emergency service.

removing the tube and reinserting a new tube, both prevention and intervention strategies must be used.

To prevent clogged feeding tubes, flush liberally (at least 30 mL water) before, between, and after each separate medication is instilled, using a 60-mL piston syringe. Too great a pressure can rupture the tube—especially small-bore feeding tubes. Do not add medications to formula or to each other because the combination could create a precipitate that clogs the tube.

Many strategies have been used to try to unclog feeding tubes. The first strategy that should be tried is to reposition the client (this may allow a kink to straighten). Alternately flush and aspirate the tube with water. Strategies that have shown inconsistent effectiveness

include instilling meat tenderizer, carbonated beverages, or cranberry juice (Stepter, 2012) or flushing with small-barrel syringes. Until 2013, only enteric-coated and extended-release pancreatic enzymes were available as unclogging agents in the United States. However, an effective uncoated enzyme product, used in combination with sodium bicarbonate, is now available (Klang, Gandhi, & Mironova, 2013). Commercial de-clogging kits containing a combination of acids, buffers, antibacterial agents, enzymes, and metal inhibitors are available.

If efforts to unclog a feeding tube are unsuccessful, the tube may need to be removed. Skill 47–4 describes the steps in removing a nasogastric tube.

Removing a Nasogastric Tube

ASSESSMENT

Assess

- For the presence of bowel sounds
- For the absence of nausea or vomiting when tube is clamped

PLANNING

DELEGATION

Due to the need for assessment of client status, the skill of removing a nasogastric tube is not delegated to UAP.

INTERPROFESSIONAL PRACTICE

Removing a nasogastric tube may be within the scope of practice for other health care providers such as PAs. Although the PA may verbally communicate their actions and plan to the health care team members, the nurse must also know where to locate their documentation in the client's health record.

IMPLEMENTATION

Preparation

- Confirm the primary care provider's order to remove the tube.
- Assist the client to a sitting position if health permits.

Equipment

- Disposable pad or towel
- Tissues
- Clean gloves
- 50-mL syringe (optional)
- Moisture-proof trash bag

- Place the disposable pad or towel across the client's chest to collect any spillage of secretions from the tube.
- Provide tissues to the client to wipe the nose and mouth after tube removal.

Removing a Nasogastric Tube—continued

Performance

- Prior to performing the removal, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. Discuss how the results will be used in planning further care or treatments.
- Perform hand hygiene and observe other appropriate infection prevention procedures (e.g., clean gloves).
- Provide for client privacy.
- Detach the tube.
 - Apply clean gloves.
 - Disconnect the nasogastric tube from the suction apparatus, if present.
 - Unpin the tube from the client's gown.
 - Remove the adhesive tape securing the tube to the nose.
- Remove the nasogastric tube.
 - Optional:* Instill 50 mL of air into the tube. **Rationale:** *This clears the tube of any contents such as feeding or gastric drainage.*
 - Ask the client to take a deep breath and to hold it. **Rationale:** *This closes the glottis, thereby preventing accidental aspiration of any gastric contents.*
 - Pinch the tube with the gloved hand. **Rationale:** *Pinching the tube prevents any contents inside the tube from draining into the client's throat.*
 - Smoothly, withdraw the tube.
- Place the tube in the trash bag. **Rationale:** *Placing the tube immediately into the bag prevents the transference of microorganisms from the tube to other articles or people.*
- Observe the intactness of the tube.
- Ensure client comfort.
 - Provide mouth care if desired.
 - Assist the client as required to blow the nose. **Rationale:** *Excessive secretions may have accumulated in the nasal passages.*
- Dispose of the equipment appropriately.
 - Place the pad, bag with tube, and gloves in the receptacle designated by the agency. **Rationale:** *Correct disposal prevents the transmission of microorganisms.*
 - Remove and discard gloves.
 - Perform hand hygiene.
- Document all relevant information.
 - Record the removal of the tube, the amount and appearance of any drainage if connected to suction, and any relevant assessments of the client.

SAMPLE DOCUMENTATION

11/8/15 1500 NG tube removed intact without difficulty. Oral & nasal care given. No bleeding or excoriation noted. Client states is hungry & thirsty. 60 mL apple juice given. No c/o nausea. ——— L. Traynor, RN

EVALUATION

- Perform a follow-up examination, such as presence of bowel sounds, absence of nausea or vomiting when tube is removed, and intactness of tissues of the nares.
- Relate findings to previous assessment data if available.
- Report significant deviations from normal to the primary care provider.

Parenteral Nutrition

Parenteral nutrition, also referred to as total parenteral nutrition (TPN) or intravenous hyperalimentation, is the IV infusion of dextrose, water, fat, proteins, electrolytes, vitamins, and trace elements. Because TPN solutions are hypertonic (highly concentrated in comparison to the solute concentration of blood), they are injected only into high-flow central veins, where they are diluted by the client's blood.

TPN is a means of achieving an anabolic state in clients who are unable to maintain a normal nitrogen balance. Such clients may include those with severe malnutrition, severe burns, bowel disease disorders (e.g., ulcerative colitis or enteric fistula), acute renal failure, hepatic failure, metastatic cancer, or major surgeries where nothing may be taken by mouth for more than 5 days.

TPN is not risk free. Infection control is of utmost importance during TPN therapy. The nurse must always observe surgical aseptic technique when changing solutions, tubing, dressings, and filters. Clients are at increased risk of fluid, electrolyte, and glucose imbalances and require frequent evaluation and modification of the TPN mixture.

TPN solutions are 10% to 50% dextrose in water, plus a mixture of amino acids and special additives such as vitamins (e.g., B complex,

C, D, K), minerals (e.g., potassium, sodium, chloride, calcium, phosphate, magnesium), and trace elements (e.g., cobalt, zinc, manganese). Additives are modified to each client's nutritional needs. Fat emulsions may be given to provide essential fatty acids to correct and/or prevent essential fatty acid deficiency or to supplement the calories for clients who, for example, have high calorie needs or cannot tolerate glucose as the only calorie source. Note that 1,000 mL of 5% glucose or dextrose contains 50 grams of sugar. Thus, a liter of this solution provides less than 200 calories!

Because TPN solutions are high in glucose, infusions are started gradually to prevent hyperglycemia. The client needs to adapt to TPN therapy by increasing insulin output from the pancreas. For example, an adult client may be given 1 liter (40 mL/h) of TPN solution the first day; if the infusion is tolerated, the amount may be increased to 2 liters (80 mL/h) for 24 to 48 hours, and then to 3 liters (120 mL/h) within 3 to 5 days. Glucose levels are monitored during the infusion.

When TPN therapy is to be discontinued, the TPN infusion rates are decreased slowly to prevent hyperinsulinemia and hypoglycemia. Weaning a client from TPN may take up to 48 hours but can occur in 6 hours as long as the client receives adequate carbohydrates either orally or intravenously.

Peripheral parenteral nutrition (PPN) is delivered into the smaller peripheral veins. PPN cannot handle as concentrated a solution as central lines, but can accommodate lipids. For example, a 20% lipid emulsion can provide nearly 2,000 Kcal/day through a peripheral vein. PPN is considered to be a safe and convenient form of therapy. One major disadvantage, however, is the frequent incidence of phlebitis (vein inflammation) associated with PPN. Substituting glycerol for dextrose may reduce vein irritation (Julian, 2013). Peripheral parenteral nutrition is administered to clients whose needs for IV nutrition will last only a short time or in whom placement of a central IV catheter is contraindicated. It is a form of therapy used more frequently to *prevent* nutritional deficits than to correct them.

Enteral or parenteral feedings may be continued beyond hospital care in the client's home or may be initiated in the home.

Evaluating

The goals established in the planning phase are evaluated according to specific desired outcomes, also established in that phase. If the outcomes are not achieved, the nurse should explore the reasons. The nurse might consider the following questions:

- Was the cause of the problem correctly identified?
- Was the family included in the teaching plan? Are family members supportive?
- Is the client experiencing symptoms that cause loss of appetite (e.g., pain, nausea, fatigue)?
- Were the outcomes unrealistic for this person?
- Were the client's food preferences considered?
- Is anything interfering with digestion or absorption of nutrients (e.g., diarrhea)?

NURSING CARE PLAN Nutrition

Assessment Data

Nursing Assessment

Mrs. Rose Santini, a 59-year-old homemaker, attends a community hospital-sponsored health fair. She approaches the nutrition information booth, and the clinical specialist in nutritional support gathers a nutritional history. Mrs. Santini is very upset about her 9-kg (20-lb) weight gain. She relates to the nurse clinician that since the death of her husband 1 month ago she has lost interest in many of her usual physical and social activities. She no longer attends YMCA exercise and swimming sessions and has lost contact with her couple's bridge group. Mrs. Santini states she is bored, depressed, and very unhappy about her appearance. She has a small frame and has always prided herself on her petite figure. She says her eating habits have changed considerably. She snacks while watching TV and rarely prepares a complete meal.

Physical Examination

Height: 162.6 cm (5'4")
 Weight: 66 kg (145 lb)
 Temperature: 37°C (98.6°F)
 Pulse: 76 beats/min
 Respirations: 16/min
 Blood pressure: 144/84 mmHg
 Triceps skinfold: 21 mm
 Small frame, weight in excess of 10% over ideal for height and frame

Diagnostic Data

CBC normal, urinalysis negative, chest x-ray negative, thyroid profile within normal limits

Nursing Interventions*/Selected Activities

Weight Reduction Assistance [1280]

Determine current eating patterns by having Mrs. Santini keep a diary of what, when, and where she eats.

Set a weekly goal for weight loss.

Encourage use of internal reward systems when goals are accomplished.

Set a realistic plan with Mrs. Santini to include reduced food intake and increased energy expenditure.

Assist client to identify motivation for eating and internal and external cues associated with eating.

Encourage attendance at support groups for weight loss and/or refer to a community weight control program.

Develop a daily meal plan with a well-balanced diet, reduced calories, and reduced fat.

Nursing Diagnosis

Overweight related to excess intake and decreased activity expenditure (as evidenced by weight gain of 9 kg (20 lb), triceps skinfold greater than normal, undesirable eating patterns)

Desired Outcomes*

Weight-Loss Behavior [1627] as evidenced by demonstrating:

- Eats three meals each day that result in a 500-calorie reduction in intake.
- Establishes a physical exercise plan that engages her in 15 to 20 minutes of exercise daily by day 5.
- Identifies eating habits that contribute to weight gain by day 2.

Rationale

Increases awareness of activities and foods that contribute to excessive intake.

The desirable weight-loss rate is 1/2–1 kg (1–2 lb) per week.

Goal setting provides motivation, which is essential for a successful weight-loss program.

A combined plan of calorie reduction and exercise can enhance weight loss since exercise increases caloric utilization.

Awareness of factors that contribute to overeating will assist the individual in planning behavior modification techniques to avoid situations that prompt excess food consumption.

Membership in a support group can enhance clients' continuation of weight-loss efforts.

Snack foods tend to be high in calories and fat and low in nutritional values.

NURSING CARE PLAN Nutrition—continued

Nursing Interventions*/Selected Activities	Rationale
Nutritional Counseling [5246]	
Facilitate identification of eating behaviors to be changed.	<i>Increases individual's awareness of those actions that contribute to excessive intake.</i>
Use accepted nutritional standards to assist Mrs. Santini in evaluating adequacy of dietary intake.	<i>Comparing the individual's dietary history with nutritional standards will facilitate identification of nutritional deficiencies and/or excesses.</i>
Help Mrs. Santini to consider factors of age, past eating experiences, culture, and finances in planning ways to meet nutritional requirements.	<i>Social, economic, physical, and psychological factors play a role in nutrition and/or malnutrition.</i>
Discuss Mrs. Santini's knowledge of the basic food groups, as well as perceptions of the needed diet modification.	<i>Helps to determine the client's knowledge base and identify misconceptions and/or gaps in understanding.</i>
Discuss food likes and dislikes.	<i>Incorporating Mrs. Santini's food preferences into the dietary plan will promote adherence to the weight-loss program.</i>
Assist Mrs. Santini in stating her feelings and concerns about goal achievement.	<i>Fear of success, failure, or other concerns may block goal achievement.</i>
Behavior Modification [4360]	
Assist Mrs. Santini to identify strengths and reinforce these.	<i>Reinforcing strengths enhances self-esteem and encourages the individual to draw on these assets during the weight-loss program.</i>
Encourage her to examine her own behavior.	<i>Involving Mrs. Santini in self-appraisal will promote identification of behaviors that may be contributing to excessive caloric intake.</i>
Identify the behavior to be changed in specific, concrete terms (e.g., stop snacking in front of the TV).	<i>Identification of specific behaviors is essential for planning behavior modification.</i>
Consider that it is easier to increase a behavior than to decrease a behavior (e.g., increase activities or hobbies that involve the hands such as sewing versus decreasing TV snacking).	<i>Habitual behaviors are difficult to change. Breaking old habits may be easier if viewed from the standpoint of increasing an enjoyable, healthy activity.</i>
Choose reinforcers that are meaningful to Mrs. Santini.	<i>Positive reinforcement is not likely to be an effective part of behavior modification if the reinforcer is meaningless to the individual.</i>

Evaluation

Outcome met. Mrs. Santini kept a dietary log for 5 days and has eaten balanced meals each day, resulting in a daily deficit of 400 to 500 calories. She is aware that she eats excessively because she is bored and depressed. She has reestablished her former social contacts including her church bridge club. Mrs. Santini has purchased a stationary bicycle and exercises 20 minutes daily. She enrolled in a knitting class that meets two nights per week. She has lost 2/3 kg (1 1/2 lb) in the past week. As a reward, Mrs. Santini renewed her membership to the YMCA.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

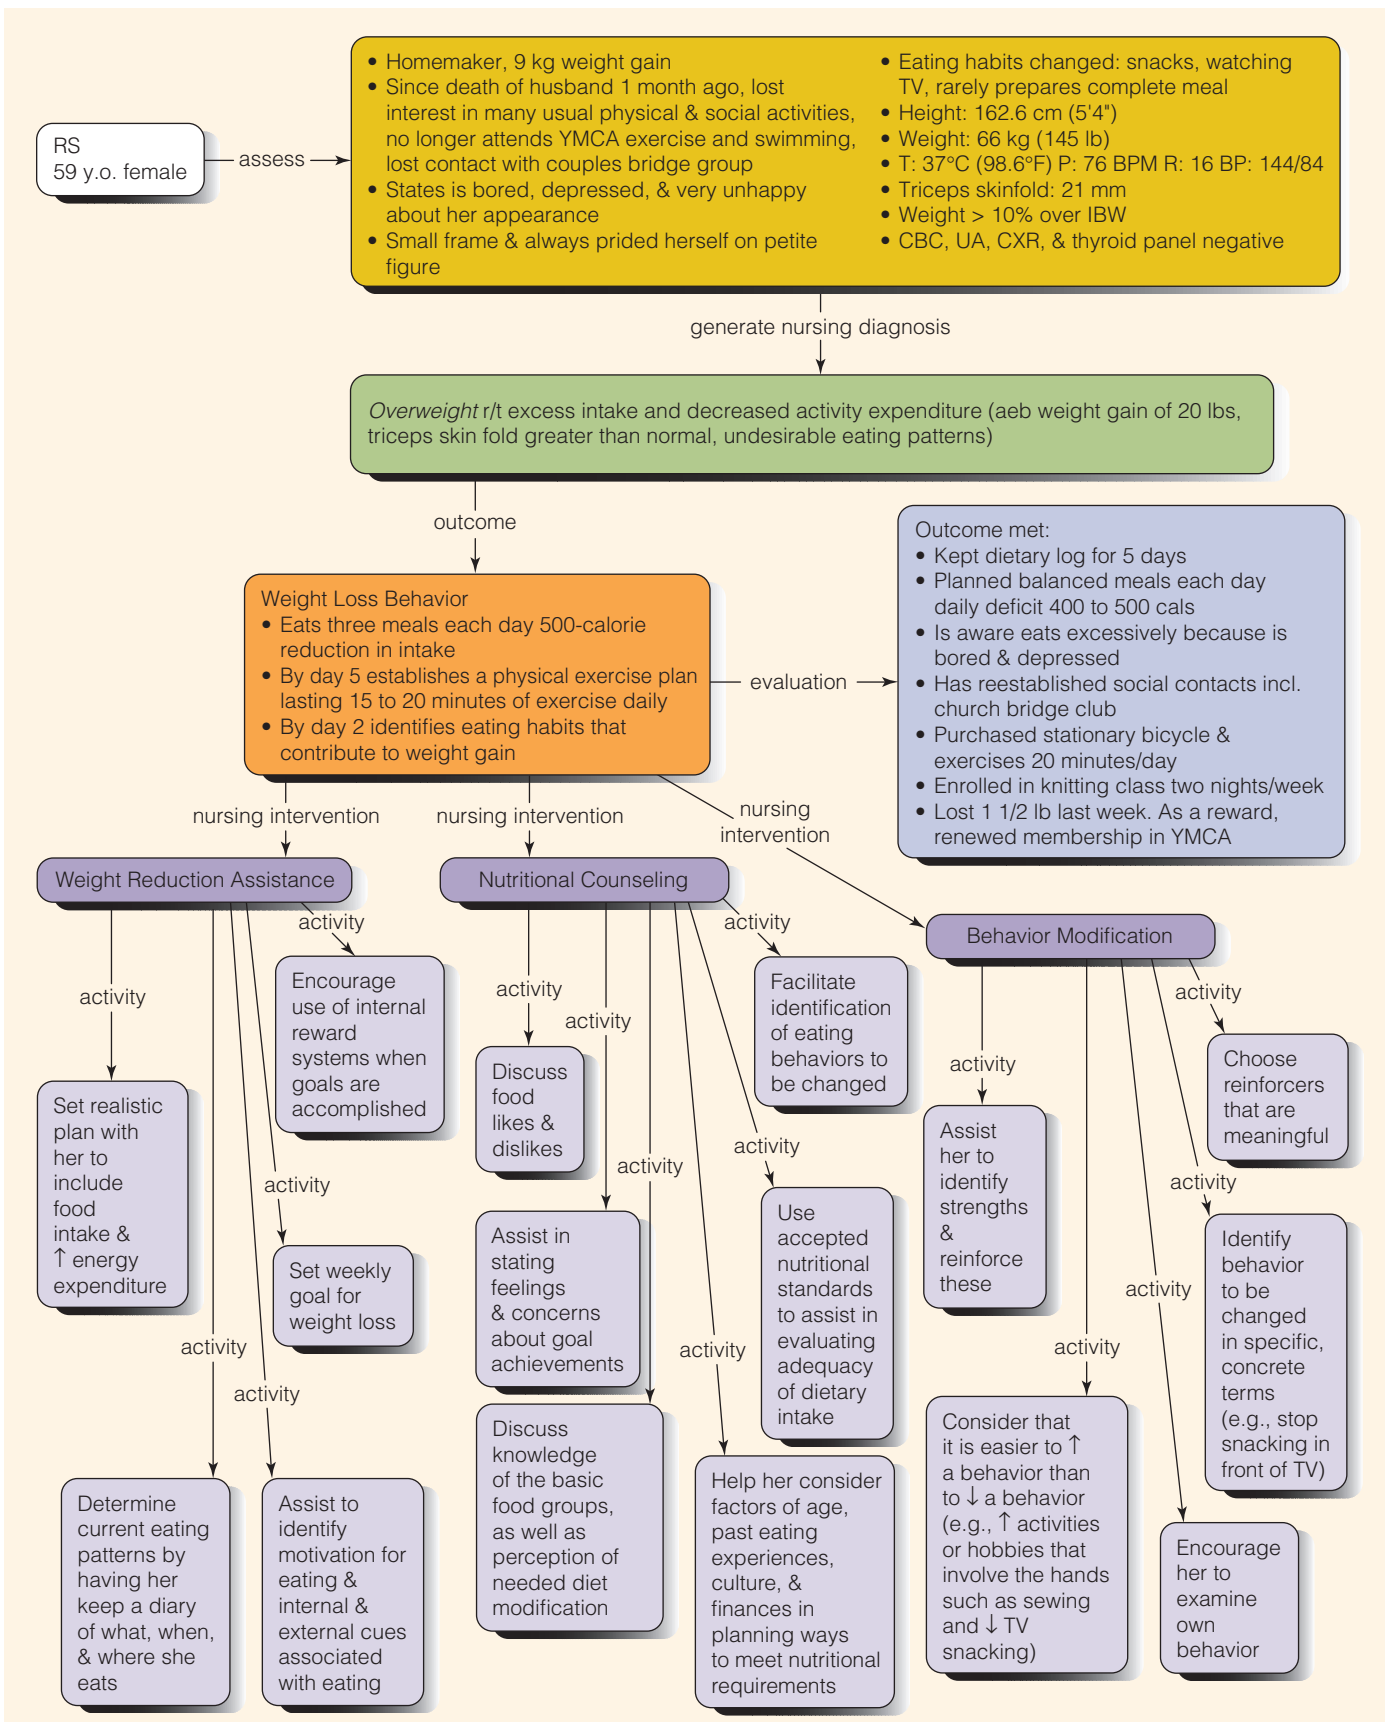

Applying Critical Thinking

1. How do Mrs. Santini's personal characteristics influence her nutritional needs?
2. What further information do you need regarding Mrs. Santini's present diet?
3. Offer suggestions for ways to modify Mrs. Santini's tendency to snack.
4. Mrs. Santini asks what her weight should be. How do you respond?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Nutrition

Chapter 47 Review

CHAPTER HIGHLIGHTS

- Essential nutrients are grouped into categories: carbohydrates, proteins, lipids, vitamins, and minerals.
- Nutrients serve three basic purposes: forming body structures (such as bones and blood), providing energy, and helping to regulate the body's biochemical reactions.
- The amount of energy that nutrients or foods supply to the body is their caloric value. The basal metabolic rate (BMR) is the rate at which the body metabolizes food to maintain the energy and requirements of a person who is awake and at rest. The amount of energy required to maintain basic body functions is referred to as the resting energy expenditure (REE).
- A person's state of energy balance can be determined by comparing caloric intake with caloric expenditure.
- Ideal body weight (IBW) is the optimal weight recommended for optimal health.
- Body mass index (BMI) and percent body fat are indicators of changes in body fat stores. They indicate whether a person's weight is appropriate for height and may provide a useful estimate of nutrition.
- Factors influencing a person's nutrition include development, gender, ethnicity and culture, beliefs about foods, personal preferences, religious practices, lifestyle, economics, medications and therapy, health, alcohol consumption, advertising, and psychological factors.
- Nutritional needs vary considerably according to age, growth, and energy requirements. Adolescents have high energy requirements due to their rapid growth; a diet plentiful in milk, meats, green and yellow vegetables, and fresh fruits is required. Middle-aged adults and older adults often need to reduce their caloric intake because of decreases in metabolic rate and activity levels.
- Various daily food guides have been developed to help healthy people meet the daily requirements of essential nutrients and to facilitate meal planning. These include the *Dietary Guidelines for Americans* and the Food Guide Pyramid/MyPlate.
- Both inadequate and excessive intakes of nutrients result in malnutrition. The effects of malnutrition can be general or specific, depending on which nutrients and what level of deficiency or excess are involved.
- Assessment of nutritional status may involve all or some of the following: nutritional screening, nursing history data, anthropometric measurements, biochemical (laboratory) data, clinical data (physical examination), calculation of the percentage of weight loss, and a dietary history.
- Nursing diagnoses for clients with nutritional problems may be broadly stated as *Imbalanced Nutrition: Less Than Body Requirements* or *Overweight*. Because nutritional problems may affect many other areas of human functioning, a nutritional problem may be the etiology of other diagnoses, such as *Activity Intolerance* and *Low Self-Esteem*.
- Major goals for clients with or at risk for nutritional problems include the following: Maintain or restore optimal nutritional status, decrease or regain specified weight, promote healthy nutritional practices, and prevent complications associated with malnutrition.
- Assisting clients and support persons with therapeutic diets is a function shared by the nurse and the dietitian. The nurse reinforces the dietitian's instructions, assists the client to make beneficial changes, and evaluates the client's response to planned changes.
- Because many hospitalized clients have poor appetites, a major responsibility of the nurse is to provide nursing interventions that stimulate their appetites.
- Whenever possible, the nurse should help incapacitated clients to feed themselves; a number of self-feeding aids help clients who have difficulty handling regular utensils.
- The nurse can refer clients to various community programs that help special subgroups of the population meet their nutritional needs.
- Enteral feedings, administered through nasogastric, nasointestinal, gastrostomy, or jejunostomy tubes, are provided when the client is unable to ingest foods or the upper GI tract is impaired.
- A nasogastric or nasointestinal tube is used to provide enteral nutrition for short-term use. A gastrostomy or jejunostomy tube can be used to supply nutrients via the enteral route for long-term use.
- The two most accurate methods of confirming GI tube placement are radiographs and pH testing of aspirate.
- Parenteral nutrition, provided when oral intake is insufficient or unadvisable, is given intravenously into a large central vein (e.g., the superior vena cava).

TEST YOUR KNOWLEDGE

1. Which of the following nursing diagnoses is most appropriate for a client with a body mass index (BMI) of 35?
 1. *Imbalanced Nutrition: Less Than Body Requirements*
 2. *Obesity*
 3. *Overweight*
 4. *Deficient Knowledge*
2. An adult reports usually eating the following each day: 3 cups dairy, 2 cups fruit, 2 cups vegetables, 5 ounces grains, and 5 ounces meat. The nurse would counsel the client to:
 1. Maintain the diet; the servings are adequate.
 2. Increase the number of servings of dairy.
 3. Decrease the number of servings of vegetables.
 4. Increase the number of servings of grains.
3. Which of the following are allowed on a full liquid diet? Select all that apply.
 - 1. Scrambled eggs
 - 2. Chocolate pudding
 - 3. Tomato juice
 - 4. Hard candy
 - 5. Mashed potatoes
 - 6. Cream of Wheat cereal
 - 7. Oatmeal cereal
 - 8. Fruit "smoothies"

4. What is the best indication of proper placement of a nasogastric tube in the stomach?
 1. Client is unable to speak.
 2. Client gags during insertion.
 3. pH of the aspirate is less than 5.
 4. Fluid is easily instilled into the tube.
5. What is the proper technique with gravity tube feeding?
 1. Hang the feeding bag 1 foot higher than the tube's insertion point into the client.
 2. Administer the next feeding only if there is less than 25 mL of residual volume from the previous feeding.
 3. Place client in the left lateral position.
 4. Administer feeding directly from the refrigerator.
6. A 55-year-old female is about 9 kg (20 lb) over her desired weight. She has been on a "low-calorie" diet with no improvement. Which statement reflects a healthy approach to the desired weight loss? "I need to:
 1. Increase my exercise to at least 30 minutes every day."
 2. Switch to a low-carbohydrate diet."
 3. Keep a list of my forbidden foods on hand at all times."
 4. Buy more organic and less processed foods."
7. An older Asian client has mild dysphagia from a recent stroke. The nurse plans the client's meals based on the need to:
 1. Have at least one serving of thick dairy (e.g., pudding, ice cream) per meal.
 2. Eliminate the beer usually ingested every evening.
 3. Include as many of the client's favorite foods as possible.
 4. Increase the calories from lipids to 40%.
8. Two months ago a client weighed 195 pounds. The current weight is 182 pounds. Calculate the client's percentage of weight loss and determine its significance.
 1. % weight loss
 2. Not significant
 3. Significant weight loss
 4. Severe weight loss

9. Which of the sites on the diagram below indicates the correct location for the tip of a small-bore nasally placed feeding tube?

Gastrointestinal tract

10. Which of the following meals would the nurse recommend to the client as highest in calcium, iron, and fiber?
 1. 3 ounces cottage cheese with 1/3 cup raisins and 1 banana
 2. 1/2 cup broccoli with 3 ounces chicken and 1/2 cup peanuts
 3. 1/2 cup spaghetti with 2 ounces ground beef and 1/2 cup lima beans plus 1/2 cup ice cream
 4. 3 ounces tuna plus 1 ounce cheese sandwich on whole-wheat bread plus a pear

See Answers to Test Your Knowledge in Appendix A.

48 Urinary Elimination

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe the process of urination, from urine formation through micturition.
2. Identify factors that influence urinary elimination.
3. Identify common causes of selected urinary problems.
4. Describe nursing assessment of urinary function, including subjective and objective data.
5. Identify normal and abnormal characteristics and constituents of urine.
6. Develop nursing diagnoses and desired outcomes related to urinary elimination.
7. Describe nursing interventions to maintain normal urinary elimination, prevent urinary tract infection, and manage urinary incontinence.
8. Delineate ways to prevent urinary infection.
9. Explain the care of clients with retention catheters or urinary diversions.
10. Verbalize the steps used in:
 - a. Applying an external urinary device.
 - b. Performing urinary catheterization.
 - c. Performing bladder irrigation.
11. Recognize when it is appropriate to delegate aspects of urinary elimination to unlicensed assistive personnel.
12. Demonstrate appropriate documentation and reporting of applying an external catheter, performing urethral urinary catheterization, and performing bladder irrigation.

INTRODUCTION

Elimination from the urinary tract is usually taken for granted. Only when a problem arises do most people become aware of their urinary habits and any associated symptoms.

A person's urinary habits depend on social culture, personal habits, and physical abilities. In North America, most people are accustomed to privacy and clean (even decorative) surroundings while they urinate.

Personal habits regarding urination are affected by the social politeness of leaving to urinate, the availability of a private clean facility, and initial bladder training. Urinary elimination is essential to health, and voiding can be postponed for only so long before the urge normally becomes too great to control.

PHYSIOLOGY OF URINARY ELIMINATION

Urinary elimination depends on the effective functioning of the upper urinary tract's kidneys and ureters and the lower urinary tract's urinary bladder, urethra, and pelvic floor (Figure 48-1 ■).

1174

Kidneys

The paired kidneys are situated on either side of the spinal column, behind the peritoneal cavity. The right kidney is slightly lower than the left due to the position of the liver. They are the primary regulators of fluid and acid-base balance in the body. The functional units of the kidneys, the nephrons, filter the blood and remove metabolic wastes. In the average adult 1,200 mL of blood, or about 21% of the cardiac output, passes through the kidneys every minute. Each kidney contains approximately 1 million nephrons. Each nephron has a **glomerulus**, a tuft of capillaries surrounded by Bowman's capsule (Figure 48-2 ■).

The endothelium of glomerular capillaries is porous, allowing fluid and solutes to readily move across this membrane into the capsule. Plasma proteins and blood cells, however, are too large to cross the membrane normally. Glomerular filtrate is similar in composition to plasma, made up of water, electrolytes, glucose, amino acids, and metabolic wastes.

From Bowman's capsule the filtrate moves into the tubule of the nephron. In the proximal convoluted tubule, most of the water and electrolytes are reabsorbed. Solutes such as glucose are reabsorbed in

Figure 48-1 ■ Anatomic structures of the urinary tract.

the loop of Henle. Other substances are secreted into the filtrate in the same area, resulting in concentrated urine. In the distal convoluted tubule, additional water and sodium are reabsorbed under the control of hormones such as antidiuretic hormone (ADH) and aldosterone. This controlled reabsorption allows regulation of fluid and electrolyte balance in the body. When fluid intake is low or the concentration of solutes in the blood is high, ADH is released from the posterior pituitary, more water is reabsorbed in the distal tubule, and less urine is excreted. By contrast, when fluid intake is high or the blood solute concentration is low, ADH is suppressed. Without ADH, the distal tubule becomes impermeable to water, and more urine is excreted. When aldosterone is released from the adrenal cortex, sodium and water are reabsorbed in greater quantities, increasing the blood volume and decreasing urinary output.

Ureters

Once the urine is formed in the kidneys, it moves through the collecting ducts into the calyces of the renal pelvis and from there into the ureters. In adults the ureters are from 25 to 30 cm (10 to 12 in.) long and about 1.25 cm (0.5 in.) in diameter. The upper end of each ureter is funnel shaped as it enters the kidney. The lower ends of the ureters enter the bladder at the posterior corners of the floor of the bladder (see Figure 48-1). At the junction between the ureter and the bladder, a flaplike fold of mucous membrane acts as a valve to prevent **reflux** (backflow) of urine up the ureters.

Bladder

The urinary bladder (vesicle) is a hollow, muscular organ that serves as a reservoir for urine and as the organ of excretion. When empty, it lies behind the symphysis pubis. In men, the bladder lies in front of the rectum and above the prostate gland (Figure 48-3 ■); in women it lies in front of the uterus and vagina (Figure 48-4 ■).

The wall of the bladder is made up of four layers: (1) an inner mucous layer; (2) a connective tissue layer; (3) three layers of smooth muscle fibers, some of which extend lengthwise, some obliquely, and some more or less circularly; and (4) an outer serous layer. The smooth muscle layers are collectively called the **detrusor muscle**. The detrusor muscle allows the bladder to expand as it fills with urine, and to contract to release urine to the outside of the body during voiding. The **trigone** at the base of the bladder is a triangular area

Figure 48-2 ■ The nephrons of the kidney are composed of six parts: the glomerulus, Bowman's capsule, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct.

Figure 48-3 ■ The male urogenital system.

Figure 48-4 ■ The female urogenital system.

marked by the ureter openings at the posterior corners and the opening of the urethra at the anterior inferior corner (see Figure 48-1).

The bladder is capable of considerable distention because of rugae (folds) in the mucous membrane lining and because of the elasticity of its walls. When full, the dome of the bladder may extend above the symphysis pubis; in extreme situations, it may extend as high as the umbilicus. Normal bladder capacity is between 300 and 600 mL of urine.

Urethra

The urethra extends from the bladder to the urinary **meatus** (opening). In the adult woman, the urethra lies directly behind the symphysis pubis, anterior to the vagina, and is between 3 and 4 cm (1.5 in.) long (see Figure 48-4). The urethra serves only as a passageway for the elimination of urine. The urinary meatus is located between the labia minora, in front of the vagina and below the clitoris. The male urethra is approximately 20 cm (8 in.) long and serves as a passageway for semen as well as urine (see Figure 48-3). The meatus is located at the distal end of the penis.

In both men and women, the urethra has a mucous membrane lining that is continuous with the bladder and the ureters. Thus, an infection of the urethra can extend through the urinary tract to the kidneys. Women are particularly prone to urinary tract infections (UTIs) because of their short urethra and the proximity of the urinary meatus to the vagina and anus.

Pelvic Floor

The vagina, urethra, and rectum pass through the pelvic floor, which consists of sheets of muscles and ligaments that provide support to the viscera of the pelvis (see Figures 48-3 and 48-4). These muscles and ligaments extend from the symphysis pubis to the coccyx forming a sling. Specific sphincter muscles contribute to the continence mechanism (see the Anatomy & Physiology Review). The internal sphincter muscle situated in the proximal urethra and the bladder neck is composed of smooth muscle under *involuntary* control. It provides active tension designed to close the urethral lumen. The external sphincter muscle is composed of skeletal muscle under *voluntary* control, allowing the individual to choose when urine is eliminated.

Urination

Micturition, **voiding**, and **urination** all refer to the process of emptying the urinary bladder. Urine collects in the bladder until pressure stimulates special sensory nerve endings in the bladder wall called stretch receptors. This occurs when the adult bladder contains between 250 and 450 mL of urine. In children, a considerably smaller volume, 50 to 200 mL, stimulates these nerves.

The stretch receptors transmit impulses to the spinal cord, specifically to the voiding reflex center located at the level of the second to fourth sacral vertebrae, causing the internal sphincter to relax and stimulating the urge to void. If the time and place are appropriate for urination, the conscious portion of the brain relaxes the external urethral sphincter muscle and urination takes place. If the time and place are inappropriate, the micturition reflex usually subsides until the bladder becomes more filled and the reflex is stimulated again.

Voluntary control of urination is possible only if the nerves supplying the bladder and urethra, the neural tracts of the cord and brain, and the motor area of the cerebrum are all intact. The individual must be able to sense that the bladder is full. Injury to any of these parts of the nervous system—for example, by a cerebral hemorrhage or spinal cord injury above the level of the sacral region—results in intermittent involuntary emptying of the bladder. Older adults whose cognition is impaired may not be aware of the need to urinate or able to respond to this urge by seeking toilet facilities.

FACTORS AFFECTING VOIDING

Numerous factors affect the volume and characteristics of the urine produced and the manner in which it is excreted.

Developmental Factors

INFANTS

Urine output varies according to fluid intake but gradually increases to 250 to 500 mL a day during the first year. An infant may urinate as often as 20 times a day. The urine of the neonate is colorless and odorless and has a specific gravity of 1.008. Because newborns and infants have immature kidneys, they are unable to concentrate urine very effectively.

Infants are born without urinary control. Most will develop this between the ages of 2 and 5 years. Control during the daytime normally precedes night-time control.

PRESCHOOLERS

The preschooler is able to take responsibility for independent toileting. Parents need to realize that accidents do occur and the child should never be punished or disciplined for this. Children often forget to wash their hands or flush the toilet and need instruction in wiping themselves. Girls should be taught to wipe from front to back to prevent contamination of the urinary tract by feces.

SCHOOL-AGE CHILDREN

The school-age child's elimination system reaches maturity during this period. The kidneys double in size between ages 5 and 10 years. During this period, the child urinates six to eight times a day. **Enuresis**, which is defined as the involuntary passing of urine

ANATOMY & PHYSIOLOGY REVIEW

Female and Male Urinary Bladders and Urethras

The pelvic floor muscles are under voluntary control and are important in controlling urination (continence). These muscles can become weakened by pregnancy and childbirth, chronic constipation, a

decrease in estrogen (menopause), being overweight, aging, and lack of general fitness.

Review the figures and find the pelvic floor muscles.

QUESTIONS

1. Do you think pelvic floor muscles can be strengthened? Provide your rationale.

2. Explain how exercising the pelvic floor muscles helps to control urination.

See student resource website for answers.

when control should be established (about 5 years of age), can be a problem for some school-age children. About 10% of all 6-year-olds experience difficulty controlling the bladder. **Nocturnal enuresis**, or bed-wetting, is the involuntary passing of urine during sleep. It has many causes but basically it occurs because the client fails to awaken when the bladder empties. Bed-wetting should not be considered a problem until after the age of 6. Nocturnal enuresis may be referred to as primary when the child has never achieved nighttime urinary control. The incidence of nocturnal enuresis declines as the child matures. Secondary enuresis is that which appears after the child has achieved dryness for a period of 6 consecutive months. It is often related to another problem such as constipation, stress, or illness and may resolve when the cause is eliminated. Recent research indicates that primary and secondary nocturnal enuresis may both be related to poor daytime voiding habits, and children should be taught to be aware of the sensation to void (Norfolk & Wootton, 2012).

OLDER ADULTS

The excretory function of the kidney diminishes with age, but usually not significantly below normal levels unless a disease process

intervenes. Blood flow can be reduced by arteriosclerosis, impairing renal function. With age, the number of functioning nephrons decreases to some degree, impairing the kidney's filtering abilities. Conditions that alter normal fluid intake and output, such as having influenza or having surgery, can compromise the kidney's ability to filter, maintain acid–base balance, and maintain electrolyte balance in older adults. It also takes a much longer time for these processes to return to normal functioning. The decrease in kidney function also places the older adult at higher risk for toxicity from medications if excretion rates are longer.

The more noticeable changes with age are those related to the bladder. Complaints of urinary urgency and urinary frequency are common. In men these changes are often due to an enlarged prostate gland, and in women they may be due to weakened muscles supporting the bladder or weakness of the urethral sphincter. The capacity of the bladder and its ability to completely empty diminish with age. This explains the need for older adults to arise during the night to void (**nocturnal frequency**) and the retention of residual urine, predisposing the older adult to bladder infections.

See Table 48–1 for a summary of the developmental changes affecting urinary output and the Lifespan Considerations feature.

Psychosocial Factors

For many people, a set of conditions helps stimulate the micturition reflex. These conditions include privacy, normal position, sufficient time, and, occasionally, running water. Circumstances that do not allow for the client's accustomed conditions may produce anxiety and muscle tension. As a result, the person is unable to relax abdominal and perineal muscles and the external urethral sphincter; thus, voiding is inhibited. People also may voluntarily suppress urination

because of perceived time pressures; for example, nurses often ignore the urge to void until they are able to take a break. This behavior can increase the risk of UTIs.

Fluid and Food Intake

The healthy body maintains a balance between the amount of fluid ingested and the amount of fluid eliminated. When the amount of fluid intake increases, therefore, the output normally increases.

TABLE 48–1 Changes in Urinary Elimination Throughout the Life Span

Stage	Variations
Fetuses	The fetal kidney begins to excrete urine between the 11th and 12th week of development.
Infants	Ability to concentrate urine is minimal; therefore, urine appears light yellow. Because of neuromuscular immaturity, voluntary urinary control is absent.
Children	Kidney function reaches maturity between the first and second year of life; urine is concentrated effectively and appears a normal amber color. Between 18 and 24 months of age, the child starts to recognize bladder fullness and is able to hold urine beyond the urge to void. At approximately 2 1/2 to 3 years of age, the child can perceive bladder fullness, hold urine after the urge to void, and communicate the need to urinate.
Adults	Full urinary control usually occurs at age 4 or 5 years; daytime control is usually achieved by age 3 years. The kidneys reach maximum size between 35 and 40 years of age. After 50 years, the kidneys begin to diminish in size and function. Most shrinkage occurs in the cortex of the kidney as individual nephrons are lost.
Older Adults	An estimated 30% of nephrons are lost by age 80. Renal blood flow decreases because of vascular changes and a decrease in cardiac output. The ability to concentrate urine declines. Bladder muscle tone diminishes, causing increased frequency of urination and nocturia (awakening to urinate at night). Diminished bladder muscle tone and contractibility may lead to residual urine in the bladder after voiding, increasing the risk of bacterial growth and infection. Urinary incontinence may occur due to mobility problems or neurologic impairments.

LIFESPAN CONSIDERATIONS Factors Affecting Voiding

INFANTS AND CHILDREN

- Urinary tract infections (UTIs) are the second most common infection in children, after respiratory infections. They are seen more frequently in newborn and young infant boys than girls and are most often due to obstructions or malformations of the urinary system in these children (Ball, Bindler, & Cowen, 2012). In older infants and children, girls have more UTIs than boys, usually due to contamination of the urethra with stool.
- Teaching proper perineal hygiene can reduce infection. Girls should learn to wipe from front to back and wear cotton underwear.
- Teach children and parents that they should go to the bathroom as soon as the sensation to void is felt and not try to hold the urine in.

OLDER ADULTS

Many changes of aging cause specific problems in urinary elimination. Many conditions can be treated to lessen symptoms. Some of the following conditions are etiologic factors in problems with urinary elimination:

- Many older men have enlarged prostate glands, which can inhibit complete emptying of the bladder, resulting in urinary retention and urgency that can cause incontinence.

- After menopause women have decreased estrogen levels, which results in a decrease in perineal tone and support of bladder, vagina, and supporting tissues. This often results in urgency and stress incontinence and can even increase the incidence of UTIs.
- Increased stiffness and joint pain, previous joint surgery, and neuromuscular problems can impair mobility, making it difficult to get to the bathroom.
- Cognitive impairment, such as in dementia, often prevents the person from understanding the need to urinate and the actions needed to perform the activity.

Interventions that may improve these conditions include:

- Medications or surgery to relieve obstructions in men and strengthen support in the urogenital area in women.
- Behavioral training for better bladder control.
- Providing safe, easy access to the bathroom or bedside commode, whether at home or in an institution. Make sure the room is well lit, the environment is safe, and the proper assistive devices are within reach (such as walkers, canes).
- Habit training, such as taking the person to the bathroom at a regular, scheduled time. This can often work very well with people who have cognitive impairments.

Certain fluids, such as alcohol, increase fluid output by inhibiting the production of antidiuretic hormone. Fluids that contain caffeine (e.g., coffee, tea, and cola drinks) also increase urine production. By contrast, food and fluids high in sodium can cause fluid retention because water is retained to maintain the normal concentration of electrolytes.

Some foods and fluids can change the color of urine. For example, beets can cause urine to appear red; foods containing carotene can cause the urine to appear yellower than usual.

Medications

Many medications, particularly those affecting the autonomic nervous system, interfere with the normal urination process and may cause retention (Box 48–1). **Diuretics** (e.g., chlorothiazide and furosemide) increase urine formation by preventing the reabsorption of water and electrolytes from the tubules of the kidney into the bloodstream. Some medications may alter the color of the urine.

Muscle Tone

Good muscle tone is important to maintain the stretch and contractility of the detrusor muscle so the bladder can fill adequately and empty completely. Clients who require a retention catheter for a long period may have poor bladder muscle tone because continuous drainage of urine prevents the bladder from filling and emptying normally. Pelvic muscle tone also contributes to the ability to store and empty urine.

Pathologic Conditions

Some diseases and pathologies can affect the formation and excretion of urine. Diseases of the kidneys may affect the ability of the nephrons to produce urine. Abnormal amounts of protein or blood cells may be present in the urine, or the kidneys may virtually stop producing urine altogether, a condition known as renal failure. Heart and circulatory disorders such as heart failure, shock, or hypertension can affect blood flow to the kidneys, interfering with urine production. If abnormal amounts of fluid are lost through another route (e.g., vomiting or high fever), the kidneys retain water and urinary output falls.

Processes that interfere with the flow of urine from the kidneys to the urethra affect urinary excretion. A urinary stone (calculus)

may obstruct a ureter, blocking urine flow from the kidney to the bladder. Hypertrophy of the prostate gland, a common condition affecting older men, may obstruct the urethra, impairing urination and bladder emptying.

Surgical and Diagnostic Procedures

Some surgical and diagnostic procedures affect the passage of urine and the urine itself. The urethra may swell following a cystoscopy, and surgical procedures on any part of the urinary tract may result in some postoperative bleeding; as a result, the urine may be red or pink tinged for a time.

Spinal anesthetics can affect the passage of urine because they decrease the client's awareness of the need to void. Surgery on structures adjacent to the urinary tract (e.g., the uterus) can also affect voiding because of swelling in the lower abdomen.

ALTERED URINE PRODUCTION

Although people's patterns of urination are highly individual, most people void about five to six times a day. People usually void when they first awaken in the morning, before they go to bed, and around mealtimes. Table 48–2 shows the average urinary output per day at different ages.

Polyuria

Polyuria (or **diuresis**) refers to the production of abnormally large amounts of urine by the kidneys, often several liters more than the client's usual daily output. Polyuria can follow excessive fluid intake, a condition known as **polydipsia**, or may be associated with diseases such as diabetes mellitus, diabetes insipidus, and chronic nephritis. Polyuria can cause excessive fluid loss, leading to intense thirst, dehydration, and weight loss.

Oliguria and Anuria

The terms *oliguria* and *anuria* are used to describe decreased urinary output. **Oliguria** is low urine output, usually less than 500 mL a day or 30 mL an hour for an adult. Although oliguria may occur because of abnormal fluid losses or a lack of fluid intake, it often indicates impaired blood flow to the kidneys or impending renal failure and should be promptly reported to the primary care provider.

BOX 48–1 Medications That May Cause Urinary Retention

- Anticholinergic medications, such as Atropine, Robinul, and Pro-Banthine
- Antidepressant and antipsychotic agents, such as tricyclic antidepressants and MAO inhibitors
- Antihistamine preparations, such as pseudoephedrine (Actifed and Sudafed)
- Antihypertensives, such as hydralazine (Apresoline) and methyldopa (Aldomet)
- Antiparkinsonism drugs, such as levodopa, trihexyphenidyl (Artane), and benztrapine mesylate (Cogentin)
- Beta-adrenergic blockers, such as propranolol (Inderal)
- Opioids, such as hydrocodone (Vicodin)

TABLE 48–2 Average Daily Urine Output by Age

Age	Amount (ml)
1–2 days	15–60
3–10 days	100–300
10 days–2 months	250–450
2 months–1 year	400–500
1–3 years	500–600
3–5 years	600–700
5–8 years	700–1,000
8–14 years	800–1,400
14 years through adulthood	1,500
Older adulthood	1,500 or less

Restoring renal blood flow and urinary output promptly can prevent renal failure and its complications. **Anuria** refers to a lack of urine production.

Should the kidneys become unable to adequately function, some mechanism of filtering the blood is necessary to prevent illness and death. This filtering is done through the use of renal **dialysis**, a technique by which fluids and molecules pass through a semi-permeable membrane according to the rules of osmosis. The two most common methods of dialysis are hemodialysis and peritoneal dialysis. In hemodialysis, the client's blood flows through vascular catheters, passes by the dialysis solution in an external machine, and then returns to the client. In peritoneal dialysis, the dialysis solution is instilled into the abdominal cavity through a catheter, allowed to rest there while the fluid and molecules exchange, and then removed through the catheter. Both hemodialysis and peritoneal dialysis must be performed at frequent intervals until the client's kidneys can resume the filtering function.

ALTERED URINARY ELIMINATION

Despite normal urine production, a number of factors or conditions can affect urinary elimination. Frequency, nocturia, urgency, and dysuria often are manifestations of underlying conditions such as a

UTI. Enuresis, incontinence, retention, and neurogenic bladder may be either a manifestation or the primary problem affecting urinary elimination. Selected factors associated with altered patterns of urine elimination are identified in Table 48–3.

Frequency and Nocturia

Urinary frequency is voiding at frequent intervals, that is, more than four to six times per day. An increased intake of fluid causes some increase in the frequency of voiding. Conditions such as UTI, stress, and pregnancy can cause frequent voiding of small quantities (50 to 100 mL) of urine. Total fluid intake and output may be normal.

Nocturia is voiding two or more times at night. Like frequency, it is usually expressed in terms of the number of times the person gets out of bed to void, for example, “nocturia × 4.”

Urgency

Urgency is the sudden, strong desire to void. There may or may not be a great deal of urine in the bladder, but the person feels a need to void immediately. Urgency accompanies psychological stress and irritation of the trigone and urethra. It is also common in people who have poor external sphincter control and unstable bladder contractions. It is not a normal finding.

TABLE 48–3 Selected Factors Associated with Altered Urinary Elimination

Pattern	Selected Associated Factors
Polyuria	Ingestion of fluids containing caffeine or alcohol Prescribed diuretic Presence of thirst, dehydration, and weight loss History of diabetes mellitus, diabetes insipidus, or kidney disease
Oliguria, anuria	Decrease in fluid intake Signs of dehydration Presence of hypotension, shock, or heart failure History of kidney disease Signs of renal failure such as elevated blood urea nitrogen (BUN) and serum creatinine, edema, hypertension
Frequency or nocturia	Pregnancy Increase in fluid intake UTI
Urgency	Presence of psychological stress UTI
Dysuria	Urinary tract inflammation, infection, or injury Hesitancy, hematuria, pyuria (pus in the urine), and frequency
Enuresis	Family history of enuresis Difficult access to toilet facilities Home stresses
Incontinence	Bladder inflammation, cerebrovascular accident (CVA; stroke), spinal cord injury, or other disease Difficulties in independent toileting (mobility impairment) Leakage when coughing, laughing, sneezing Cognitive impairment Retention Distended bladder on palpation and percussion Associated signs, such as pubic discomfort, restlessness, frequency, and small urine volume Recent anesthesia Recent perineal surgery Presence of perineal swelling Medications prescribed Lack of privacy or other factors inhibiting micturition

Dysuria

Dysuria means voiding that is either painful or difficult. It can accompany a stricture (decrease in caliber) of the urethra, urinary infections, and injury to the bladder and urethra. Often clients will say they have to push to void or that burning accompanies or follows voiding. The burning may be described as severe, like a hot poker, or more subdued, like a sunburn. Often, **urinary hesitancy** (a delay and difficulty in initiating voiding) is associated with dysuria.

Enuresis

Enuresis is involuntary urination in children beyond the age when voluntary bladder control is normally acquired, usually 4 or 5 years of age. Nocturnal enuresis often is irregular in occurrence and affects boys more often than girls. Diurnal (daytime) enuresis may be persistent and pathologic in origin. It affects women and girls more frequently.

Urinary Incontinence

Urinary incontinence (UI), or involuntary leakage of urine or loss of bladder control, is a health symptom, not a disease. It is only normal in infants. It has been estimated that 20 million women and 6 million men experience some type of UI in their lifetime (Scemons, 2013, p. 53). Shultz (2012) found that 30% of homebound older adults are incontinent, and UI contributed significantly to their being homebound. More than half of all residents in long-term care (LTC) facilities are incontinent and UI is the second leading cause of institutionalization (p. 32). In spite of the high numbers of adults with UI, it is underreported and undertreated, and can lead to a decreased quality of life (Keyock & Newman, 2011).

Direct and indirect costs are associated with UI. The annual cost of around \$20 billion for incontinence is higher than for chronic diseases such as arthritis (Scemons, 2013). The majority of direct cost is spent on routine care including pads, diapers, and laundry related to frequent clothing changes. Other costs include medications and surgical treatment. Indirect costs relate to quality-of-life issues and psychosocial consequences. Studies have shown that incontinent women have an increased incidence of social isolation, social withdrawal, less positive relationships with others, poorer perceived health, negative effect on sexual function and intimacy, increased incidence of depression, and a barrier to social interest, physical activity, and other everyday activities (Schultz, 2012).

The four main types of UI are stress urinary incontinence, urge urinary incontinence, mixed urinary incontinence, and overflow incontinence.

STRESS URINARY INCONTINENCE

Stress urinary incontinence (SUI) occurs because of weak pelvic floor muscles and/or urethral hypermobility, causing urine leakage with such activities as laughing, coughing, sneezing, or any body movement that puts pressure on the bladder. Facts that make women more likely to experience SUI include shorter urethras, the trauma to the pelvic floor associated with childbirth, and changes related to menopause. For men, SUI may result after a prostatectomy. Keyock and Newman (2011) stress the importance of clients understanding that SUI is not related to emotional stress

but is “caused by increased pressure or ‘stress’ on the bladder as well as anatomical changes to the urethra, and pelvic floor muscle weakness” (p. 26).

URGE URINARY INCONTINENCE

This type of incontinence is described as an urgent need to void and the inability to stop micturition (passage of urine). The urine leakage can range from a few drops to soaking of undergarments. Urge incontinence is a major symptom of an overactive bladder (National Association for Continence [NAFC], 2014).

MIXED URINARY INCONTINENCE

Mixed incontinence is diagnosed when symptoms of both stress UI and urgency UI are present. It is very common among middle-age and older women (Scemons, 2013). Treatment is usually based on which type of UI is the most bothersome to the client.

OVERFLOW INCONTINENCE

This is “continuous involuntary leakage or dribbling of urine that occurs with incomplete bladder emptying” (Scemons, 2013, p. 55). It can be seen in men with an enlarged prostate and clients with a neurologic disorder (e.g., multiple sclerosis, Parkinson’s disease, spinal cord injury). An impaired neurologic function can interfere with the normal mechanisms of urine elimination, resulting in a **neurogenic bladder**. The client with a neurogenic bladder does not perceive bladder fullness and is therefore unable to control the urinary sphincters. The bladder may become flaccid and distended or spastic, with frequent involuntary urination.

Urinary Retention

When emptying of the bladder is impaired, urine accumulates and the bladder becomes overdistended, a condition known as **urinary retention**. Overdistention of the bladder causes poor contractility of the detrusor muscle, further impairing urination. Common causes of urinary retention include prostatic hypertrophy (enlargement), surgery, and some medications (see Box 48–1). Acute urinary retention is the most common complication in the first 2 to 4 hours postoperatively (Palese, Buchini, Deroma, & Barbone, 2010). Causes of chronic urinary retention can include paraplegia, quadriplegia, multiple sclerosis, and urethral or perineal trauma (Bullman, 2011, p. 259).

Clients with urinary retention may experience overflow incontinence, eliminating 25 to 50 mL of urine at frequent intervals. The bladder is firm and distended on palpation and may be displaced to one side of the midline.

●○○ NURSING MANAGEMENT

Assessing

A complete assessment of a client’s urinary function includes the following:

- Nursing history
- Physical assessment of the genitourinary system, hydration status, and examination of the urine
- Relating the data obtained to the results of any diagnostic tests and procedures.

Nursing History

The nurse determines the client's normal voiding pattern and frequency, appearance of the urine and any recent changes, any past or current problems with urination, the presence of an ostomy, and factors influencing the elimination pattern.

Examples of interview questions to elicit this information are shown in the Assessment Interview. The number of questions asked depends on the individual and the responses to the first three categories.

Physical Assessment

Complete physical assessment of the urinary tract usually includes percussion of the kidneys to detect areas of tenderness. Palpation and percussion of the bladder are also performed. If the client's history or current problems indicate a need for it, the urethral meatus of both male and female clients is inspected for swelling, discharge, and inflammation.

Because problems with urination can affect the elimination of wastes from the body, it is important for the nurse to assess the skin for color, texture, and tissue turgor as well as the presence of edema. If incontinence, dribbling, or dysuria is noted in the history, the skin of the perineum should be inspected for irritation because contact with urine can excoriate the skin.

Assessing Urine

Normal urine consists of 96% water and 4% solutes. Organic solutes include urea, ammonia, creatinine, and uric acid. Urea is the chief organic solute. Inorganic solutes include sodium, chloride, potassium, sulfate, magnesium, and phosphorus. Sodium chloride is the most abundant inorganic salt. Variations in color can occur. Characteristics of normal and abnormal urine are shown in Table 48–4.

Measuring Urinary Output

Normally, the kidneys produce urine at a rate of approximately 60 mL/h or about 1,500 mL/day. Urine output is affected by many factors, including fluid intake, body fluid losses through other routes

such as perspiration and breathing or diarrhea, and the cardiovascular and renal status of the individual.

Urine outputs below 30 mL/h may indicate low blood volume or kidney malfunction and must be reported. To measure fluid output the nurse follows these steps:

- Wear clean gloves to prevent contact with microorganisms or blood in urine.
- Ask the client to void in a clean urinal, bedpan, commode, or toilet collection device ("hat") (Figure 48–5 ■).
- Instruct the client to keep urine separate from feces and to avoid putting toilet paper in the urine collection container.
- Pour the voided urine into a calibrated container.
- Hold the container at eye level, read the amount in the container. Containers usually have a measuring scale on the inside.
- Record the amount on the fluid intake and output sheet, which may be at the bedside or in the bathroom.
- Rinse the urine collection and measuring containers with cool water and store appropriately.
- Remove gloves and perform hand hygiene.
- Calculate and document the total output at the end of each shift and at the end of 24 h on the client's chart.

Many clients can measure and record their own urine output when the procedure is explained to them.

When measuring urine from a client who has a urinary catheter, the nurse follows these steps:

- Apply clean gloves.
- Take the calibrated container to the bedside.
- Place the container under the urine collection bag so that the spout of the bag is above the container but not touching it. The calibrated container is not sterile, but the inside of the collection bag is sterile (Figure 48–6 ■).
- Open the spout and permit the urine to flow into the container.
- Close the spout, then proceed as described in the previous list.

ASSESSMENT INTERVIEW Urinary Elimination

VOIDING PATTERN

- How many times do you urinate during a 24-hour period?
- Has this pattern changed recently?
- Do you need to get out of bed to void at night? How often?

DESCRIPTION OF URINE AND ANY CHANGES

- How would you describe your urine in terms of color, clarity (clear, transparent, or cloudy), and odor (faint or strong)?

URINARY ELIMINATION PROBLEMS

- What problems have you had or do you now have with passing your urine?
- Passage of small amounts of urine?
- Voiding at more frequent intervals?
- Trouble getting to the bathroom in time, or feeling an urgent need to void?
- Painful voiding?
- Difficulty starting urine stream?
- Frequent dribbling of urine or feeling of bladder fullness associated with voiding small amounts of urine?
- Reduced force of stream?
- Accidental leakage of urine? If so, when does this occur (e.g., when coughing, laughing, or sneezing; at night; during the day)?

- Past urinary tract illness such as infection of the kidney, bladder, or urethra? History of renal, ureteral, or bladder surgery?

FACTORS INFLUENCING URINARY ELIMINATION

- *Medications.* What medications are you taking? Do you know if any of your medications increase urinary output or cause retention of urine? Note specific medication and dosage.
- *Fluid intake.* How much and what kind of fluid do you drink each day (e.g., six glasses of water, two cups of coffee, three cola drinks with or without caffeine)?
- *Environmental factors.* Do you have any problems with toileting (mobility, removing clothing, toilet seat too low, facility without grab bar)?
- *Stress.* Are you experiencing any major stress? If so, what are the stressors? Do you think these affect your urinary pattern?
- *Disease.* Have you had or do you have any illnesses that may affect urinary function, such as hypertension, heart disease, neurologic disease, cancer, prostatic enlargement, or diabetes?
- *Diagnostic procedures and surgery.* Have you recently had a cystoscopy or anesthetic?

TABLE 48-4 Characteristics of Normal and Abnormal Urine

Characteristic	Normal	Abnormal	Nursing Considerations
Amount in 24 hours (adult)	1,200–1,500 mL	Under 1,200 mL A large amount over intake	Urinary output normally is approximately equal to fluid intake. Output of less than 30 mL/h may indicate decreased blood flow to the kidneys and should be immediately reported.
Color, clarity	Straw, amber Transparent	Dark amber Cloudy Dark orange Red or dark brown Mucous plugs, viscid, thick	Concentrated urine is darker in color. Dilute urine may appear almost clear, or very pale yellow. Some foods and drugs may color urine. Red blood cells in the urine (hematuria) may be evident as pink, bright red, or rusty brown urine. Menstrual bleeding can also color urine but should not be confused with hematuria. White blood cells, bacteria, pus, or contaminants such as prostatic fluid, sperm, or vaginal drainage may cause cloudy urine.
Odor	Faint aromatic	Offensive	Some foods (e.g., asparagus) cause a musty odor; infected urine can have a fetid odor; urine high in glucose has a sweet odor.
Sterility	No microorganisms present	Microorganisms present	Urine in the bladder is sterile. Urine specimens, however, may be contaminated by bacteria from the perineum during collection.
pH	4.5–8	Over 8 Under 4.5	Freshly voided urine is normally somewhat acidic. Alkaline urine may indicate a state of alkalosis, UTI, or a diet high in fruits and vegetables. More acidic urine (low pH) is found in starvation, with diarrhea, or with a diet high in protein foods or cranberries.
Specific gravity	1.010–1.025	Over 1.025 Under 1.010	Concentrated urine has a higher specific gravity; diluted urine has a lower specific gravity.
Glucose	Not present	Present	Glucose in the urine indicates high blood glucose levels (greater than 180 mg/dL) and may be indicative of undiagnosed or uncontrolled diabetes mellitus.
Ketone bodies (acetone)	Not present	Present	Ketones, the end product of the breakdown of fatty acids, are not normally present in urine. They may be present in the urine of clients who have uncontrolled diabetes mellitus, who are in a state of starvation, or who have ingested excessive amounts of aspirin.
Blood	Not present	Occult (microscopic) Bright red	Blood may be present in the urine of clients who have UTI, kidney disease, or bleeding from the urinary tract.

**Figure 48-5** ■ A urine “hat”—a urine collection device for the toilet.**Figure 48-6** ■ Urine being measured from a urine collection bag.**Measuring Residual Urine**

Postvoid residual (PVR) (urine remaining in the bladder following voiding) is normally 50 to 100 mL. However, a bladder outlet obstruction (e.g., enlargement of the prostate gland) or loss of bladder muscle tone may interfere with complete emptying of the bladder

during urination. Manifestations of urine retention may include frequent voiding of small amounts (e.g., less than 100 mL in an adult), urinary stasis, and UTI. PVR is measured to assess the amount of retained urine after voiding and determine the need for interventions (e.g., medications to promote detrusor muscle contraction).

To measure PVR, the nurse catheterizes or bladder scans the client after voiding (Figure 48–7 ■). The amount of urine voided and the amount obtained by catheterization or bladder scan are measured and recorded. An indwelling catheter may be inserted if the PVR exceeds a specified amount.

Diagnostic Tests

Blood levels of two metabolically produced substances, urea and creatinine, are routinely used to evaluate renal function. The kidneys through filtration and tubular secretion normally eliminate both urea and creatinine. Urea, the end product of protein metabolism, is measured as **blood urea nitrogen (BUN)**. Creatinine is produced in relatively constant quantities by the muscles. The **creatinine clearance** test uses 24-hour urine and serum creatinine levels to determine the glomerular filtration rate, a sensitive indicator of renal function. Other tests related to urinary functions such as collecting urine specimens, measuring specific gravity, and visualization procedures are described in Chapter 34 ∞.

Diagnosing

NANDA International (Herdman & Kamitsuru, 2014) includes two general diagnostic labels for urinary elimination:

- **Impaired Urinary Elimination:** dysfunction in urine elimination
- **Readiness for Enhanced Urinary Elimination:** a pattern of urinary functions for meeting eliminatory needs, which can be strengthened.

It is suggested that a more specific diagnostic label be used when possible. The more specific NANDA International nursing diagnoses related to urinary elimination include the following:

- *Functional Urinary Incontinence*
- *Overflow Urinary Incontinence*
- *Reflex Urinary Incontinence*

Figure 48–7 ■ A handheld, portable ultrasound device can measure bladder urine volume noninvasively.

- *Stress Urinary Incontinence*
- *Urge Urinary Incontinence*
- *Risk for Urge Urinary Incontinence*
- *Urinary Retention*

See Box 48–2 for definitions of NANDA diagnoses related to incontinence.

Clinical examples of assessment data clusters and related nursing diagnoses, outcomes, and interventions are shown in the Nursing Care Plan and Concept Map at the end of this chapter.

Evidence-Based Practice What Is the Effectiveness of the Ultrasound Bladder Scanner in Reducing Urinary Tract Infections?

EVIDENCE-BASED PRACTICE

Urinary retention, a common complication postoperatively, can lead to complications, client discomfort, and a longer hospitalization stay. Two ways to detect and monitor urinary retention are with an ultrasound bladder scanner or with intermittent catheterization. Catheterization is an invasive procedure and increases the risk of UTI. On the other hand, the bladder scanner is noninvasive and permits evaluation of the bladder volume so that catheterization is only performed when the volume is over a designated amount. Palese and colleagues (2010) believed that there was a need to analyze the available research comparing the use of the bladder scanner followed by the decision to catheterize or not catheterize versus the clinical judgment of the nurse who decides whether to catheterize or not catheterize the client and the effect of these procedures in reducing catheter-associated UTIs (CAUTIs). A meta-analysis study was conducted to synthesize the evidence available in the literature on the effectiveness of the ultrasound bladder scanner in reducing the risk of UTI. The criteria for studies to be included in the research included the following: type of subject (hospitalized male and female subjects age 18 or over whose treatment required a need to evaluate bladder urinary volume); type of intervention (use of bladder scanner versus the clinical judgment of the nurses in evaluation

of acute urinary retention followed by a decision whether or not to catheterize the client); and type of outcome (occurrence of at least one CAUTI before release from the hospital).

A total of 61 articles were found and 58 were excluded based on the criteria. The three studies that remained had some variation; for example, subjects in one study were neurosurgical and those in the other two studies were orthopedic; each study used a different type of scanner; evaluations were performed at 8 hours or 4 to 6 hours after surgery or the period was not indicated in one study; and the cutoff amount of when to catheterize varied from less than 499 mL to less than 800 mL. In spite of these variations, based on the statistical analyses, the studies were considered homogeneous. The researchers stated that the “use of bladder ultrasound reduced the risk of CAUTI by some 73%” (p. 2976).

IMPLICATIONS

A limitation of this study was the small number of appropriate studies included in the meta-analysis. Nevertheless, the use of the bladder scanner as a noninvasive assessment tool should become a common practice of nurses who provide care to surgical clients who develop acute urinary retention.

BOX 48-2 Definitions of NANDA International Incontinence Diagnoses

- *Functional Urinary Incontinence*—inability of usually continent person to reach toilet in time to avoid unintentional loss of urine
- *Overflow Urinary Incontinence*—involuntary loss of urine associated with overdistention of the bladder
- *Reflex Urinary Incontinence*—involuntary loss of urine at somewhat predictable intervals when a specific bladder volume is reached
- *Stress Urinary Incontinence*—sudden leakage of urine with activities that increase intra-abdominal pressure
- *Urge Urinary Incontinence*—involuntary passage of urine occurring soon after a strong sense of urgency to void
- *Risk for Urge Urinary Incontinence*—vulnerable to involuntary passage of urine occurring soon after a strong sensation or urgency to void, which may compromise health

From *NANDA International Nursing Diagnoses: Definitions and Classification, 2015–2017*, by T. H. Herdman and S. Kamitsuru (Eds.), 2014, Oxford, United Kingdom: Wiley-Blackwell.

Problems of urinary elimination also may become the etiology for other problems experienced by the client. Examples include the following:

- **Risk for Infection** if the client has urinary retention or undergoes an invasive procedure such as catheterization or cystoscopic examination.
- **Situational Low Self-Esteem** or **Social Isolation** if the client is incontinent. Incontinence can be physically and emotionally distressing to clients because it is considered socially unacceptable. Often the client is embarrassed about dribbling or having an accident and may restrict normal activities for this reason.
- **Risk for Impaired Skin Integrity** if the client is incontinent. Bed linens and clothes saturated with urine irritate and macerate the skin. Prolonged skin dampness leads to dermatitis (inflammation of the skin) and subsequent formation of dermal ulcers.
- **Toileting Self-Care Deficit** if the client has functional incontinence.
- **Risk for Deficient Fluid Volume** or **Excess Fluid Volume** if the client has impaired urinary function associated with a disease process.

- **Disturbed Body Image** if the client has a urinary diversion ostomy.
- **Deficient Knowledge** if the client requires self-care skills to manage (e.g., a new urinary diversion ostomy).
- **Risk for Caregiver Role Strain** if the client is incontinent and being cared for by a family member for extended periods.
- **Risk for Social Isolation** if the client is incontinent.

Planning

The goals established will vary according to the diagnosis and defining characteristics. Examples of overall goals for clients with urinary elimination problems may include the following:

- Maintain or restore a normal voiding pattern.
- Regain normal urine output.
- Prevent associated risks such as infection, skin breakdown, fluid and electrolyte imbalance, and lowered self-esteem.
- Perform toileting activities independently with or without assistive devices.
- Contain urine with the appropriate device, catheter, ostomy appliance, or absorbent product.

Appropriate preventive and corrective nursing interventions that relate to these must be identified. Specific nursing activities associated with each of these interventions can be selected to meet the client's individual needs. Examples of clinical applications of these using NANDA, NIC, and NOC designations are shown in the Nursing Care Plan and Concept Map at the end of the chapter.

Planning for Home Care

To provide for continuity of care, the nurse needs to consider the client's needs for teaching and assistance with care in the home. Discharge planning includes assessment of the client and family's resources and abilities for self-care, available financial resources, and the need for referrals and home health services. Home Care Assessment outlines an assessment of home care capabilities related to urinary elimination problems and needs. Client Teaching addresses the learning needs of the client and family.

DRUG CAPSULE

Anticholinergic Agent oxybutynin ER (Ditropan XL)

THE CLIENT WITH MEDICATIONS FOR URGE URINARY INCONTINENCE

Anticholinergic agents reduce urgency and frequency by blocking muscarinic receptors in the detrusor muscle of the bladder, thereby inhibiting contractions and increasing storage capacity. They are useful in relieving symptoms associated with voiding problems in clients with neurogenic bladder and reflex neurogenic bladder, and urge UI.

NURSING RESPONSIBILITIES

- Monitor for constipation, dry mouth, urinary retention, blurred vision, and mental confusion in older adults; symptoms may be dose related.
- Keep primary care provider informed of expected responses to therapy (e.g., effect on urinary frequency, urge incontinence, nocturia, and bladder emptying).
- Start with small doses in clients over the age of 75.

- Try using intermittently.
- Oxybutynin is contraindicated in clients with urinary retention, gastrointestinal motility problems (partial or complete GI obstruction, paralytic ileus), or uncontrolled narrow-angle glaucoma.

CLIENT AND FAMILY TEACHING

- Explain the reason for taking oxybutynin.
- Explain the side effects and the importance of reporting them to the health care provider.
- Exercise caution in hot environments. By suppressing sweating, oxybutynin can cause fever and heat stroke.
- Provide strategies for managing dry mouth.
- Instruct and advise regarding behavioral therapies for urge suppression.

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

Home Care Assessment Urinary Elimination

PATIENT-CENTERED CARE

CLIENT AND ENVIRONMENT

- *Self-care abilities:* ability to consume adequate fluids, to perceive bladder fullness, to ambulate and get to the toilet, to manipulate clothing for toileting, and to perform hygiene measures after toileting
- *Current level of knowledge:* fluid and dietary intake modifications to promote normal patterns of urinary elimination, bladder training methods, and specific techniques to promote voiding care for indwelling catheter or ostomy (if appropriate)
- *Assistive devices required:* ambulatory aids such as walker, cane, or wheelchair; safety devices such as grab bars; toileting aids such as raised toilet seat, urinal, commode, or bedpan; presence of a urinary catheter
- *Physical layout of the toileting facilities:* presence of mobility aids; toilet at correct height to enable older clients to get up after voiding
- *Home environment factors that interfere with toileting:* distance to the bathroom from living areas or bedrooms; barriers such as stairways, scatter rugs, clutter, or narrow doorways that interfere with bathroom access; lighting (including night lighting)
- *Urinary elimination problems:* type of incontinence and precipitating factors; manifestations of UTI such as dysuria, frequency,

urgency; evidence of prostatic hypertrophy and effect on urination; ability to perform self-catheterization and care for other urinary elimination devices such as indwelling catheter, urinary diversion ostomy, or condom drainage

FAMILY

- *Caregiver availability, skills, and responses:* ability and willingness to assume responsibilities for care, including assisting with toileting, intermittent catheterization, indwelling catheter care, urinary drainage devices or ostomy care; ready access to laundry facilities; access to and willingness to use respite or relief caregivers
- *Family role changes and coping:* effect on spousal and family roles, sleep/rest patterns, sexuality, and social interactions
- *Financial resources:* ability to purchase protective pads and garments, supplies for catheterization or ostomy care

COMMUNITY

- *Environment:* access to public restrooms and sanitary facilities
- *Current knowledge of and experience with community resources:* medical and assistive equipment and supply companies, home health agencies, local pharmacies, available financial assistance, support and educational organizations

Implementing**Maintaining Normal Urinary Elimination**

Most interventions to maintain normal urinary elimination are independent nursing functions. These include promoting adequate fluid intake, maintaining normal voiding habits, and assisting with toileting.

Promoting Fluid Intake

Increasing fluid intake increases urine production, which in turn stimulates the micturition reflex. A normal daily intake averaging 1,500 mL of measurable fluids is adequate for most adult clients.

Many clients have increased fluid requirements, necessitating a higher daily fluid intake. For example, clients who are perspiring excessively (have diaphoresis) or who are experiencing abnormal fluid losses through vomiting, gastric suction, diarrhea, or wound drainage require fluid to replace these losses in addition to their normal daily intake requirements.

Clients who are at risk for UTI or urinary calculi (stones) should consume 2,000 to 3,000 mL of fluid daily. Dilute urine and frequent urination reduce the risk of UTI as well as stone formation.

Increased fluid intake may be contraindicated for some clients such as people with kidney failure or heart failure. For these clients, a fluid restriction may be necessary to prevent fluid overload and edema.

Maintaining Normal Voiding Habits

Prescribed medical therapies often interfere with a client's normal voiding habits. When a client's urinary elimination pattern is adequate, the nurse helps the client adhere to normal voiding habits as much as possible (see Practice Guidelines).

Assisting with Toileting

Clients who are weakened by a disease process or impaired physically may require assistance with toileting. The nurse should assist these clients to the bathroom and remain with them if they are at risk for

falling. The bathroom should contain an easily accessible call signal to summon help if needed. Clients also need to be encouraged to use handrails placed near the toilet.

For clients unable to use bathroom facilities, the nurse provides urinary equipment close to the bedside (e.g., urinal, bedpan, commode) and provides the necessary assistance to use them.

Preventing Urinary Tract Infections

The rate of UTI is greater in women than men because of the short urethra and its proximity to the anal and vaginal areas. Most UTIs are caused by bacteria common to the intestinal environment (e.g., *Escherichia coli*). These gastrointestinal bacteria can colonize the perineal area and move into the urethra, especially when there is urethral trauma, irritation, or manipulation.

For women who have experienced a UTI, nurses need to provide instructions about ways to prevent a recurrence. The following guidelines are useful for anyone:

- Drink eight 8-ounce glasses of water per day to flush bacteria out of the urinary system.
- Practice frequent voiding (every 2 to 4 hours) to flush bacteria out of the urethra and prevent organisms from ascending into the bladder. Void immediately after intercourse.
- Avoid use of harsh soaps, bubble bath, powder, or sprays in the perineal area. These substances can be irritating to the urethra and encourage inflammation and bacterial infection.
- Avoid tight-fitting pants or other clothing that creates irritation to the urethra and prevents ventilation of the perineal area.
- Wear cotton rather than nylon underclothes. Accumulation of perineal moisture facilitates bacterial growth. Cotton enhances ventilation of the perineal area.
- Girls and women should always wipe the perineal area from front to back following urination or defecation in order to prevent introduction of gastrointestinal bacteria into the urethra.
- If recurrent urinary infections are a problem, take showers rather than baths. Bacteria present in bath water can readily enter the urethra.

CLIENT TEACHING

Urinary Elimination in the Home Setting

FACILITATING URINARY ELIMINATION SELF-CARE

- Teach the client and family to maintain easy access to toilet facilities, including removing scatter rugs and ensuring that halls and doorways are free of clutter.
- Suggest graduated lighting for night-time voiding: a dim night-light in the bedroom and low-wattage hallway lighting.
- Advise the client and family to install grab bars and elevated toilet seats as needed.
- Provide for instruction in safe transfer techniques. Contact physical therapy to provide training as needed.
- Suggest clothing that is easily removed for toileting, such as elastic waist pants or Velcro closures.

PROMOTING URINARY ELIMINATION

- Instruct the client to respond to the urge to void as soon as possible; avoid voluntary urinary retention.
- Teach the client to empty the bladder completely at each voiding.
- Emphasize the importance of drinking eight to ten 8-ounce glasses of water daily.
- Teach female clients about pelvic muscle exercises to strengthen perineal muscles.
- Inform the client about the relationship between tobacco use and bladder cancer and provide information about smoking cessation programs as indicated.
- Teach the client to promptly report any of the following to the primary care provider: pain or burning on urination, changes in urine color or clarity, malodorous urine, or changes in voiding patterns (e.g., nocturia, frequency, dribbling).

ASEPSIS

- Teach the client to maintain perineal-genital cleanliness, washing with soap and water daily and cleansing the anal and perineal area after defecating.
- Instruct female clients to wipe from front to back (from the urinary meatus toward the anus) after voiding, and to discard toilet paper after each swipe.
- Provide information about products to protect the skin, clothing, and furniture for clients who are incontinent. Emphasize the importance of cleaning and drying the perineal area after incontinence episodes. Instruct in the use of protective skin barrier products as needed.
- Teach clients with an indwelling catheter and their family about care measures such as cleaning the urinary meatus, managing and emptying the collection device, maintaining a closed system, and bladder irrigation or flushing if ordered.
- For clients with a urinary diversion, teach about care of the stoma, drainage devices, and surrounding skin. For continent diversions, teach the client how to catheterize the stoma to drain urine.
- For clients with an indwelling catheter or urinary diversion, emphasize the importance of maintaining a generous fluid intake (2.5 to 3 quarts daily) and of promptly reporting changes in urinary output, signs of urinary retention such as abdominal

pain, and manifestations of UTI such as malodorous urine, abdominal discomfort, fever, or confusion.

MEDICATIONS

- Emphasize the importance of taking medications as prescribed. Instruct the client to take the full course of antibiotics ordered to treat a UTI, even though symptoms are relieved.
- Inform the client and family about any expected changes in urine color or odor associated with prescribed medications.
- For clients with urinary retention, emphasize the need to contact the primary care provider before taking any medication (even over-the-counter medications such as antihistamines) that may exacerbate symptoms.
- For clients taking medications that may damage the kidneys (e.g., aminoglycoside antibiotics), stress the importance of maintaining a generous fluid intake while taking the medication.
- Suggest measures to reduce anticipated side effects of prescribed medications, such as increasing intake of potassium-rich foods when taking a potassium-depleting diuretic such as furosemide.

DIETARY ALTERATIONS

- Teach the client about dietary changes to promote urinary function, such as consuming cranberry juice and foods that acidify the urine to reduce the risk of repeated UTIs or forming calcium-based urinary stones. See the *Dietary Measures* section on page 1198.
- Instruct clients with stress or urge incontinence to limit their intake of caffeine, alcohol, citrus juices, and artificial sweeteners because these are bladder irritants that may increase incontinence. Also, teach clients to limit their evening fluid intake to reduce the risk of night-time incontinence episodes.

MEASURES SPECIFIC TO URINARY PROBLEMS

- Provide instructions for clients with specific urinary problems or treatments such as these:
 - a. Timed urine specimens (see Chapter 34 ∞)
 - b. Urinary incontinence
 - c. Urinary retention
 - d. Retention catheters.

REFERRALS

- Make appropriate referrals to home health agencies, community agencies, or social services for assistance with resources such as installing grab bars and raised toilet seats; providing wheelchair access to bathrooms; obtaining toileting aids such as commodes, urinals, or bedpans; and services such as home health aides for assistance with activities of daily living.

COMMUNITY AGENCIES AND OTHER RESOURCES

- Provide information about resources for durable medical equipment such as commodes or raised toilet seats, possible financial assistance, and medical supplies such as drainage bags, incontinence briefs, or protective pads.
- Suggest additional sources of information and help such as the National Council of Independent Living, United Ostomy Association, National Association for Continence, and Simon Foundation for Continence.

Managing Urinary Incontinence

It is important to remember that UI is *not* a normal part of aging and often is treatable. The preliminary assessment and identification of the symptoms of UI are truly within the scope of nursing practice. All clients should be asked about their voiding patterns. Older adults who are incontinent while in their home or who manage to contain or conceal their incontinence from others do not consider themselves

incontinent. Therefore, if asked if they are incontinent, they may deny it. However, asking if they lose urine when they cough, sneeze, or laugh or if they need to use some type of incontinence product may provide more accurate information (Keyock & Newman, 2011). Independent nursing interventions for clients with UI include (a) a behavior-oriented continence training program that may consist of bladder retraining, habit training, and pelvic floor muscle exercises;

PRACTICE GUIDELINES**Maintaining Normal Voiding Habits****POSITIONING**

- Assist the client to a normal position for voiding: standing for male clients; for female clients, squatting or leaning slightly forward when sitting. These positions enhance movement of urine through the tract by gravity.
- If the client is unable to ambulate to the lavatory, use a bedside commode for females and a urinal for males standing at the bedside.
- If necessary, encourage the client to push over the pubic area with the hands or to lean forward to increase intra-abdominal pressure and external pressure on the bladder.

RELAXATION

- Provide privacy for the client. Many people cannot void in the presence of another person.
- Allow the client sufficient time to void.
- Suggest the client read or listen to music.
- Provide sensory stimuli that may help the client relax. Pour warm water over the perineum of a female or have the client sit in a warm bath to promote muscle relaxation. Applying a hot water bottle to the lower abdomen of both men and women may also foster muscle relaxation.

- Turn on running water within hearing distance of the client to stimulate the voiding reflex and to mask the sound of voiding for people who find this embarrassing.
- Provide ordered analgesics and emotional support to relieve physical and emotional discomfort to decrease muscle tension.

TIMING

- Assist clients who have the urge to void immediately. Delays only increase the difficulty in starting to void, and the desire to void may pass.
- Offer toileting assistance to the client at usual times of voiding, for example, on awakening, before or after meals, and at bedtime.

FOR CLIENTS WHO ARE CONFINED TO BED

- Warm the bedpan. A cold bedpan may prompt contraction of the perineal muscles and inhibit voiding.
- Elevate the head of the client's bed to Fowler's position, place a small pillow or rolled towel at the small of the back to increase physical support and comfort, and have the client flex the hips and knees. This position simulates the normal voiding position as closely as possible.

(b) meticulous skin care; and (c) for males, application of an external drainage device (condom-type catheter device).

CLINICAL ALERT!

If the client has any type of incontinence, recommend the use of incontinence pads because they are designed to absorb urine as opposed to feminine hygiene pads.

Continence (Bladder) Retraining

A continence retraining program requires the involvement of the nurse, the client, and support people. Clients must be alert and physically able to participate in the training protocol. A bladder retraining program may include the following:

- Education of the client and support people.
- **Bladder retraining**, which requires that the client postpone voiding, resist or inhibit the sensation of urgency, and void according to a timetable rather than according to the urge to void. The goals are to gradually lengthen the intervals between urination to correct the client's frequent urination, to stabilize the bladder, and to diminish urgency. This form of training may be used for clients who have bladder instability and urge incontinence. Delayed voiding provides larger voided volumes and longer intervals between voiding. Initially, voiding may be encouraged every 2 to 3 hours except during sleep and then every 4 to 6 hours. A vital component of bladder training is inhibiting the urge-to-void sensation. To do this, the nurse instructs the client to practice deep, slow breathing until the urge diminishes or disappears. This is performed every time the client has a premature urge to void. See Practice Guidelines.
- **Habit training**, also referred to as scheduled toileting, attempts to keep clients dry by having them void at regular intervals, such as every 2 to 4 hours. The goal is to keep the client dry and is a common therapy for frail older clients and those who are bedridden or have Alzheimer's disease (NAFC, 2013).

PRACTICE GUIDELINES**Bladder Retraining**

- Determine the client's voiding pattern and encourage voiding at those times, or establish a regular voiding schedule and help the client to maintain it, whether the client feels the urge or not (e.g., on awakening, every 1 or 2 hours during the day and evening, before retiring at night, every 4 hours at night). The stretching-relaxing sequence of such a schedule tends to increase bladder muscle tone and promote more voluntary control. Encourage the client to inhibit the urge-to-void sensation when a premature urge to void is experienced. Instruct the client to practice slow, deep breathing until the urge diminishes or disappears.
- When the client finds that voiding can be controlled, the intervals between voiding can be lengthened slightly without loss of continence.
- Regulate fluid intake, particularly during evening hours, to help reduce the need to void during the night.
- Encourage fluids between the hours of 0600 and 1800.
- Avoid excessive consumption of citrus juices, carbonated beverages (especially those containing artificial sweeteners), alcohol, and drinks containing caffeine because these irritate the bladder, increasing the risk of incontinence.
- Schedule diuretics early in the morning.
- Explain to clients that adequate fluid intake is required to ensure adequate urine production that stimulates the micturition reflex.
- Apply protector pads to keep the bed linen dry and provide specially made waterproof underwear to contain the urine and decrease the client's embarrassment. Avoid using diapers, which are demeaning and also suggest that incontinence is permissible.
- Assist the client with an exercise program to increase the general muscle tone and a pelvic muscle exercise program aimed at strengthening the pelvic floor muscles.
- Provide positive reinforcements to encourage continence. Praise clients for attempting to toilet and for maintaining continence.

Pelvic Floor Muscle Exercises

Pelvic floor muscle (PFM), or Kegel, exercises help to strengthen pelvic floor muscles (see Figures 48–3 and 48–4) and can reduce or eliminate episodes of incontinence. The client can identify the perineal muscles by tightening the anal sphincter as if to control the passing of gas or to hold a bowel movement.

Keyock and Newman (2011) describe two types of muscle contractions to practice PFM. One is a quick 2-second contraction where the client squeezes the pelvic muscle quickly and hard and then relaxes immediately. The other is a slow 3-, 5-, or 10-second long contraction. The pelvic muscle is relaxed after the sustained contraction. The client gradually builds up to the 10-second sustained contraction. When the exercise is properly performed, contraction of the muscles of the buttocks and thighs is avoided. PFM can be performed anytime, anywhere, sitting or standing. Specific client instructions for performing PFM are summarized in Client Teaching.

Maintaining Skin Integrity

Skin that is continually moist becomes macerated (softened). Urine that accumulates on the skin is converted to ammonia, which is very irritating to the skin. Because both skin irritation and maceration predispose the client to skin breakdown and ulceration, the incontinent person requires meticulous skin care. To maintain skin integrity, the nurse washes the client's perineal area with mild soap and water or a commercially prepared no-rinse cleanser after episodes of incontinence. The nurse then rinses the area thoroughly if soap and water were used, and dries it gently and thoroughly. Clean, dry clothing or bed linen should be provided. The nurse applies barrier ointments or creams to protect the skin from contact with urine. If it is necessary to pad the client's clothes for protection, the nurse should use products that absorb wetness and leave a dry surface in contact with the skin.

Specially designed incontinence drawsheets provide significant advantages over standard drawsheets for incontinent clients confined to bed. These sheets are like a drawsheet but are double layered, with a quilted upper nylon or polyester surface and an absorbent viscose rayon layer below. The rayon soaker layer generally has a waterproof backing on its underside. Fluid (i.e., urine) passes through the upper

CLIENT TEACHING

Pelvic Floor Muscle Exercises (Kegels)

- Complete two sets of exercises: a quick contraction followed by immediate relaxation and a long contraction followed by relaxation.
- Contract your pelvic floor muscle (PFM) whereby you pull your rectum, urethra, and vagina up inside, and contract the PFM, followed by relaxation. Do *not* hold your breath or tighten your thighs, buttocks, or abdomen while doing PFM exercises.
- Complete 45 of the quick and 45 of the long contraction exercises each day (Keyock & Newman, 2011, p. 32). Gradually increase the long contractions up to a full 10 seconds.
- Make the exercises part of your daily life, for example, before getting out of bed in the morning, when working at the kitchen sink, or on your way to the bathroom. The exercises can be done anywhere, anytime, and in any position.
- To control episodes of stress incontinence, perform a pelvic muscle contraction when initiating any activity that increases intra-abdominal pressure, such as coughing, laughing, sneezing, or lifting.

quilted layer and is absorbed and dispersed by the viscose rayon, leaving the quilted surface dry to the touch. This absorbent sheet helps maintain skin integrity; it does not stick to the skin when wet, decreases the risk of bedsores, and reduces odor.

Applying External Urinary Draining Devices

The application of a condom or external catheter connected to a urinary drainage system can be used for incontinent males. Use of a condom appliance is preferable to insertion of a retention catheter because the risk of UTI is minimal.

Methods of applying condoms vary. The nurse needs to follow the manufacturer's instructions when applying a condom. First the nurse determines when the client experiences incontinence. Some clients may require a condom appliance at night only, others continuously. Skill 48–1 describes how to apply and remove an external catheter.

Applying an External Urinary Device

PURPOSES

- To collect urine and control urinary incontinence
- To permit the client physical activity while controlling UI
- To prevent skin irritation as a result of UI

ASSESSMENT

- Review the client record to determine a voiding pattern and other pertinent data, such as latex sensitivity/allergy.

PLANNING

- Discuss the use of external urinary devices with the client and/or family. Research has shown that condom catheters may be more comfortable than an indwelling catheter and cause fewer urinary tract infections (Kyle, 2011).
- Determine if the client has had an external catheter previously and any difficulties with it.
- Perform any procedures that are best completed without the catheter in place; for example, weighing the client would be easier without the tubing and bag.

- Apply clean gloves to examine the client's penis for swelling or excoriation that would contraindicate use of the condom catheter.

DELEGATION

Applying a condom catheter may be delegated to unlicensed assistive personnel (UAP). However, the nurse must determine if the specific client has unique needs such as impaired circulation or latex allergy that would require special training of the UAP in the use of the condom catheter. Abnormal findings must be validated and interpreted by the nurse.

Applying an External Urinary Device—continued

Equipment

- Condom sheath of appropriate size: small, medium, large, extra large. Use the manufacturer's size guide as indicated. Use latex-free silicone for clients with latex allergies. Use self-adhering condoms, or those with Velcro, tape, or other external securing device. ①
- Leg drainage bag if ambulatory or urinary drainage bag with tubing
- Clean gloves
- Basin of warm water and soap
- Washcloth and towel

① An external or condom catheter.

IMPLEMENTATION

Preparation

- Assemble the leg drainage bag or urinary drainage bag for attachment to the condom sheath.
- If the condom supplied is not rolled onto itself, roll the condom outward onto itself to facilitate easier application.

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Position the client in either a supine or a sitting position. Provide for client privacy.
 - Drape the client appropriately with the bath blanket, exposing only the penis.
4. Apply clean gloves.
5. Inspect and clean the penis.
 - Clean the genital area and dry it thoroughly. **Rationale:** *This minimizes skin irritation and excoriation after the condom is applied.*
6. Apply and secure the condom.
 - Roll the condom smoothly over the penis, leaving 2.5 cm. (1 in.) between the end of the penis and the rubber or plastic connecting tube. ② **Rationale:** *This space prevents irritation of the tip of the penis and provides for full drainage of urine.*
 - Secure the condom firmly, but not too tightly, to the penis. Some condoms have an adhesive inside the proximal end that adheres to the skin of the base of the penis. Many condoms are packaged with special tape. If neither is present, use a strip of elastic tape or Velcro around the base of the penis over the condom. Ordinary tape is *contraindicated* because it is not flexible and can stop blood flow.
7. Securely attach the urinary drainage system.
 - Make sure that the tip of the penis is not touching the condom and that the condom is not twisted. **Rationale:** *A twisted condom could obstruct the flow of urine.*
 - Attach the urinary drainage system to the condom.
 - Remove and discard gloves.
 - Perform hand hygiene.
 - If the client is to remain in bed, attach the urinary drainage bag to the bed frame.
 - If the client is ambulatory, attach the bag to the client's leg. ③ **Rationale:** *Attaching the drainage bag to the leg helps control*

② A self-adhering condom rolled over the penis.

③ Urinary drainage leg bag.

the movement of the tubing and prevents twisting of the thin material of the condom appliance at the tip of the penis.

8. Teach the client about the drainage system.
 - Instruct the client to keep the drainage bag below the level of the condom and to avoid loops or kinks in the tubing. Instruct the client to report pain, irritation, swelling, or wetness/leaking around the penis to health care personnel.

Applying an External Urinary Device—continued

9. Inspect the penis 30 minutes following condom application and at least every 4 hours. Check urine flow. Document these findings.
 - Assess the penis for swelling and discoloration. **Rationale:** *This indicates that the condom is too tight.*
 - Assess urine flow if the client has voided. Normally, some urine is present in the tube if the flow is not obstructed.
 - Assess for redness and/or skin blistering the first few days. **Rationale:** *This could indicate a latex allergy.*
10. Change the condom as indicated and provide skin care. In most settings, the condom is changed daily.
 - Remove the elastic or Velcro strip, apply clean gloves, and roll off the condom.
 - Wash the penis with soapy water, rinse, and dry it thoroughly.
 - Assess the foreskin for signs of irritation, swelling, and discoloration.
11. Document in the client record using forms or checklists supplemented by narrative notes when appropriate. Record the application of the condom, the time, and pertinent observations, such as irritated areas on the penis.
 - Reapply a new condom.
 - Remove and discard gloves.
 - Perform hand hygiene.

SAMPLE DOCUMENTATION

4/22/2015 2145 Condom catheter applied for the night per client request. Glans clean, skin intact. Catheter attached to bedside collection bag. Instructed to notify staff if pain, irritation, swelling, or wetness/leaking occurs. Verbalized that he would _____ L. Chan, RN

EVALUATION

- Perform a detailed follow-up based on findings that deviated from expected or normal for the client. Relate findings to previous assessment data if available.
- Report significant deviations from normal to the primary care provider.

Managing Urinary Retention

Interventions that assist the client to maintain a normal voiding pattern, discussed earlier, also apply when dealing with urinary retention. If these actions are unsuccessful, the primary care provider may order a cholinergic drug such as bethanechol chloride (Urecholine) to stimulate bladder contraction and facilitate voiding. Clients who have a **flaccid** bladder (weak, soft, and lax bladder muscles) may use manual pressure on the bladder to promote bladder emptying. This is known as **Credé's maneuver** or Credé's method. It is not advised without a primary care provider or nurse practitioner's order and is used only for clients who have lost and are not expected to regain voluntary bladder control. When all measures fail to initiate voiding, urinary catheterization may be necessary to empty the bladder completely. An indwelling Foley catheter may be inserted until the underlying cause is treated. Alternatively, intermittent straight catheterization (every 3 to 4 hours) may be performed because the risk of UTI may be less than with an indwelling catheter.

Urinary Catheterization

Urinary catheterization is the introduction of a catheter into the urinary bladder. This is usually performed only when absolutely necessary, because the danger exists of introducing microorganisms into the bladder. The most frequent health care–associated infection is a UTI, and indwelling urethral catheters cause 80% of these UTIs (Institute for Healthcare Improvement [IHI], 2011). A catheter-associated urinary tract infection (**CAUTI**) is a “urinary tract infection that occurs while an indwelling catheter is in place or within 48 hours of its removal” (Seckel, 2013, p. 63). Clients with a CAUTI remain in the hospital longer and need to be placed on antibiotic therapy, which increases health care costs. The high incidence and high costs related to CAUTI, in addition to the fact that most are preventable, resulted in the Centers for Medicare and Medicaid Services (CMS) not reimbursing hospitals unless the CAUTI was documented as present on

admission (Magers, 2013). It is well documented that the risk to the client of developing a CAUTI correlates to the duration of the catheter being in place. According to the Centers for Disease Control and Prevention, the risk of infection increases by 5% for each day that a catheter remains in place (Lee & Carter, 2013, p. 53). Oman et al. (2012) reported that urinary catheters are often “retained for days because of convenience, misunderstanding of their necessity/appropriateness, or lack of clear orders for removal” (p. 548). Best practice is to remove a urinary catheter that is not necessary. Box 48–3 provides evidence-based guidelines for preventing CAUTIs.

SAFETY ALERT!

SAFETY

2014 National Patient Safety Goals (The Joint Commission, 2013)

Goal 7: Reduce the Risk of Health Care–Associated Infections

- Implement evidence-based practices to prevent indwelling catheter-associated urinary tract infections (CAUTI).
 - Insert indwelling urinary catheters according to established evidence-based guidelines.
 - Manage indwelling urinary catheters according to established evidence-based guidelines.
 - Measure and monitor catheter-associated urinary tract infection prevention processes and outcomes in high-volume areas.

Another hazard is trauma with urethral catheterization, particularly in the male client, whose urethra is longer and more tortuous. It is important to insert a catheter along the normal contour of the urethra. Damage to the urethra can occur if the catheter is forced through strictures or at an incorrect angle. In males, the urethra is normally curved, but it can be straightened by elevating the penis to a position perpendicular to the body.

BOX 48-3 Preventing or Reducing the Risk of CAUTIs**AVOID UNNECESSARY USE OF URINARY CATHETERS**

- Develop criteria for appropriate catheter insertion.
- Consider alternatives to an indwelling catheter such as external condom catheter.
- Use a bladder scanner to assess for urinary retention.

INSERT URINARY CATHETERS USING ASEPTIC TECHNIQUE

- Catheters should only be inserted by trained individuals.
- Use aseptic technique and sterile equipment.
- Catheter kit should include a catheter and all necessary items in one place.
- Use the smallest catheter possible that allows for proper drainage and decreases urethral trauma.

MAINTAIN THE URINARY CATHETER

- Use hand hygiene and standard precautions during any manipulation of the catheter or collecting system.
- Maintain a sterile, closed drainage system.
- Maintain unobstructed urine flow; keep catheter and tubing from kinking.
- Keep the collection bag below the level of the bladder at all times, but do not rest the bag on the floor.
- Empty the collection bag regularly with a separate, clean collecting container for each client; and prevent contact of the drainage spigot with the nonsterile collecting container.

PRACTICES TO AVOID

- Irrigation of catheters, except in cases of catheter obstruction
- Disconnecting the catheter from the drainage tubing
- Replacing catheters routinely
- Cleaning the periurethral area with antiseptics. Routine hygiene (cleaning the meatus during daily bathing) is appropriate

REVIEW URINARY CATHETER NECESSITY DAILY AND REMOVE PROMPTLY

- Assess the need for catheter in daily nursing assessments; contact the primary care provider if criteria not met.
- Develop nursing protocols that allow nurses to remove urinary catheters if criteria for necessity are not met and there are no contraindications for removal.
- Implement automatic stop orders for 48 to 72 hours after catheter insertion. Continue catheter use only with a documented order from the primary care provider.
- Use alerts in chart or computerized charting system to inform the primary care provider of the presence of a catheter and require an order for continued use.

From *How-to-Guide: Prevent Catheter-Associated Urinary Tract Infections*, by IHI, 2011, Cambridge, MA: Author; "Using Evidence-Based Practice to Reduce Catheter-Associated Urinary Tract Infections," by T. L. Magers, 2013, *American Journal of Nursing*, 113(6), pp. 34–42; and "Maintaining Urinary Catheters: What Does the Evidence Say?" by M. A. Seckel, 2013, *Nursing*, 43(2), pp. 63–65.

BOX 48-4 Selecting a Urinary Catheter

- Determine the appropriate catheter length by the client's gender. For adult female clients use a 22-cm catheter; for adult male clients, a 40-cm catheter.
- Determine appropriate catheter size by the size of the urethral canal. Use sizes such as #8 or #10 for children, #14 or #16 for adults. Men frequently require a larger size than women, for example, #18. The lumen of a silicone catheter is slightly larger than that of a same-sized latex catheter.
- Select the appropriate balloon size. For adults, use a 5-mL balloon to facilitate optimal urine drainage. The smaller balloons allow more complete bladder emptying because the catheter tip is closer to the urethral opening in the bladder. However, a 30-mL balloon is commonly used to achieve hemostasis of the prostatic area following a prostatectomy. Use 3-mL balloons for children.

Catheters are commonly made of rubber or plastics although they may be made from latex, silicone, or polyvinyl chloride (PVC). They are sized by the diameter of the lumen using the French (Fr) scale: the larger the number, the larger the lumen. Either straight catheters, inserted to drain the bladder and then immediately removed, or retention catheters, which remain in the bladder to drain urine, may be used. Box 48-4 provides guidelines for catheter selection.

The straight catheter is a single-lumen tube with a small eye or opening about 1.25 cm (0.5 in.) from the insertion tip (Figure 48-8 ■).

The retention, or Foley, catheter is a double-lumen catheter. The outside end of this two-way retention catheter is bifurcated; that is, it has two openings, one to drain the urine, the other to inflate the balloon (Figure 48-9 ■). The larger lumen drains urine from the bladder and the second smaller lumen is used to inflate the balloon near

the tip of the catheter to hold the catheter in place within the bladder. Some catheter manufacturers apply an antimicrobial coating to their catheters to reduce CAUTIs.

A variation of the indwelling catheter is the coudé (elbowed) catheter, which has a curved tip (Figure 48-10 ■). This is sometimes used for men who have a hypertrophied prostate, because its tip is somewhat stiffer than a regular catheter and thus it can be better controlled during insertion, and passage is often less traumatic.

Clients who require continuous or intermittent bladder irrigation may have a three-way Foley catheter (Figure 48-11 ■). The three-way catheter has a third lumen through which sterile irrigating fluid can flow into the bladder. The fluid then exits the bladder through the drainage lumen, along with the urine.

The size of the retention catheter balloon is indicated on the catheter along with the diameter, for example, "#16 Fr—5 mL balloon." The purpose of the catheter balloon is to secure the catheter in the bladder. Historically, nurses pretested the catheter balloon to prevent insertion of a defective catheter. Some catheter manufacturers (e.g., Bard) test the balloon as part of their quality assurance process and do not recommend pretesting of the balloon by the nurse. Pretesting of *silicone* balloons in particular is *not* recommended because the silicone can form a cuff or crease at the balloon area that can cause trauma to the urethra during catheter insertion. It is important to follow the manufacturer's instructions for the proper volume to use for balloon inflation. Improperly inflated catheter balloons may cause drainage and deflation difficulties.

Retention catheters are usually connected to a closed gravity drainage system. This system consists of the catheter, drainage tubing, and a collecting bag for the urine. A closed system cannot be opened anywhere along the system, from catheter to collecting bag. Some health facilities, however, may use an open system, which consists of

Figure 48-8 ■ Red-rubber or plastic Robinson straight catheters.

Figure 48-9 ■ An indwelling/retention (Foley) catheter with the balloon inflated.

Figure 48-11 ■ A three-way Foley catheter often used for continuous bladder irrigation.
Courtesy Covidien.

Figure 48-10 ■ A coudé catheter.

separate packages for the catheter and the drainage tubing and collecting bag. The open system requires the nurse to be especially vigilant to ensure sterile technique is maintained when connecting the catheter and drainage tubing. The closed system is preferred because it reduces the risk of microorganisms entering the system and infecting the urinary tract. Urinary drainage systems typically depend on the force of gravity to drain urine from the bladder to the collecting bag.

Skill 48-2 describes catheterization of females and males, using straight and retention catheters.

Performing Urinary Catheterization

PURPOSES

- To relieve discomfort due to bladder distention or to provide gradual decompression of a distended bladder
- To assess the amount of residual urine if the bladder empties incompletely
- To obtain a sterile urine specimen
- To empty the bladder completely prior to surgery
- To facilitate accurate measurement of urinary output for critically ill clients whose output needs to be monitored hourly
- To provide for intermittent or continuous bladder drainage and/or irrigation
- To prevent urine from contacting an incision after perineal surgery

ASSESSMENT

- Determine the most appropriate method of catheterization based on the purpose and any criteria specified in the order such as total amount of urine to be removed or size of catheter to be used.
- Use a straight catheter if only a one-time urine specimen is needed, if amount of residual urine is being measured, or if temporary decompression/emptying of the bladder is required.
- Use an indwelling/retention catheter if the bladder must remain empty, intermittent catheterization is contraindicated, or continuous urine measurement/collection is needed.
- Assess the client's overall condition. Determine if the client is able to participate and hold still during the procedure and if

the client can be positioned supine with head relatively flat. For female clients, determine if she can have knees bent and hips externally rotated.

- Determine when the client last voided or was last catheterized.
- If catheterization is being performed because the client has been unable to void, when possible, complete a bladder scan to assess the amount of urine present in the bladder. **Rationale:** *This prevents catheterizing the bladder when insufficient urine is present. Often, a minimum of 500 to 800 mL of urine indicates urinary retention and the client should be reassessed until that amount is present.*

PLANNING

- Allow adequate time to perform the catheterization. Although the entire procedure can require as little as 15 minutes, several sources of difficulty could result in a much longer period of time. If possible, it should not be performed just prior to or after a meal.
- Some clients may feel uncomfortable being catheterized by nurses of the opposite gender. If this is the case, obtain the client's permission. Also consider whether agency policy requires or encourages having a person of the client's same gender present for the procedure.

DELEGATION

Due to the need for sterile technique and detailed knowledge of anatomy, insertion of a urinary catheter is not delegated to UAP.

Equipment

- Sterile catheter of appropriate size (An extra catheter should also be at hand.)
- Catheterization kit **1** or individual sterile items:
 - Sterile gloves
 - Waterproof drape(s)
 - Antiseptic solution
 - Cleansing balls
 - Forceps
 - Water-soluble lubricant
 - Urine receptacle
 - Specimen container

IMPLEMENTATION

Preparation

- If using a catheterization kit, read the label carefully to ensure that all necessary items are included.
- Apply clean gloves and perform routine perineal care to cleanse gross contamination. For women, use this time to locate the urinary meatus relative to surrounding structures. **2**
- Remove and discard gloves.
 - Perform hand hygiene.

1 A closed indwelling catheter insertion kit.

- For an indwelling catheter:
 - Syringe prefilled with sterile water in amount specified by catheter manufacturer
 - Collection bag and tubing
- 5–10 mL 2% Xylocaine gel or water-soluble lubricant for male urethral injection (if agency permits)
- Clean gloves
- Supplies for performing perineal cleansing
- Bath blanket or sheet for draping the client
- Adequate lighting (Obtain a flashlight or lamp if necessary.)

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.

Performing Urinary Catheterization—continued

2 To expose the urinary meatus, separate the labia minora and retract the tissue upward.

3 When cleaning the urinary meatus, move the swab downward.

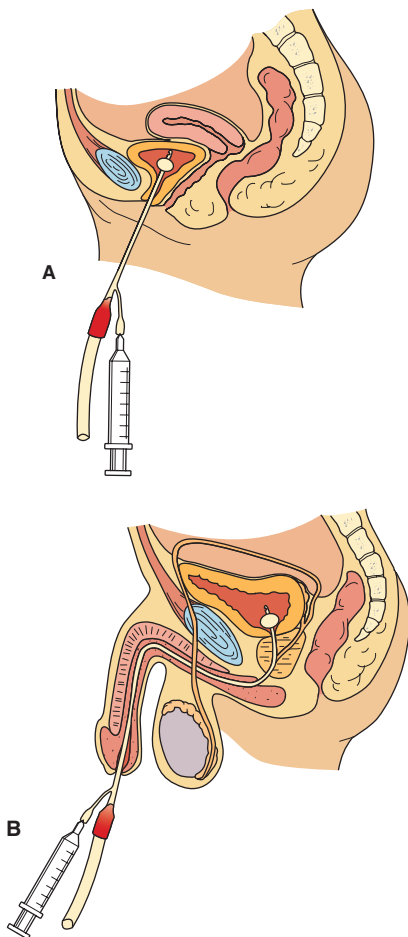

4. Place the client in the appropriate position and drape all areas except the perineum.
 - *Female:* supine with knees flexed, feet about 2 feet apart, and hips slightly externally rotated, if possible
 - *Male:* supine, thighs slightly abducted or apart
5. Establish adequate lighting. Stand on the client's right if you are right-handed, on the client's left if you are left-handed.
6. If using a collecting bag and it is not contained within the catheterization kit, open the drainage package and place the end of the tubing within reach. **Rationale:** Because one hand is needed to hold the catheter once it is in place, open the package while two hands are still available.
7. If agency policy permits, apply clean gloves and inject 10 to 15 mL Xylocaine gel into the urethra of the male client. Wipe the underside of the penile shaft to distribute the gel up the urethra. Wait at least 5 minutes for the gel to take effect before inserting the catheter.
8. Remove and discard gloves.
 - Perform hand hygiene.
9. Open the catheterization kit. Place a waterproof drape under the buttocks (female) or penis (male) without contaminating the center of the drape with your hands.
10. Apply sterile gloves.
11. Organize the remaining supplies:
 - Saturate the cleansing balls with the antiseptic solution.
 - Open the lubricant package.
 - Remove the specimen container and place it nearby with the lid loosely on top.
12. Attach the prefilled syringe to the indwelling catheter inflation hub. Apply agency policy and/or manufacturer recommendation regarding pretesting of the balloon. **Rationale:** There is little research regarding pretesting of the balloon; however, some balloons (e.g., silicone) may form a cuff on deflation that can irritate the urethra on insertion.
13. Lubricate the catheter 2.5 to 5 cm (1 to 2 in.) for females, 15 to 17.5 cm (6 to 7 in.) for males, and place it with the drainage end inside the collection container.
14. If desired, place the fenestrated drape over the perineum, exposing the urinary meatus.
15. Cleanse the meatus. Note: *The nondominant hand is considered contaminated once it touches the client's skin.*
 - *Females:* Use your nondominant hand to spread the labia so that the meatus is visible. Establish firm but gentle pressure on the labia. The antiseptic may make the tissues slippery but the labia must not be allowed to return over the cleaned meatus. Note: *Location of the urethral meatus is best identified during the cleansing process. Pick up a cleansing ball with the forceps in your dominant hand and wipe one side of the labia majora in an anteroposterior direction.* 3 Use great care that wiping the client does not contaminate this sterile hand. Use a new ball for the opposite side. Repeat for the labia minora. Use the last ball to cleanse directly over the meatus.
 - *Males:* Use your nondominant hand to grasp the penis just below the glans. If necessary, retract the foreskin. Hold the penis firmly upright, with slight tension. **Rationale:** *Lifting the penis in this manner helps straighten the urethra.* Pick up a cleansing ball with the forceps in your dominant hand and wipe from the center of the meatus in a circular motion around the glans. Use great care that wiping the client does not contaminate the sterile hand. Use a new ball and repeat three more times. The antiseptic may make the tissues slippery but the foreskin must not be allowed to return over the cleaned meatus nor the penis be dropped.
16. Insert the catheter.
 - Grasp the catheter firmly 5 to 7.5 cm (2 to 3 in.) from the tip. Ask the client to take a slow deep breath and insert the catheter as the client exhales. Slight resistance is expected as the catheter passes through the sphincter. If necessary, twist the catheter or hold pressure on the catheter until the sphincter relaxes.
 - Advance the catheter 5 cm (2 in.) farther after the urine begins to flow through it. **Rationale:** *This is to be sure it is fully in the bladder, will not easily fall out, and the balloon is in the bladder completely.* For male clients, some experts recommend advancing the catheter to the "Y" bifurcation of the catheter. Check your agency's policy.

Performing Urinary Catheterization—continued

- If the catheter accidentally contacts the labia or slips into the vagina, it is considered contaminated and a new, sterile catheter must be used. The contaminated catheter may be left in the vagina until the new catheter is inserted to help avoid mistaking the vaginal opening for the urethral meatus.
17. Hold the catheter with the nondominant hand.
 18. For an indwelling catheter, inflate the retention balloon with the designated volume.
 - Without releasing the catheter (and, for females, without releasing the labia), hold the inflation valve between two fingers of your nondominant hand while you attach the syringe (if not left attached earlier) and inflate with your dominant hand. If the client complains of discomfort, immediately withdraw the instilled fluid, advance the catheter farther, and attempt to inflate the balloon again.
 - Pull gently on the catheter until resistance is felt to ensure that the balloon has inflated and to place it in the trigone of the bladder. **4**
 19. Collect a urine specimen if needed. For a straight catheter, allow 20 to 30 mL to flow into the bottle without touching the catheter to the bottle. For an indwelling catheter preattached

to a drainage bag, a specimen may be taken from the bag this initial time only.

20. Allow the straight catheter to continue draining into the urine receptacle. If necessary (e.g., open system), attach the drainage end of an indwelling catheter to the collecting tubing and bag.
21. Examine and measure the urine. In some cases, only 750 to 1,000 mL of urine are to be drained from the bladder at one time. Check agency policy for further instructions if this should occur.
22. Remove the straight catheter when urine flow stops. For an indwelling catheter, secure the catheter tubing to the thigh for female clients or the upper thigh or lower abdomen for male clients to prevent movement on the urethra or excessive tension or pulling on the retention balloon (Fisher, 2010; Herter & Kazer, 2010). Adhesive and nonadhesive catheter-securing devices are available and should be used to secure the catheter tubing to the client. **5** **Rationale:** *This prevents unnecessary trauma to the urethra.*

4 Placement of indwelling catheter and inflated balloon of a closed system in *A*, female client and *B*, male client.

A

B

5 Catheter securement devices: *A*, nonadhesive device (Velcro strap); *B*, adhesive device.

Performing Urinary Catheterization—continued

6 Correct position for urine drainage bag and tubing.

23. Next, hang the bag below the level of the bladder. No tubing should fall below the top of the bag. 6
24. Wipe any remaining antiseptic or lubricant from the perineal area. Replace the foreskin if retracted earlier. Return the client to a comfortable position. Instruct the client on positioning and moving with the catheter in place.
25. Discard all used supplies in appropriate receptacles.
26. Remove and discard gloves.
 - Perform hand hygiene.
27. Document the catheterization procedure including catheter size and results in the client record using forms or checklists supplemented by narrative notes when appropriate.

SAMPLE DOCUMENTATION

2/24/2015 0530 Client agreed to insertion of pre-op catheter as per order. #16 Fr Foley with 5-mL balloon inserted without difficulty, secured to thigh, connected to straight drainage. Immediate return of 300 mL pale, clear, yellow urine ————— G. Hampton, RN

EVALUATION

- Notify the primary care provider of the catheterization results.
- Perform a detailed follow-up based on findings that deviated from expected or normal for the client. Relate findings to previous assessment data if available.
- Teach the client how to care for the indwelling catheter, to drink more fluids, and provide other appropriate instructions.

LIFESPAN CONSIDERATIONS CATHETERIZATION

Infants and Children

- Adapt the size of the catheter for pediatric clients.
- Ask a family member to assist in holding the child during catheterization, if appropriate.

OLDER ADULTS

When catheterizing older clients, be very attentive to problems of limited movement, especially in the hips. Arthritis, or previous hip

or knee surgery, may limit their movement and cause discomfort. Modify the position (e.g., side-lying) as needed to perform the procedure safely and comfortably. For women, obtain the assistance of another nurse to flex and hold the client's knees and hips as necessary or place her in a modified Sims' position.

Home Care Considerations Catheterization

PATIENT-CENTERED CARE

For intermittent catheterization, instruct the client to:

- Follow instructions for clean technique.
- Wash hands well with warm water and soap prior to handling equipment or performing catheterization.
- Monitor for signs and symptoms of UTI including burning, urgency, abdominal pain, and cloudy urine; in older adults, confusion may be an early sign.
- Ensure adequate oral intake of fluids.
- After each catheterization, assess the urine for color, odor, clarity, and the presence of blood.
- Wash rubber catheters thoroughly with soap and water after use, dry, and store in a clean place.

For indwelling catheters, instruct the client to:

- Never pull on the catheter.
- Secure the catheter tubing to your leg using a catheter-securing device.

- Ensure that there are no kinks or twists in the tubing.
- Keep the urine drainage bag below the level of the bladder. A leg bag may substitute for a hanging bag for those who are upright.
- Empty the drainage bag regularly.
- Take a shower rather than a tub bath. *Sitting in a tub allows bacteria easier access to the urinary tract.*
- Monitor for signs and symptoms of UTI including burning, urgency, abdominal pain, cloudy urine; in older adults, confusion may be an early sign.
- Ensure adequate oral intake of fluids.

Clients who have indwelling catheters for lengthy periods of time need to have the catheter and bag changed at regular intervals. Changing equipment once a month is often the standard, although agency policy may differ.

Nursing Interventions for Clients with Indwelling Catheters

Nursing care of the client with an indwelling catheter and continuous drainage is largely directed toward preventing infection of the urinary tract and encouraging urinary flow through the drainage system. It includes encouraging large amounts of fluid intake, accurately recording the fluid intake and output, changing the retention catheter and tubing, maintaining the patency of the drainage system, preventing contamination of the drainage system, and teaching these measures to the client.

Fluids

The client with a retention catheter should drink up to 3,000 mL/day if permitted. Large amounts of fluid ensure a large urine output, which keeps the bladder flushed out and decreases the likelihood of urinary stasis and subsequent infection. Large volumes of urine also minimize the risk of sediment or other particles obstructing the drainage tubing.

Dietary Measures

Acidifying the urine of clients with a retention catheter may reduce the risk of UTI and calculus formation. Foods such as eggs, cheese, meat and poultry, whole grains, cranberries, plums and prunes, and tomatoes tend to increase the acidity of urine. Conversely, most fruits and vegetables, legumes, and milk and milk products result in alkaline urine.

Perineal Care

No special cleaning other than routine hygienic care is necessary for clients with retention catheters, nor is special meatal care recommended. The nurse should check agency practice in this regard.

Changing the Catheter and Tubing

Routine changing of catheter and tubing is *not* recommended. Collection of sediment in the catheter or tubing and impaired urine drainage are indicators for changing the catheter and drainage system. When this occurs the catheter and drainage system are removed and discarded, and a new sterile catheter with a closed drainage system is inserted using aseptic technique.

Removing Indwelling Catheters

Indwelling catheters are removed after their purpose has been achieved, usually on the order of the primary care provider. Unfortunately, not all primary care providers know which of their clients has an indwelling catheter. As a result, some facilities have incorporated an alert system that requires the provider to take an action after a specified time frame. Also, some health care facilities allow the nurse to remove an indwelling catheter through the use of a protocol with specific criteria (Wenger, 2010).

If the catheter has been in place for a short time (e.g., 48 to 72 hours), the client usually has little difficulty regaining normal urinary elimination patterns. Swelling of the urethra, however, may initially interfere with voiding, so the nurse should regularly assess the client for urinary retention until voiding is reestablished.

Clients who have had a retention catheter for a prolonged period may require bladder retraining to regain bladder muscle tone. With

an indwelling catheter in place, the bladder muscle does not stretch and contract regularly as it does when the bladder fills and empties by voiding. A few days before removal, the catheter may be clamped for specified periods of time (e.g., 2 to 4 hours), then released to allow the bladder to empty. This allows the bladder to distend and stimulates its musculature. Check agency policy regarding bladder training procedures.

To remove a retention catheter the nurse follows these steps:

- Obtain a receptacle for the catheter (e.g., a disposable basin); a clean, disposable towel; clean gloves; and a sterile syringe to deflate the balloon. The syringe should be large enough to withdraw all the solution in the catheter balloon. The size of the balloon is indicated on the label at the end of the catheter.
- Ask the client to assume a supine position as for a catheterization.
- *Optional:* Obtain a sterile specimen before removing the catheter. Check agency protocol.
- Remove the catheter-securing device attaching the catheter to the client, apply gloves, and then place the towel between the legs of the female client or over the thighs of the male.
- Insert the syringe into the injection port of the catheter, and withdraw the fluid from the balloon. After the fluid has been aspirated, the walls of the balloon do not deflate to their original shape but collapse into uneven ridges, forming a “cuff” around the catheter. This cuff is more pronounced with a silicone catheter (Wilson, 2012). This cuff can cause discomfort to the client as the catheter is removed. Little research exists about the balloon cuffing that occurs following deflation of a catheter balloon. One recent research study by Chung and So (2012) specifically tested four balloon deflation methods. They found that active deflation (rapid deflation of balloon within 5 seconds) caused the greatest degree of catheter balloon cuffing, followed by passive deflation (very slow active deflation over 30 seconds). Passive autodeflation (attaching an empty syringe to the balloon inflow channel to allow for gentle autodeflation) and excision of the balloon inflow channel caused the least cuffing (p. 176).
- Do not pull the catheter while the balloon is inflated; doing so will injure the urethra.
- After all of the fluid is removed from the balloon, gently withdraw the catheter and place it in the waste receptacle.
- Dry the perineal area with a towel.
 - Measure the urine in the drainage bag.
- Remove and discard gloves.
 - Perform hand hygiene.
- Record the removal of the catheter. Include in the recording (a) the time the catheter was removed; (b) the amount, color, and clarity of the urine; (c) the intactness of the catheter; and (d) instructions given to the client.
- Provide the client with either a urinal (men), bedpan, commode, or toilet collection device (“hat”) to be used with each, subsequent unassisted void.
- Following removal of the catheter, determine the time of the first voiding and the amount voided during the first 8 hours. Compare this output to the client’s intake.
- Observe for dysfunctional voiding behaviors (i.e., < 100 mL per void), which might indicate urinary retention. If this occurs, perform an assessment of PVR using a bladder scanner if available.

CLIENT TEACHING

Clean Intermittent Self-Catheterization

- Catheterize as often as needed to maintain. At first, catheterization may be necessary every 2 to 3 hours, increasing to 4 to 6 hours.
- Attempt to void before catheterization; insert the catheter to remove residual urine if unable to void or if amount voided is insufficient (e.g., less than 100 mL).
- Assemble all needed supplies ahead of time. Good lighting is essential, especially for women.
- Wash your hands.
- Clean the urinary meatus with either a towelette or soapy washcloth, then rinse with a wet washcloth. Women should clean the area from front to back.
- Assume a position that is comfortable and that facilitates passage of the catheter, such as a semireclining position in bed or sitting on a chair or the toilet. Men may prefer to stand over the toilet; women may prefer to stand with one foot on the side of the bathtub.
- Apply lubricant to the catheter tip (1 in. [2.5 cm] for women; 2 to 6 in. [5 to 15 cm] for men).
- Insert the catheter until urine flows through.
 - a. If a woman, locate the meatus using a mirror or other aid, or use the “touch” technique as follows:
 - Place the index finger of your nondominant hand on your clitoris.
 - Place the third and fourth fingers at the vagina.
 - Locate the meatus between the index and third fingers.
 - Direct the catheter through the meatus and then upward and forward.
 - b. If a man, hold the penis with a slight upward tension at a 60- to 90-degree angle to insert the catheter. Return the penis to its natural position when urine starts to flow.
- Hold the catheter in place until all urine is drained.
- Withdraw the catheter slowly *to ensure complete drainage of urine*.
- Wash the catheter with soap and water; store in a clean container. Replace the catheter when it becomes difficult to clean, or too soft or hard to insert easily.
- Contact your care provider if your urine becomes cloudy or contains sediment; if you have bleeding, difficulty, or pain when passing the catheter; or if you have a fever.
- Drink at least 2,000 to 2,500 mL of fluid a day *to ensure adequate bladder filling and flushing*. To keep your urine acidic and reduce the risk of bladder infections, drink cranberry and prune juices.

Generally a PVR greater than 200 mL will require straight catheterization as needed.

Clean Intermittent Self-Catheterization

Clean intermittent self-catheterization (CISC) is performed by many clients who have some form of neurogenic bladder dysfunction such as that caused by spinal cord injury and multiple sclerosis. Clean or medical aseptic technique is used. Intermittent self-catheterization has these benefits:

- Enables the client to retain independence and gain control of the bladder.
- Reduces incidence of UTI.
- Protects the upper urinary tract from reflux.
- Allows normal sexual relations without incontinence.
- Reduces the use of aids and appliances.
- Frees the client from embarrassing dribbling.

The procedure for self-catheterization is similar to that used by the nurse to catheterize a client. Essential steps are outlined in the accompanying Client Teaching. Because the procedure requires physical and mental preparation, client assessment is important. The client should have:

- Sufficient manual dexterity to manipulate a catheter
- Sufficient mental ability
- Motivation and acceptance of the procedure
- For women, reasonable agility to access the urethra
- Bladder capacity greater than 100 mL.

Before teaching CISC, the nurse should establish the client's voiding patterns, the volume voided, fluid intake, and residual amounts. CISC is easier for males to learn because of the visibility of the urinary meatus. Females need to learn initially with the aid of a

mirror but eventually should perform the procedure by using only the sense of touch (as described in Client Teaching).

Urinary Irrigations

An **irrigation** is a flushing or washing-out with a specified solution. Bladder irrigation is carried out on a primary care provider's order, usually to wash out the bladder and sometimes to apply a medication to the bladder lining. Catheter irrigations may also be performed to maintain or restore the patency of a catheter, for example, to remove pus or blood clots blocking the catheter. Sterile technique is used.

The closed method is the preferred technique for catheter or bladder irrigation because it is associated with a lower risk of UTI. Closed catheter irrigations may be either continuous or intermittent. This method is most often used for clients who have had genitourinary surgery. The continuous irrigation helps prevent blood clots from occluding the catheter. A three-way, or triple lumen, catheter (see Figure 48–11) is generally used for closed irrigations. The irrigating solution flows into the bladder through the irrigation port of the catheter and out through the urinary drainage lumen of the catheter.

Occasionally an open irrigation may be necessary to restore catheter patency. The risk of injecting microorganisms into the urinary tract is greater with open irrigations, because the connection between the indwelling catheter and the drainage tubing is broken. Strict precautions must be taken to maintain the sterility of both the drainage tubing connector and the interior of the indwelling catheter.

The open method of catheter or bladder irrigation is performed with double-lumen indwelling catheters. It may be necessary for clients who develop blood clots and mucous fragments that occlude the catheter or when it is undesirable to change the catheter. Techniques for bladder irrigation are outlined in Skill 48–3.

Performing Bladder Irrigation

PURPOSES

- To maintain the patency of a urinary catheter and tubing (closed continuous irrigation)
- To free a blockage in a urinary catheter or tubing (open intermittent irrigation)

ASSESSMENT

- Determine the client's current urinary drainage system. Review the client record for recent intake and output and any difficulties the client has been experiencing with the system. Review the results of previous irrigations.
- Assess the client for any discomfort, bladder spasms, or distended bladder.

PLANNING

Before irrigating a catheter or bladder, check (a) the reason for the irrigation; (b) the order authorizing the continuous or intermittent irrigation (in most agencies, a primary care provider's order is required); (c) the type of sterile solution, the amount and strength to be used, and the rate (if continuous); and (d) the type of catheter in place. If these are not specified on the client's chart, check agency protocol.

DELEGATION

Due to the need for sterile technique, urinary irrigation is generally not delegated to UAP. If the client has continuous irrigation, the UAP may care for the client and note abnormal findings. These must be validated and interpreted by the nurse.

IMPLEMENTATION

Performance

1. Prior to performing the procedure, introduce self and verify the client's identity using agency protocol. Explain to the client what you are going to do, why it is necessary, and how he or she can participate. The irrigation should not be painful or uncomfortable. Discuss how the results will be used in planning further care or treatments.
2. Perform hand hygiene and observe other appropriate infection prevention procedures.
3. Provide for client privacy.
4. Apply clean gloves.
5. Empty, measure, and record the amount and appearance of urine present in the drainage bag. **Rationale:** Emptying the drainage bag allows more accurate measurement of urinary output after the irrigation is in place or completed. Assessing the character of the urine provides baseline data for later comparison.
6. Discard urine and gloves.
7. Prepare the equipment.
 - Perform hand hygiene.
 - Connect the irrigation infusion tubing to the irrigating solution and flush the tubing with solution, keeping the tip sterile. **Rationale:** Flushing the tubing removes air and prevents it from being instilled into the bladder.
 - Apply clean gloves and cleanse the port with antiseptic swabs.
 - Connect the irrigation tubing to the input port of the three-way catheter.
 - Connect the drainage bag and tubing to the urinary drainage port if not already in place.
 - Remove and discard gloves.
 - Perform hand hygiene.
8. Irrigate the bladder.
 - For closed continuous irrigation using a three-way catheter, open the clamp on the urinary drainage tubing (if present).
 - 1 **Rationale:** This allows the irrigating solution to flow out of the bladder continuously.
 - a. Apply clean gloves.

Equipment

- Clean gloves (two pairs)
- Retention catheter in place
- Drainage tubing and bag (if not in place)
- Drainage tubing clamp
- Antiseptic swabs
- Sterile receptacle
- Sterile irrigating solution warmed or at room temperature (Label the irrigant clearly with the words *Bladder Irrigation*, including the information about any medications that have been added to the original solution, and the date, time, and nurse's initials.)
- Infusion tubing
- IV pole

1 A continuous bladder irrigation (CBI) setup.

- b. Open the regulating clamp on the irrigating fluid infusion tubing and adjust the flow rate as prescribed by the primary care provider or to 40 to 60 drops per minute if not specified.
 - c. Assess the drainage for amount, color, and clarity. The amount of drainage should equal the amount of irrigant entering the bladder plus expected urine output. Empty the bag frequently so that it does not exceed half full.
- For closed intermittent irrigation, determine whether the solution is to remain in the bladder for a specified time.
 - a. If the solution is to remain in the bladder (a bladder irrigation or instillation), close the clamp to the urinary drainage

Performing Bladder Irrigation—continued

tubing. **Rationale:** Closing the flow clamp allows the solution to be retained in the bladder and in contact with bladder walls.

- b. If the solution is being instilled to irrigate the catheter, open the flow clamp on the urinary drainage tubing.

Rationale: Irrigating solution will flow through the urinary drainage port and tubing, removing mucous shreds or clots.
- c. If a three-way catheter is used, open the flow clamp to the irrigating fluid infusion tubing, allowing the specified amount of solution to infuse. Then close the clamp on the infusion tubing.

or

- d. If a two-way catheter is used, connect an irrigating syringe with a needleless adapter to the injection port on the drainage tubing and instill the solution.
- e. After the specified period the solution is to be retained has passed, open the drainage tubing flow clamp and allow the bladder to empty.
- f. Assess the drainage for amount, color, and clarity. The amount of drainage should equal the amount of irrigant entering the bladder plus expected urine output.
- g. Remove and discard gloves.
 - Perform hand hygiene.
9. Assess the client and the urinary output.
 - Assess the client's comfort.
 - Apply clean gloves.
 - Empty the drainage bag and measure the contents. Subtract the amount of irrigant instilled from the total volume of drainage to obtain the volume of urine output.
 - Remove and discard gloves.
 - Perform hand hygiene.
10. Document findings in the client record using forms or checklists supplemented by narrative notes when appropriate.
 - Note any abnormal constituents such as blood clots, pus, or mucous shreds.

Variation: Open Irrigation Using a Two-Way Indwelling Catheter

1. Assemble the equipment. Use an irrigation tray ② or assemble individual items, including:
 - Clean gloves
 - Disposable water-resistant towel
 - Sterile irrigating solution
 - Sterile irrigation set
 - Sterile basin
 - Sterile 30- to 50-mL irrigating syringe
 - Antiseptic swabs
 - Sterile protective cap for catheter drainage tubing
2. Prepare the client (see steps 1–5 of main procedure for catheter irrigation).
3. Prepare the equipment.
 - Perform hand hygiene.
 - Using aseptic technique, open supplies and pour the irrigating solution into the sterile basin or receptacle. **Rationale:** Aseptic technique is vital to reduce the risk of instilling microorganisms into the urinary tract during the irrigation.

② An irrigation set.

- Place the disposable water-resistant towel under the catheter.
 - Apply clean gloves.
 - Disconnect catheter from drainage tubing and place the catheter end in the sterile basin. Place sterile protective cap over end of drainage tubing. **Rationale:** The end of the drainage tubing will be considered contaminated if it touches bed linens or skin surfaces.
 - Draw the prescribed amount of irrigating solution into the syringe, maintaining the sterility of the syringe and solution.
4. Irrigate the bladder.
 - Insert the tip of the syringe into the catheter opening.
 - Gently and slowly inject the solution into the catheter at approximately 3 mL per second. In adults, about 30 to 40 mL generally is instilled for catheter irrigations; 100 to 200 mL may be instilled for bladder irrigation or instillation. **Rationale:** Gentle instillation reduces the risks of injury to bladder mucosa and of bladder spasms.
 - Remove the syringe and allow the solution to drain back into the basin.
 - Continue to irrigate the client's bladder until the total amount to be instilled has been injected or when fluid returns are clear and/or clots are removed.
 - Remove the protective cap from the drainage tube and wipe with antiseptic swab.
 - Reconnect the catheter to drainage tubing.
 - Remove and discard gloves.
 - Perform hand hygiene.
 - Assess the drainage for amount, color, and clarity. The amount of drainage should equal the amount of irrigant entering the bladder plus any urine that may have been dwelling in the bladder. Determine the amount of fluid used for the irrigation and subtract from total output on the client's I&O record.
 5. Assess the client and the urinary output and document the procedure as in steps 8 and 9 above.

EVALUATION

- Perform detailed follow-up based on findings that deviated from expected or normal for the client. Relate findings to previous assessment data if available.
- Report significant deviations from normal to the primary care provider.

Suprapubic Catheter Care

A **suprapubic catheter** is inserted surgically through the abdominal wall above the symphysis pubis into the urinary bladder. The suprapubic catheter may have a balloon or pigtail that holds it in the bladder depending on the manufacturer (Figure 48–12 ■). The health care provider inserts the catheter using local anesthesia or during bladder or vaginal surgery. The catheter may be secured in place with sutures to reinforce the security of the catheter and is then attached to a closed drainage system. The suprapubic catheter may be placed for temporary bladder drainage until the client is able to resume normal voiding (e.g., after urethral, bladder, or vaginal surgery) or it may become a permanent device (e.g., urethral or pelvic trauma).

Care of clients with a suprapubic catheter includes regular assessments of the client's urine, fluid intake, and comfort; maintenance of a patent drainage system; skin care around the insertion site; and periodic clamping of the catheter preparatory to removing it if it is not a permanent appliance. If the catheter is temporary, orders generally include leaving the catheter open to drainage for 48 to 72 hours, then clamping the catheter for 3- to 4-hour periods during the day until the client can void satisfactory amounts. Satisfactory voiding is determined by measuring the client's residual urine after voiding.

Care of the catheter insertion site involves sterile technique. Dressings around the newly placed suprapubic catheter are changed whenever they are soiled with drainage to prevent bacterial growth around the insertion site and reduce the potential for infection. Cleanse with 4×4s with chlorhexidine gluconate and warm water. The area is dressed with a 4×4 and taped in an occlusive fashion (Bullman, 2011). Securing the catheter tube to the abdomen helps to reduce tension at the insertion site. For catheters that have been in place for an extended period, no dressing may be needed and the healed insertion tract enables removal and replacement of the catheter as needed. Formation, however, of a healed insertion tract takes approximately 6 weeks to 6 months to develop. Before that time, the catheter needs to be replaced within 30 minutes if it falls out to prevent the opening from closing over (Bullman, 2011; Winder, 2012). The nurse assesses the insertion area at regular intervals. If pubic hair invades the

insertion site, it may be carefully trimmed with scissors. Any redness or discharge at the skin around the insertion site must be reported.

Urinary Diversions

A urinary diversion is the surgical rerouting of urine from the kidneys to a site other than the bladder. Clients with bladder cancer often need a urinary diversion when the bladder must be removed or bypassed. There are two categories of diversions: incontinent and continent.

Incontinent

With incontinent diversions clients have no control over the passage of urine and require the use of an external ostomy appliance to contain the urine. Urinary diversions may or may not involve the removal of the bladder (cystectomy). Examples of incontinent diversions include ureterostomy, nephrostomy, vesicostomy, and ileal conduits. A **ureterostomy** is when one or both of the ureters may be brought directly to the side of the abdomen to form small stomas. This procedure, however, has some disadvantages in that the stomas provide direct access for microorganisms from the skin to the kidneys, the small stomas are difficult to fit with an appliance to collect the urine, and they may narrow, impairing urine drainage. A **nephrostomy** diverts urine from the kidney via a catheter inserted into the renal pelvis to a nephrostomy tube and bag (Figure 48–13 ■). A **vesicostomy** may be formed when the bladder is left intact but voiding through the urethra is not possible (e.g., due to an obstruction or a neurogenic bladder). The ureters remain connected to the bladder, and the bladder wall is surgically attached to an opening in the skin below the navel, forming an opening (stoma) for urinary drainage.

The most common incontinent urinary diversion is the **ileal conduit** or ileal loop (Figure 48–14 ■). In this procedure, a segment of the ileum is removed and the intestinal ends are reattached. One end of the portion removed is closed with sutures to create a pouch, and the other end is brought out through the abdominal wall to create a stoma. The ureters are implanted into the ileal pouch. The ileal stoma is more readily fitted with an appliance than ureterostomies because of its larger size. The mucous membrane lining of the ileum also provides some protection from ascending infection. Urine drains continuously from the ileal pouch.

Figure 48–12 ■ A suprapubic catheter in place: A, using a pigtail loop; B, using a balloon to keep catheter in place.

Figure 48-13 ■ A nephrostomy.

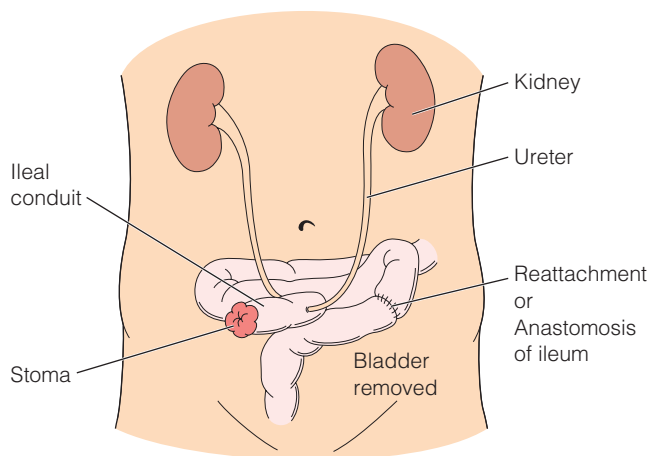

Figure 48-14 ■ An incontinent urinary diversion (ileal conduit).

Continent

Continent urinary diversion involves creation of a mechanism that allows the client to control the passage of urine, either by intermittent catheterization of the internal reservoir (e.g., Kock pouch) or by creating a neobladder or internal pouch.

The Kock (pronounced “coke”) pouch, or continent ileal bladder conduit, also uses a portion of the ileum to form a reservoir for urine (Figure 48-15 ■). In this procedure, nipple valves are formed by doubling the tissue backward into the reservoir where the pouch connects to the skin and the ureters connect to the pouch. These valves close as the pouch fills with urine, preventing leakage and reflux of urine back toward the kidneys. The client empties the pouch by inserting a clean catheter approximately every 2 to 3 hours at first and increases to every 5 to 6 hours as the pouch expands. Over time, the pouch can expand to between 600 and 1,000 mL (Avent, 2012, p. 51). Between catheterizations, a small dressing is worn to protect the stoma and clothing.

A continent diversion with a neobladder involves replacing a diseased or damaged bladder with a piece of ileum and colon that is located in the same location as the bladder that was removed (Avent, 2012). A pouch or new bladder is created. The ureters are sutured to one end of the new pouch/bladder and this new bladder is then sutured to the functional urethra to facilitate client voiding control (Figure 48-16 ■). The client will need to relearn how to void. Voiding occurs when the urethral sphincter muscle relaxes and abdominal straining occurs to put pressure on the pouch.

Figure 48-15 ■ The Kock pouch—a continent urinary diversion.

When caring for clients with a urinary diversion, the nurse must accurately assess intake and output; note any changes in urine color, odor, or clarity (mucous shreds are commonly seen in the urine of clients with an ileal diversion); and frequently assess the condition of the stoma and surrounding skin. Clients who must wear a urine collection appliance are at risk for impaired skin integrity because of irritation by urine. Well-fitting appliances are vital. The nurse should consult with the wound ostomy continence nurse (WOCN) to identify strategies for management of stoma and peristomal problems when selecting the most appropriate appliance for the client's needs. The steps of changing a urostomy appliance are similar to those described in the procedure for changing a bowel diversion appliance (see Chapter 49 ∞). However, there are some differences, including the following: Incontinent urinary diversions drain continually. As a result, some type of wicking material (e.g., rolled dry gauze pad or tampon) can be placed over the stoma to absorb the urine and keep the skin dry throughout the measurement and change of the ostomy appliance (Avent, 2012). Immediately following surgery, ureteral stents may be present and protruding from the stoma. These remain in place for 10 to 14 days postop

Figure 48–16 ■ A neobladder.

and are removed by either the surgeon or the WOCN, depending on institutional protocol. Ureteral stents are used to maintain the patency of ureters at the anastomotic sites.

Clients with urinary diversions may experience body image and sexuality problems and may require assistance in coping with these changes and managing the stoma. Most clients are able to resume their normal activities and lifestyle.

Evaluating

Using the overall goals and desired outcomes identified in the planning stage, the nurse collects data to evaluate the effectiveness of nursing activities. If the desired outcomes are not achieved, explore the reasons before modifying the care plan. For example, if the outcome “Remains dry between voidings and at night” is not met, examples of questions that need to be considered include:

- What is the client’s perception of the problem?
- Does the client understand and comply with the health care instructions provided?
- Is access to toilet facilities a problem?
- Can the client manipulate clothing for toileting? Can adjustments be made to allow easier disrobing?
- Are scheduled toileting times appropriate?
- Is there adequate transition lighting for night-time toileting?
- Are mobility aids such as a walker, elevated toilet seat, or grab bar needed? If currently used, are they appropriate or adequate?
- Is the client performing pelvic floor muscle exercises appropriately as scheduled?
- Is the client’s fluid intake adequate? Does the timing of fluid intake need to be adjusted (e.g., restricted after dinner)?
- Is the client restricting caffeine, citrus juice, carbonated beverages, and artificial sweetener intake?
- Is the client taking a diuretic? If so, when is the medication taken? Do the times need to be adjusted (e.g., taking second dose no later than 4 PM)?
- Should continence aids such as a condom catheter or absorbent pads be used?

NURSING CARE PLAN Urinary Elimination

Assessment Data

Nursing Assessment

Mr. John Baker is a 68-year-old shopkeeper who was admitted to the hospital with urinary retention, hematuria, and fever. The admitting nurse gathers the following information when taking a nursing history. Mr. Baker states he has noticed urinary frequency during the day for the past 2 weeks, and that he doesn’t feel he has emptied his bladder after urinating. He also has to get up two or three times during the night to urinate. During the past few days, he has had difficulty starting urination and dribbles afterward. He verbalizes the embarrassment his urinary problems cause in his dealings with the public. Mr. Baker is concerned about the cause of this urinary problem. He is diagnosed with benign prostatic hypertrophy (BPH) and referred to a urologist who suggests a transurethral resection of the prostate (TURP) in several months. He is placed on antibiotic therapy.

Physical Examination

Height: 185.4 cm (6’2”)
 Weight: 85.7 kg (189 lb)
 Temperature: 38.1°C (100.6°F)
 Pulse: 88 beats/min
 Respirations: 20/min
 Blood pressure: 146/86 mmHg
 Catheterization for urinary retention yielded 300 mL amber urine, Foley left in place for 2 days

Diagnostic Data

CBC normal; urinalysis: amber, clear, pH 6.5, specific gravity 1.025, negative for glucose, protein, ketone, RBCs, and bacteria; IVP: evidence of enlarged prostate gland

Nursing Diagnosis

Impaired Urinary Elimination (dysfunction in urine elimination) related to bladder neck obstruction by enlarged prostate gland (as evidenced by dysuria, frequency, nocturia, dribbling, hesitancy, and bladder distention)

Desired Outcomes*

Urinary Continence [0502] sometimes demonstrated as evidenced by:

- Able to start and stop stream
- Empties bladder completely

Knowledge: Treatment

Regimen [1813] as evidenced by substantial knowledge of:

- Self-care responsibilities for ongoing treatment
- Self-monitoring techniques

NURSING CARE PLAN Urinary Elimination—continued

Nursing Interventions*/Selected Activities	Rationale
URINARY INCONTINENCE CARE [0610]	
Monitor urinary elimination, including consistency, odor, volume, and color.	<i>These parameters help determine adequacy of urinary tract function.</i>
Help the client select appropriate incontinence garment or pad for short-term management while more definitive treatment is designed.	<i>Appropriate undergarments can help diminish the embarrassing aspects of urinary incontinence.</i>
Instruct Mr. Baker to limit fluids for 2 to 3 hours before bedtime.	<i>Decreased fluid intake several hours before bedtime will decrease the incidence of urinary retention and overflow incontinence, and promote rest.</i>
Instruct him to drink a minimum of 1,500 mL (six 8-ounce glasses) fluids per day.	<i>Increased fluids during the day will increase urinary output and discourage bacterial growth.</i>
Limit ingestion of bladder irritants (e.g., colas, coffee, tea, and chocolate).	<i>Alcohol, coffee, and tea have a natural diuretic effect and are bladder irritants.</i>
URINARY RETENTION CARE [0620]	
Instruct Mr. Baker or a family member to record urinary output.	<i>Serves as an indicator of urinary tract and renal function and of fluid balance.</i>
Monitor degree of bladder distention by palpation and percussion and/or bladder scanner.	<i>An enlarged prostate compresses the urethra so that urine is retained. Checking for bladder distention provides information about bladder emptying and potential residual urine.</i>
Implement intermittent catheterization, as appropriate.	<i>Helps maintain tonicity of the bladder muscle by preventing overdistention and providing for complete emptying.</i>
Provide enough time for bladder emptying (10 minutes).	<i>In addition to the effect of an enlarged prostate on the bladder, stress or anxiety can inhibit relaxation of the urinary sphincter. Sufficient time should be allowed for micturition.</i>
Instruct the client in ways to avoid constipation or stool impaction.	<i>Impacted stool may place pressure on the bladder outlet, causing urinary retention.</i>
TEACHING: DISEASE PROCESS [5602]	
Appraise Mr. Baker's current level of knowledge about benign prostatic hypertrophy.	<i>Assessing the client's knowledge will provide a foundation for building a teaching plan based on his present understanding of his condition.</i>
Explain the pathophysiology of the disease and how it relates to urinary anatomy and function.	<i>In this case, urinary retention and overflow incontinence are caused by obstruction of the bladder neck by an enlarged prostate gland.</i>
Describe the rationale behind management, therapy, and treatment recommendations.	<i>Adequate information about treatment options is important to diminish anxiety, promote compliance, and enhance decision making.</i>
Instruct Mr. Baker on which signs and symptoms to report to the health care provider (e.g., burning on urination, hematuria, oliguria).	<i>In the individual with prostatic hypertrophy, urinary retention and an overdistended bladder reduce blood flow to the bladder wall, making it more susceptible to infection from bacterial growth. Monitoring for these manifestations of UTI is essential to prevent urosepsis.</i>

EVALUATION

Outcomes partially met. Following removal of the Foley catheter, Mr. Baker reported continued difficulty initiating a urinary stream but experienced less dribbling and nocturia. He and his wife selected an undergarment that was acceptable to Mr. Baker and he reports that he feels more confident. Intermittent catheterization not indicated. Intake is approximately 200 mL in excess of output. He is able to discuss the correlation between his enlarged prostate and urinary difficulties. A transurethral resection of the prostate is scheduled in 2 weeks.

*The NOC # for desired outcomes and the NIC # for nursing interventions are listed in brackets following the appropriate outcome or intervention. Outcomes, interventions, and activities selected are only a sample of those suggested by NOC and NIC and should be further individualized for each client.

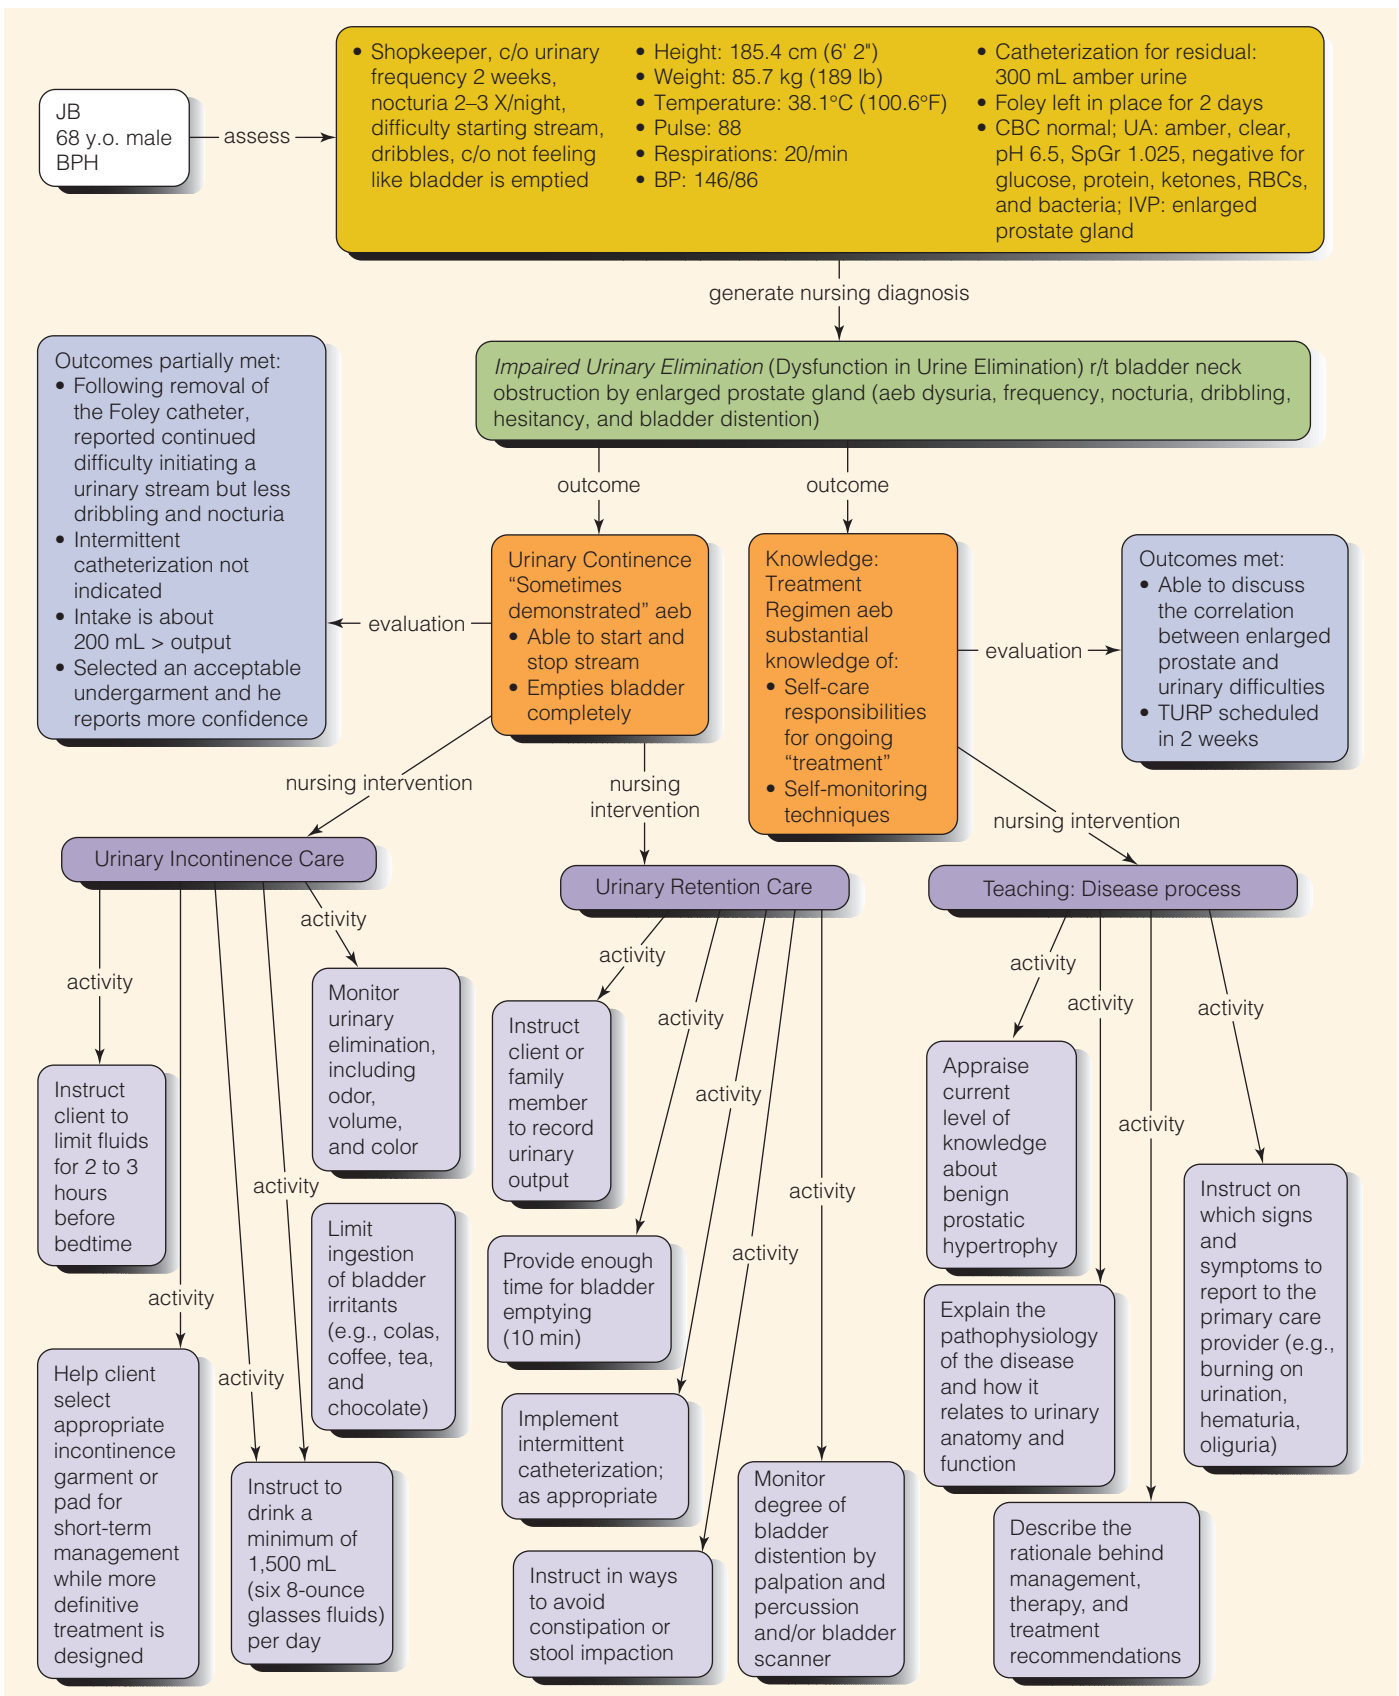

APPLYING CRITICAL THINKING

1. Considering Mr. Baker's history and assessment data, what other physical conditions could explain his symptoms?
2. The primary care provider has recommended surgery. What assumptions will the nurse need to validate in helping prepare Mr. and Mrs. Baker for this surgery?
3. It does not appear that other alternatives have been considered. Why might this be so?
4. Incontinence can lead to client decisions to limit social interactions. What would be an appropriate response if Mr. Baker states that he will just stay home until he has his surgery?

See Critical Thinking Possibilities on student resource website.

CONCEPT MAP

Urinary Elimination

Chapter 48 Review

CHAPTER HIGHLIGHTS

- Urinary elimination depends on normal functioning of the upper urinary tract's kidneys and ureters and the lower urinary tract's urinary bladder, urethra, and pelvic floor.
- Urine is formed in the nephron, the functional unit of the kidney, through a process of filtration, reabsorption, and secretion. Hormones such as antidiuretic hormone (ADH) and aldosterone affect the reabsorption of sodium and water, thus affecting the amount of urine formed.
- The normal process of urination is stimulated when sufficient urine collects in the bladder to stimulate stretch receptors. Impulses from stretch receptors are transmitted to the spinal cord and the brain, causing relaxation of the internal sphincter (unconscious control) and, if appropriate, relaxation of the external sphincter (conscious control).
- In the adult, urination generally occurs after 250 to 450 mL of urine has collected in the bladder.
- Many factors influence a person's urinary elimination, including growth and development, psychosocial factors, fluid intake, medications, muscle tone, various diseases and conditions, and surgical and diagnostic procedures.
- Alterations in urine production and elimination include polyuria, oliguria, anuria, frequency, nocturia, urgency, dysuria, enuresis, incontinence, and retention. Each may have various influencing and associated factors that need to be identified.
- Millions of Americans, mostly women, suffer from urinary incontinence (UI). UI can have a significant impact on the client's quality of life, creating physical problems, such as skin breakdown and also psychosocial problems, such as social isolation and withdrawal, less positive relationships with others, poorer perceived health, negative effect on sexual function and intimacy, depression, and a barrier to physical and everyday activities.
- The four main types of UI are stress urinary incontinence, urge urinary incontinence, mixed urinary incontinence, and overflow incontinence.
- Nurses, as part of their clinical practice, should assess all clients for UI. Assessment of a client's urinary function includes (a) a nursing history that identifies voiding patterns, recent changes, past and current problems with urination, and factors influencing the elimination pattern; (b) a physical assessment of the genitourinary system; (c) inspection of the urine for amount, color, clarity, and odor; and, if indicated, (d) testing of urine for specific gravity, pH, and the presence of glucose, ketone bodies, protein, and occult blood.
- Many NANDA-approved nursing diagnoses may apply to clients with altered urinary elimination patterns, for example, *Functional Urinary Incontinence*, *Urinary Retention*, and related diagnoses such as *Risk for Infection*.
- Goals for the client with problems with urinary elimination include maintaining or restoring normal voiding patterns and preventing associated risks such as skin breakdown.
- In planning for home care, the nurse considers the client's needs for teaching and assistance in the home.
- Interventions include assisting the client to maintain adequate fluid intake and normal voiding patterns, and assisting with toileting.
- The most common cause of UTI is bacteria. Women in particular are prone to UTIs because of their short urethras.
- Urinary catheterization is frequently required for clients with urinary retention but is only performed when all other measures to facilitate voiding fail. Sterile technique is essential to prevent urinary infections.
- It is well documented that the risk to the client of developing a CAUTI correlates to the duration of the catheter being in place.
- Care of clients with indwelling catheters is directed toward assessing the necessity for the catheter, preventing infection of the urinary tract, and encouraging urinary flow through the drainage system.
- Clients with urinary retention may be taught to perform clean intermittent self-catheterization to enhance their independence, reduce the risk of infection, and eliminate incontinence.
- Bladder or catheter irrigations may be used to apply medication to bladder walls or maintain catheter patency.
- A urinary diversion is the surgical rerouting of urine from the kidneys to a site other than the bladder. There are two categories of diversions: incontinent and continent.

TEST YOUR KNOWLEDGE

1. The nurse recognizes that urinary elimination changes may occur even in healthy older adults because of which of the following?
 1. The bladder distends and its capacity increases.
 2. Older adults ignore the need to void.
 3. Urine becomes more concentrated.
 4. The amount of urine retained after voiding increases.
2. During assessment of the client with urinary incontinence, the nurse is most likely to assess for which of the following? Select all that apply.
 1. Perineal skin irritation
 2. Fluid intake of less than 1,500 mL/day
 3. History of antihistamine intake
 4. History of frequent urinary tract infections
 5. A fecal impaction
3. Which action represents the appropriate nursing management of a client wearing a condom catheter?
 1. Ensure that the tip of the penis fits snugly against the end of the condom.
 2. Check the penis for adequate circulation 30 minutes after applying.
 3. Change the condom every 8 hours.
 4. Tape the collecting tubing to the lower abdomen.
4. The catheter slips into the vagina during a straight catheterization of a female client. The nurse does which action?
 1. Leaves the catheter in place and gets a new sterile catheter.
 2. Leaves the catheter in place and asks another nurse to attempt the procedure.
 3. Removes the catheter and redirects it to the urinary meatus.
 4. Removes the catheter, wipes it with a sterile gauze, and redirects it to the urinary meatus.

5. Which statement indicates a need for further teaching of the home care client with a long-term indwelling catheter?
 1. "I will keep the collecting bag below the level of the bladder at all times."
 2. "Intake of cranberry juice may help decrease the risk of infection."
 3. "Soaking in a warm tub bath may ease the irritation associated with the catheter."
 4. "I should use clean technique when emptying the collecting bag."
6. During shift report, the nurse learns that an older female client is unable to maintain continence after she senses the urge to void and becomes incontinent on the way to the bathroom. Which nursing diagnosis is most appropriate?
 1. *Stress Urinary Incontinence*
 2. *Reflex Urinary Incontinence*
 3. *Functional Urinary Incontinence*
 4. *Urge Urinary Incontinence*
7. A female client has a urinary tract infection (UTI). Which teaching points by the nurse would be helpful to the client? Select all that apply.
 1. Limit fluids to avoid the burning sensation on urination.
 2. Review symptoms of UTI with the client.
 3. Wipe the perineal area from back to front.
 4. Wear cotton underclothes.
 5. Take baths rather than showers.
8. The nurse will need to assess the client's performance of clean intermittent self-catheterization (CISC) for a client with which urinary diversion?
 1. Ileal conduit
 2. Kock pouch
 3. Neobladder
 4. Vesicostomy
9. Which focus is the nurse most likely to teach for a client with a flaccid bladder?
 1. Habit training: Attempt voiding at specific time periods.
 2. Bladder training: Delay voiding according to a preschedule timetable.
 3. Credé's maneuver: Apply gentle manual pressure to the lower abdomen.
 4. Kegel exercises: Contract the pelvic muscles.
10. Which of the following behaviors indicates that the client on a bladder training program has met the expected outcomes? Select all that apply.
 1. Voids each time there is an urge.
 2. Practices slow, deep breathing until the urge decreases.
 3. Uses adult diapers, for "just in case."
 4. Drinks citrus juices and carbonated beverages.
 5. Performs pelvic muscle exercises.

See Answers to Test Your Knowledge in Appendix A.

49 Fecal Elimination

LEARNING OUTCOMES

After completing this chapter, you will be able to:

1. Describe the physiology of defecation.
2. Distinguish normal from abnormal characteristics and constituents of feces.
3. Identify factors that influence fecal elimination and patterns of defecation.
4. Identify common causes and effects of selected fecal elimination problems.
5. Describe methods used to assess fecal elimination.
6. Identify examples of nursing diagnoses, outcomes, and interventions for clients with elimination problems.
7. Identify measures that maintain normal fecal elimination patterns.
8. Describe the purpose and action of commonly used enema solutions.
9. Describe essentials of fecal stoma care for clients with an ostomy.
10. Recognize when it is appropriate to delegate assistance with fecal elimination to unlicensed assistive personnel.
11. Verbalize the steps used in:
 - a. Administering an enema.
 - b. Changing a bowel diversion ostomy appliance.
12. Demonstrate appropriate documentation and reporting related to fecal elimination.

INTRODUCTION

Nurses frequently are consulted or involved in assisting clients with elimination problems. These problems can be embarrassing to clients and can cause considerable discomfort. The elimination of feces is a prominent public topic in North America. For example, laxative advertisements, describing such feelings as tiredness due to irregularity, keep the subject in the public consciousness. Some older adults are preoccupied with their bowels. People who have had a bowel movement once a day for 75 years can view missing one day as a serious problem.

PHYSIOLOGY OF DEFECTION

Elimination of the waste products of digestion from the body is essential to health. The excreted waste products are referred to as **feces** or **stool**.

Large Intestine

The large intestine extends from the ileocecal (ileocolic) valve, which lies between the small and large intestines, to the anus. The colon (large intestine) in the adult is generally about 125 to 150 cm (50 to 60 in.) long. It has seven parts: the cecum; ascending, transverse, and descending colons; sigmoid colon; rectum; and anus (Figure 49-1 ■).

The large intestine is a muscular tube lined with mucous membrane. The muscle fibers are both circular and longitudinal, permitting the intestine to enlarge and contract in both width and length. The longitudinal muscles are shorter than the colon and therefore cause the large intestine to form pouches, or **haustra**.

The colon's main functions are the absorption of water and nutrients, the mucoid protection of the intestinal wall, and fecal elimination. The contents of the colon normally represent foods ingested over the previous 4 days, although most of the waste products are excreted within 48 hours of **ingestion** (the act of taking in food). The waste products leaving the stomach through the small intestine and then passing through the ileocecal valve are called **chyme**. The ileocecal valve, located at the junction of the ileum of the small intestine and the first part of the large intestine, regulates the flow of chyme into the large intestine and prevents backflow into the ileum. As much as 1,500 mL of chyme passes into the large intestine daily, and all but about 100 mL is reabsorbed in the proximal half of the colon. The 100 mL of fluid is excreted in the feces.

The colon also serves a protective function in that it secretes mucus. This mucus contains large amounts of bicarbonate ions. The mucous secretion is stimulated by excitation of parasympathetic nerves. During extreme stimulation—for example, as a result of emotions—large amounts of mucus are secreted, resulting in

Figure 49-1 ■ The large intestine.

From *Medical Terminology: A Living Language*, 5th ed., by B. F. Fremgen and S. S. Frucht, 2013, Upper Saddle River, NJ: Pearson Education, Inc.

the passage of stringy mucus with little or no feces. Mucus serves to protect the wall of the large intestine from trauma by the acids formed in the feces, and it serves as an adherent for holding the fecal material together. Mucus also protects the intestinal wall from bacterial activity.

The colon acts to transport along its lumen the products of digestion, which are eventually eliminated through the anal canal. These products are flatus and feces. **Flatus** is largely air and the by-products of the digestion of carbohydrates. Three types of movements occur in the large intestine: haustral churning, colon peristalsis, and mass peristalsis. **Haustral churning** involves movement of the chyme back and forth within the haustra. In addition to mixing the contents, this action aids in the absorption of water and moves the contents forward to the next haustra. **Peristalsis** is wavelike movement produced by the circular and longitudinal muscle fibers of the intestinal walls; it propels the intestinal contents forward. Colon peristalsis is very sluggish and is thought to move the chyme very little along the large intestine. **Mass peristalsis**, the third type of colonic movement, involves a wave of powerful muscular contraction that moves over large areas of the colon. Usually mass peristalsis occurs after eating, stimulated by the presence of food in the stomach and small intestine. In adults, mass peristaltic waves occur only a few times a day.

Rectum and Anal Canal

The rectum in the adult is usually 10 to 15 cm (4 to 6 in.) long; the most distal portion, 2.5 to 5 cm (1 to 2 in.) long, is the anal canal. The rectum has folds that extend vertically. Each of the vertical folds contains a vein and an artery. It is believed that these folds help retain feces within the rectum. When the veins become distended, as can occur with repeated pressure, a condition known as **hemorrhoids** occurs (Figure 49-2 ■).

The anal canal is bounded by an internal and an external sphincter muscle (Figure 49-3 ■). The internal sphincter is under involuntary control, and the external sphincter normally is voluntarily controlled. The internal sphincter muscle is innervated by the autonomic nervous system; the external sphincter is innervated by the somatic nervous system.

Figure 49-2 ■ Internal and external hemorrhoids.

Defecation

Defecation is the expulsion of feces from the anus and rectum. It is also called a *bowel movement*. The frequency of defecation is highly individual, varying from several times per day to two or three times per week. The amount defecated also varies from person to person. When peristaltic waves move the feces into the sigmoid colon and the rectum, the sensory nerves in the rectum are stimulated and the individual becomes aware of the need to defecate.

CLINICAL ALERT!

Individuals (especially children) may use very different terms for a bowel movement. The nurse may need to try several different common words before finding one the client understands.

When the internal anal sphincter relaxes, feces move into the anal canal. After the individual is seated on a toilet or bedpan, the external anal sphincter is relaxed voluntarily. Expulsion of the feces is

Figure 49-3 ■ The rectum, anal canal, and anal sphincters: A, open; B, closed.

assisted by contraction of the abdominal muscles and the diaphragm, which increases abdominal pressure, and by contraction of the muscles of the pelvic floor, which moves the feces through the anal canal. Normal defecation is facilitated by (a) thigh flexion, which increases the pressure within the abdomen, and (b) a sitting position, which increases the downward pressure on the rectum.

If the defecation reflex is ignored, or if defecation is consciously inhibited by contracting the external sphincter muscle, the urge to defecate normally disappears for a few hours before occurring again. Repeated inhibition of the urge to defecate can result in expansion of the rectum to accommodate accumulated feces and eventual loss of sensitivity to the need to defecate. Constipation can be the ultimate result.

Feces

Normal feces are made of about 75% water and 25% solid materials. They are soft but formed. If the feces are propelled very quickly along

the large intestine, there is not time for most of the water in the chyme to be reabsorbed and the feces will be more fluid, containing perhaps 95% water. Normal feces require a normal fluid intake; feces that contain less water may be hard and difficult to expel.

Feces are normally brown, chiefly due to the presence of stercobilin and urobilin, which are derived from bilirubin (a red pigment in bile). Another factor that affects fecal color is the action of bacteria such as *Escherichia coli* or staphylococci, which are normally present in the large intestine. The action of microorganisms on the chyme is also responsible for the odor of feces. Table 49-1 lists the characteristics of normal and abnormal feces.

The amount of gas produced per day varies among individuals; passing gas around 13 to 21 times a day is normal (National Digestive Diseases Information Clearinghouse, 2013). The gases include carbon dioxide, methane, hydrogen, oxygen, and nitrogen. Some are swallowed with food and fluids taken by mouth, others are formed through the action of bacteria on the chyme in the large intestine, and other gas diffuses from the blood into the gastrointestinal tract.

FACTORS THAT AFFECT DEFECTION

Defecation patterns vary at different stages of life. Circumstances of diet, fluid intake and output, activity, psychological factors, defecation habits, medications, diagnostic and medical procedures, pathologic conditions, and pain also affect defecation.

Development

Newborns and infants, toddlers, children, and older adults are groups within which members have similarities in elimination patterns.

NEWBORNS AND INFANTS

Meconium is the first fecal material passed by the newborn, normally up to 24 hours after birth. It is black, tarry, odorless, and sticky. Transitional stools, which follow for about a week, are generally greenish yellow; they contain mucus and are loose.

Infants pass stool frequently, often after each feeding. Because the intestine is immature, water is not well absorbed and the stool is soft, liquid, and frequent. When the intestine matures, bacterial flora increase. After solid foods are introduced, the stool becomes less frequent and firmer.

Infants who are breast-fed have light yellow to golden feces, and infants who are taking formula will have dark yellow or tan stool that is more formed.

TODDLERS

Some control of defecation starts at 1 1/2 to 2 years of age. By this time, children have learned to walk, and the nervous and muscular systems are sufficiently well developed to permit bowel control. A desire to control daytime bowel movements and to use the toilet generally starts when the child becomes aware of (a) the discomfort caused by a soiled diaper and (b) the sensation that indicates the need for a bowel movement. Daytime control is typically attained by age 2 1/2, after a process of toilet training.

SCHOOL-AGE CHILDREN AND ADOLESCENTS

School-age children and adolescents have bowel habits similar to those of adults. Patterns of defecation vary in frequency, quantity, and

TABLE 49–1 Characteristics of Normal and Abnormal Feces

Characteristic	Normal	Abnormal	Possible Cause
Color	Adult: brown	Clay or white	Absence of bile pigment (bile obstruction); diagnostic study using barium
	Infant: yellow	Black or tarry	Drug (e.g., iron); bleeding from upper gastrointestinal tract (e.g., stomach, small intestine); diet high in red meat and dark green vegetables (e.g., spinach)
		Red	Bleeding from lower gastrointestinal tract (e.g., rectum); some foods (e.g., beets)
		Pale	Malabsorption of fats; diet high in milk and milk products and low in meat
		Orange or green	Intestinal infection
Consistency	Formed, soft, semisolid, moist	Hard, dry	Dehydration; decreased intestinal motility resulting from lack of fiber in diet, lack of exercise, emotional upset, laxative abuse
		Diarrhea	Increased intestinal motility (e.g., due to irritation of the colon by bacteria)
Shape	Cylindrical (contour of rectum) about 2.5 cm (1 in.) in diameter in adults	Narrow, pencil-shaped, or stringlike stool	Obstructive condition of the rectum
Amount	Varies with diet (about 100–400 g/day)		
Odor	Aromatic: affected by ingested food and individual's own bacterial flora	Pungent	Infection, blood
Constituents	Small amounts of undigested roughage, sloughed dead bacteria and epithelial cells, fat, protein, dried constituents of digestive juices (e.g., bile pigments, inorganic matter)	Pus	Mucus
		Parasites	Bacterial infection
		Blood	Inflammatory condition
		Large quantities of fat	Gastrointestinal bleeding
		Foreign objects	Malabsorption Accidental ingestion

consistency. Some school-age children may delay defecation because of an activity such as play.

OLDER ADULTS

Toner and Claros (2012) state that “up to half of all older adults suffer from constipation” (p. 32). This is due, in part, to reduced activity levels, inadequate fluid and fiber intake, and muscle weakness. Many older people believe that “regularity” means a bowel movement every day. Those who do not meet this criterion often seek over-the-counter (OTC) preparations to relieve what they believe to be constipation. Older adults should be advised that normal patterns of bowel elimination vary considerably. For some, a normal pattern may be every other day; for others, twice a day. Constipation can be relieved by increasing the fiber intake to 20 to 35 grams per day, unless contraindicated (Tabloski & Connell, 2014). Adequate roughage in the diet, adequate exercise, and 6 to 8 glasses of fluid daily are other essential preventive measures for constipation. A cup of hot water or tea at a regular time in the morning is helpful for some. Responding to the **gastrocolic reflex** (increased peristalsis of the colon after food has entered the stomach) is also an important consideration. For example, toileting is recommended 30 minutes after meals, especially after breakfast when the gastrocolic reflex is strongest (Toner & Claros, 2012).

The older adult should be warned that consistent use of laxatives inhibits natural defecation reflexes and is thought to cause rather than cure constipation. The habitual user of laxatives eventually requires larger or stronger doses because the effect is progressively reduced with continual use. Laxatives may also interfere with the body's electrolyte balance and decrease the absorption of certain vitamins. The reasons for constipation can range from lifestyle habits (e.g., lack of exercise) to serious malignant disorders (e.g., colorectal cancer). The nurse should evaluate any complaints of constipation carefully for each individual. A change in bowel habits over several weeks with or without weight loss, pain, or fever should be referred to a primary care provider for a complete medical evaluation. See Clinical Manifestations for risk factors and symptoms of colorectal cancer.

Diet

Sufficient bulk (cellulose, fiber) in the diet is necessary to provide fecal volume. Inadequate intake of dietary fiber contributes to the risk of developing obesity, type 2 diabetes, coronary artery disease, and colon cancer. Fiber is classified into two categories: insoluble fiber and soluble fiber. Insoluble fiber promotes the movement of material through the digestive system and increases stool bulk. Sources

CLINICAL MANIFESTATIONS

Colorectal Cancer

RISK FACTORS

- Nonmodifiable
 - Age (risk increases after age 50)
 - Race (African Americans and Jews of Eastern European descent)
 - Personal or family history of colorectal polyps
 - Personal history of inflammatory bowel disease
- Modifiable
 - Cigarette smoking
 - Poor diet (e.g., low in fiber and high in fat; high amounts of red meats and/or processed meats)
 - Lack of physical activity
 - Heavy consumption of alcohol

SYMPTOMS

Inform clients to see their primary care provider if they have any of the following:

- A change in bowel habits such as diarrhea, constipation, or narrowing of the stool that lasts for more than a few days
- A feeling of needing to have a bowel movement that is not relieved by doing so
- Rectal bleeding or blood in the stool (often, though, the stool will look normal)
- Cramping or steady abdominal pain
- Weakness and fatigue
- Unexpected weight loss

From "The Facts About Colorectal Cancer," by P. Walden, 2011, *Nursing made Incredibly Easy!*, 9(5), pp. 37–44; "What You Need to Know About Cancer of the Colon and Rectum," by National Cancer Institute, n.d. Retrieved from <http://www.cancer.gov/cancertopics/wyntk/colon-and-rectal/page1/AllPages#4>; "What Are the Risk Factors for Colorectal Cancer?" by American Cancer Society, 2014b. Retrieved from <http://www.cancer.org/cancer/colonandrectumcancer/detailedguide/colorectal-cancer-signs-and-symptoms>.

of insoluble fiber include whole-wheat flour, wheat bran, nuts, and many vegetables. Soluble fiber dissolves in water to form a gel-like material. It can help lower blood cholesterol and glucose levels (Mayo Clinic, 2012). Sources of soluble fiber include oats, peas, beans, apples, citrus fruits, carrots, barley, and psyllium. The Mayo Clinic recommends the following daily amount of fiber:

Men ages 50 and younger: 38 grams

Men ages 51 and older: 30 grams

Women ages 50 and younger: 25 grams

Women ages 51 and older: 21 grams.

It is important to drink plenty of water because fiber works best when it absorbs water.

Bland diets and low-fiber diets are lacking in bulk and therefore create insufficient residue of waste products to stimulate the reflex for defecation. Low-residue foods, such as rice, eggs, and lean meats, move more slowly through the intestinal tract. Increasing fluid intake with such foods increases their rate of movement.

Certain foods are difficult or impossible for some people to digest. This inability results in digestive upsets and, in some instances, the passage of watery stools. Irregular eating can also impair regular defecation. Individuals who eat at the same times every day usually have a regularly timed, physiological response to the food intake and a regular pattern of peristaltic activity in the colon.

Spicy foods can produce diarrhea and flatus in some individuals. Excessive sugar can also cause diarrhea. Other foods that may influence bowel elimination include the following:

- Gas-producing foods, such as cabbage, onions, cauliflower, bananas, and apples
- Laxative-producing foods, such as bran, prunes, figs, chocolate, and alcohol
- Constipation-producing foods, such as cheese, pasta, eggs, and lean meat.

Fluid Intake and Output

Even when fluid intake is inadequate or output (e.g., urine or vomitus) is excessive for some reason, the body continues to reabsorb fluid from the chyme as it passes along the colon. The chyme becomes drier than normal, resulting in hard feces. In addition, reduced fluid intake slows the chyme's passage along the intestines, further increasing the reabsorption of fluid from the chyme. Healthy fecal elimination usually requires a daily fluid intake of 2,000 to 3,000 mL. If chyme moves abnormally quickly through the large intestine, however, there is less time for fluid to be absorbed into the blood; as a result, the feces are soft or even watery.

Activity

Activity stimulates peristalsis, thus facilitating the movement of chyme along the colon. Weak abdominal and pelvic muscles are often ineffective in increasing the intra-abdominal pressure during defecation or in controlling defecation. Weak muscles can result from lack of exercise, immobility, or impaired neurologic functioning. Clients confined to bed are often constipated.

Psychological Factors

Some people who are anxious or angry experience increased peristaltic activity and subsequent nausea or diarrhea. In contrast, people who are depressed may experience slowed intestinal motility, resulting in constipation. How a person responds to these emotional states is the result of individual differences in the response of the enteric nervous system to vagal stimulation from the brain.

Defecation Habits

Early bowel training may establish the habit of defecating at a regular time. Many people defecate after breakfast, when the gastrocolic reflex causes mass peristaltic waves in the large intestine. If a person ignores this urge to defecate, water continues to be reabsorbed, making the feces hard and difficult to expel. When the normal defecation reflexes are inhibited or ignored, these conditioned reflexes tend to be progressively weakened. When habitually ignored, the urge to defecate is ultimately lost. Adults may ignore these reflexes because of the pressures of time or work. Hospitalized clients may suppress the urge because of embarrassment about using a bedpan, because of lack of privacy, or because defecation is too uncomfortable.

Medications

Some drugs have side effects that can interfere with normal elimination. Some cause diarrhea; others, such as large doses of certain tranquilizers and repeated administration of morphine and codeine, cause

constipation because they decrease gastrointestinal activity through their action on the central nervous system. Iron supplements act more locally on the bowel mucosa and can cause constipation or diarrhea.

Some medications directly affect elimination. **Laxatives** are medications that stimulate bowel activity and so assist fecal elimination. Other medications soften stool, facilitating defecation. Certain medications suppress peristaltic activity and may be used to treat diarrhea.

Medications can also affect the appearance of the feces. Any drug that causes gastrointestinal bleeding (e.g., aspirin products) can cause the stool to be red or black. Iron salts lead to black stool because of the oxidation of the iron; antibiotics may cause a gray-green discoloration; and antacids can cause a whitish discoloration or white specks in the stool. Pepto-Bismol, a common OTC drug, causes stools to be black.

Diagnostic Procedures

Before certain diagnostic procedures, such as visualization of the colon (colonoscopy or sigmoidoscopy), the client is restricted from ingesting food or fluid. The client may also be given a cleansing enema prior to the examination. In these instances normal defecation usually will not occur until eating resumes.

Anesthesia and Surgery

General anesthetics cause the normal colonic movements to cease or slow by blocking parasympathetic stimulation to the muscles of the colon. Clients who have regional or spinal anesthesia are less likely to experience this problem.

Surgery that involves direct handling of the intestines can cause temporary cessation of intestinal movement. This condition, called ileus, usually lasts 24 to 48 hours. Listening for bowel sounds that reflect intestinal motility is an important nursing assessment following surgery.

Pathologic Conditions

Spinal cord injuries and head injuries can decrease the sensory stimulation for defecation. Impaired mobility may limit the client's ability to respond to the urge to defecate and the client may experience constipation. Or, a client may experience fecal incontinence because of poorly functioning anal sphincters.

Pain

Clients who experience discomfort when defecating (e.g., following hemorrhoid surgery) often suppress the urge to defecate to avoid the pain. Such clients can experience constipation as a result. Clients taking narcotic analgesics for pain may also experience constipation as a side effect of the medication.

FECAL ELIMINATION PROBLEMS

Four common problems are related to fecal elimination: constipation, diarrhea, bowel incontinence, and flatulence.

Constipation

Constipation may be defined as fewer than three bowel movements per week. This infers the passage of dry, hard stool or the passage of no stool. It occurs when the movement of feces through the

BOX 49–1 Sample Defining Characteristics of Constipation

- Decreased frequency of defecation
- Hard, formed stools
- Straining at stool; painful defecation
- Reports of rectal fullness or pressure or incomplete bowel evacuation
- Abdominal pain, cramps, or distention
- Anorexia, nausea
- Headache

large intestine is slow, thus allowing time for additional reabsorption of fluid from the large intestine. Associated with constipation are difficult evacuation of stool and increased effort or straining of the voluntary muscles of defecation. The person may also have a feeling of incomplete stool evacuation after defecation. However, it is important to define constipation in relation to the person's regular elimination pattern. Some people normally defecate only a few times a week; other people defecate more than once a day. Careful assessment of the person's habits is necessary before a diagnosis of constipation is made. Box 49–1 lists the common defining characteristics of constipation.

Many causes and factors contribute to constipation. Among them are the following:

- Insufficient fiber intake
- Insufficient fluid intake
- Insufficient activity or immobility
- Irregular defecation habits
- Change in daily routine
- Lack of privacy
- Chronic use of laxatives or enemas
- Irritable bowel syndrome (IBS)
- Pelvic floor dysfunction or muscle damage
- Poor motility or slow transit
- Neurologic conditions (e.g., Parkinson's disease), stroke, or paralysis
- Emotional disturbances such as depression or mental confusion
- Medications such as opioids, iron supplements, antihistamines, antacids, and antidepressants
- Habitual denial and ignoring the urge to defecate.

Constipation can cause health problems for some clients. In children constipation is often associated with changes in activity, diet, and toileting habits (Ball, Bindler, & Cowen, 2014). Straining associated with constipation often is accompanied by holding the breath. This Valsalva maneuver can present serious problems to people with heart disease, brain injuries, or respiratory disease. Holding the breath while bearing down increases intrathoracic pressure and vagal tone, slowing the pulse rate.

FECAL IMPACTION

Fecal impaction is a mass or collection of hardened feces in the folds of the rectum. Impaction results from prolonged retention and accumulation of fecal material. In severe impactions the feces accumulate and extend well up into the sigmoid colon and beyond. A client who has a fecal impaction will experience the passage of liquid fecal seepage (diarrhea) and no normal stool. The liquid portion of

DRUG CAPSULE

Emollient or Surfactant docusate calcium (Surfak) docusate sodium (Colace)**CLIENT WITH DRUGS FOR TREATING THE LOWER GASTROINTESTINAL TRACT**

Docusates lower the surface tension of fecal material, which allows water and lipids to penetrate the stool, resulting in a softer fecal mass. They do not stimulate peristalsis.

Docusates are commonly used for prevention of constipation and to decrease the strain of defecation in individuals who should avoid straining during bowel movements (e.g., cardiac disease [prevent Valsalva maneuver], eye surgery, rectal surgery).

NURSING RESPONSIBILITIES

- Assess the client for abdominal distention, bowel sounds, and usual bowel movement frequency.
- Evaluate the effectiveness of medication.

CLIENT AND FAMILY TEACHING

- Advise the client to drink a glass of fluid (e.g., water, juice, milk) with each dose.
- Explain that it may take 1 to 3 days to soften fecal material.
- Advise the client not to take docusate within 2 hours of other laxatives, especially mineral oil, because it may cause increased absorption of the mineral oil.
- Discuss other forms of bowel regulation (e.g., increasing fiber intake, fluid intake, and activity).

Note: Prior to administering any medication, review all aspects with a current drug handbook or other reliable source.

the feces seeps out around the impacted mass. Impaction can also be assessed by digital examination of the rectum, during which the hardened mass can often be palpated.
